

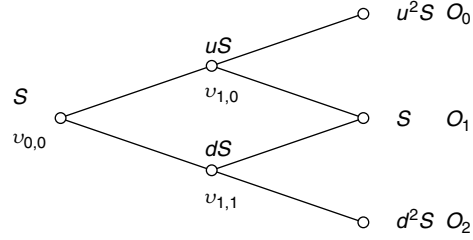

Figure 2 Two-period binomial tree

successive value is obtained from the previous one by multiplication by an independent positive random factor.

Consider the two-period case of Figure 2 and a contingent claim with exercise value O at time 2 where $O = O_0, O_1, O_2$ in the three states as shown. By the one-period argument, the no-arbitrage price for the claim at time 1 is $v_{1,0} = (q_0 O_0 + q_1 O_1)/R$ if the price is uS and $v_{1,1} = (q_0 O_1 + q_1 O_2)/R$ if the price is dS . However, now our contingent claim is equivalent to a one-period claim with payoff $v_{1,0}, v_{1,1}$, so its value at time 0 is just $(q_0 v_{1,0} + q_1 v_{1,1})/R$, which is equal to

$$v_{0,0} = E_Q \left[\frac{1}{R^2} O \right] \quad (7)$$

Generalizing to n periods and a claim that pays amounts $O_0, \dots, O_n$ at time n , the value at time 0 is

$$v_{0,0} = E_Q \left[\frac{1}{R^n} O \right] = \frac{1}{R^n} \sum_{j=0}^n C_j^n q_0^{n-j} q_1^j O_j \quad (8)$$

where C_j^n is the binomial coefficient $C_j^n = n!/(j!(n-j)!)$. From equation (3) the initial hedge ratio (the number N of shares is the hedging portfolio at time 0) is

$$\begin{aligned} N &= \frac{v_{1,0} - v_{1,1}}{uS - dS} \\ &= \frac{1}{SR^{n-1}(u-d)} \sum_{j=0}^{n-1} C_j^{n-1} q_0^{n-1-j} q_1^j (O_j - O_{j+1}) \end{aligned} \quad (9)$$

For example, suppose $S = 100$, $R = 1.001$, $u = 1.04$, $n = 25$, and O is a call option with strike $K = 100$, so that $O_j = [Su^{n-2j} - K]^+$. The option value

is $v_{0,0} = 9.086$ and $N = 0.588$. The initial holding in the bank is therefore $v_{0,0} - NS = -49.72$. This is the typical situation: hedging involves leverage (borrowing from the bank to invest in shares).

Scaling the Binomial Model

Now let us consider scaling the binomial model to a continuous limit. Take a fixed time horizon T and think of the price $S(i)$ above, now written $S_n(i)$, as the price at time $iT/n = i\Delta t$. Suppose the continuously compounding rate of interest is r , so that $R = e^{r\Delta t}$. Finally, define $h = \log u$ and $X(i) = \log(S(i)/S(0))$; then $X(i)$ is a random walk on the lattice $\{\dots -2h, -h, 0, h, \dots\}$ with right and left probabilities q_0, q_1 as defined earlier and $X(0) = 0$. If we now take $h = \sigma\sqrt{\Delta t}$ for some constant σ , we find that

$$q_0, q_1 = \frac{1}{2} \pm \frac{h}{2\sigma^2} \left(r - \frac{1}{2}\sigma^2 \right) + O(h^2) \quad (10)$$

Thus $Z(i) := X(i) - X(i-1)$ are independent random variables with

$$\begin{aligned} EZ(i) &= \frac{h^2}{\sigma^2} \left(r - \frac{1}{2}\sigma^2 \right) + O(h^3) \\ &= \left(r - \frac{1}{2}\sigma^2 \right) \Delta t + O(n^{-3/2}) \end{aligned} \quad (11)$$

and

$$\text{var}(Z(i)) = \sigma^2 \Delta t + O(n^{-2}) \quad (12)$$

Hence $X_n(T) := X(n) = \sum_{i=1}^n Z(i)$ has mean μ_n and variance V_n such that $\mu_n \rightarrow (r - \sigma^2/2)T$ and $V_n \rightarrow \sigma^2 T$ as $n \rightarrow \infty$. By the central limit theorem, the distribution of $X_n(T)$ converges weakly to the normal distribution with the limiting mean and variance. If the contingent claim payoff is a continuous bounded function $O = h(S_n(n))$, then the option value converges to a normal expectation that can be written as

$$\begin{aligned} V_0(S) &= \frac{e^{-rT}}{\sqrt{2\pi}} \int_{-1}^1 h \left(S \exp \left(r - \frac{1}{2}\sigma^2 \right) T \right. \\ &\quad \left. + \sigma\sqrt{T}x \right) e^{-\frac{1}{2}x^2} dx \end{aligned} \quad (13)$$

This is the Black–Scholes formula. It can be given in more explicit terms when, for example, $h(S) = [S - K]^+$, the standard call option (see **Black–Scholes Formula**).

American Options

In the multiperiod binomial model, the basic computational step is the backward recursion

$$v_{i-1,j} = \frac{1}{R} (q_0 v_{i,j} + q_1 v_{i,j+1}) \quad (14)$$

defining the values at time step $i-1$ from those at time i by discounted conditional expectation, starting with the exercise values $v_{n,j} = O_j$ at the final time n . In an American option, we have the right to exercise at any time, the exercise value at time i being some given function $h(i, S_i)$, for example, $h(i, S_i) = [K - S_i]^+$ for an American put. The exercise value at node (i, j) in the binomial tree is therefore $\tilde{h}(i, j) = h(i, Su^{i-2j})$. In this case, it is natural to replace equation (14) by

$$v_{i-1,j} = \max\{v_{i-1,j}^c, \tilde{h}(i-1, j)\} \quad (15)$$

where $v_{i-1,j}^c$ is given by the right-hand side of equation (14). At each node $(i-1, j)$, we compare the “continuation value” $v_{i-1,j}^c$ with the “immediate exercise” value $\tilde{h}(i-1, j)$ and take the larger value. This intuition is correct, and the value $v_{0,0}$ obtained by applying equation (15) for $i = n, n-1, \dots, 1$ with starting condition $v_{n,j} = \tilde{h}(n, j)$ is the unique arbitrage-free value of the American option at time 0.

The reader should refer to **American Options** for a complete treatment, but, in outline, the argument establishing the above claim is as follows. The algorithm divides the set of nodes into two, the *stopping set* $\mathcal{S} = \{(i, j) : v_{i,j} = \tilde{h}(i, j)\}$ and the complementary *continuation set* $\mathcal{C}$. By definition, $(n, j) \in \mathcal{S}$ for $j = 0, \dots, n$. Let τ^* be the stopping time $\tau^* = \min\{i : S_i \in \mathcal{S}\}$. Then τ^* is the optimal time at which the holder of the option should exercise. The process $V_i = v_{i,S_i}/R^i$ is a supermartingale, while the stopped process $V_{i \wedge \tau^*}$ is a martingale with the property that $V_{i \wedge \tau^*} \geq h(i \wedge \tau^*, S_{i \wedge \tau^*})/R^i$. These facts follow from the general theory of optimal stopping, but are not hard to establish directly in the present case. The value $V_{i \wedge \tau^*}$ can be replicated by trading in the underlying asset (using the basic hedging strategy (3))

derived for the one-period model). It follows that this strategy (call it $\mathcal{SR}$) is the *cheapest superreplicating strategy*, that is, $x = v_{0,0}$ is the minimum capital required to construct a trading strategy with value X_i at time i with the property that $X_i \geq h(i, S_i)$ for all i almost surely. If the seller of the option is paid more than $v_{0,0}$, then he or she can put the excess in the bank and employ the trading strategy $\mathcal{SR}$, which is guaranteed to cover his or her obligation to the buyer whenever he or she chooses to exercise. Conversely, if the seller will accept $p < v_{0,0}$ for the option then the buyer should short $\mathcal{SR}$, obtaining an initial value $v_{0,0}$ of which p is paid to the seller and $v_{0,0} - p$ placed in (for clarity) a second bank account. The short strategy has value $-X_i$ and the buyer exercises at τ^* , receiving from the seller the exercise value $h(\tau^*, S_{\tau^*}) = X_{\tau^*}$, which is equal and opposite to the value of the short hedge at τ^* . Thus, there is an arbitrage opportunity for one party or the other unless the price is $v_{0,0}$.

The impact of the binomial model as introduced by Cox *et al.* [1] is largely due to the fact that the European option pricer can be turned into an American option pricer by a trivial one-line modification of the code. Pricing American options in (essentially) the Black–Scholes model was recognized as a free-boundary problem in partial differential equations (PDE) by McKean [3] in 1965, but the only computational techniques were PDE methods (see **Finite Difference Methods for Early Exercise Options**) generally designed for much more complicated problems.

Computations in the Binomial Model

Nowadays the binomial model is rarely, if ever, used for practical problems, largely because it is comprehensively outperformed by the trinomial tree (see **Tree Methods**).

First, the form of the tree given above is probably not the best if we want to regard the tree as an approximation to the Black–Scholes model. We see from equation (10) that the risk-neutral probabilities q_0, q_1 depend on r , so if we want to calibrate the model to the market yield curve we will need time-varying q_0, q_1 . This can be avoided if we write the Black–Scholes model as

$$S_t = F_{0,t} M_t \quad (16)$$

where $F_{0,t}$ is the forward price quoted at time 0 for exchange at time t and

$$M_t = \exp\left(\sigma W_t - \frac{1}{2}\sigma^2 t\right) \quad (17)$$

is the exponential martingale with Brownian motion W_t . See **Black–Scholes Formula** for this representation. $F_{0,t}$ only depends on the spot price S_0 and the yield curve (and the dividend yield, if any), so the only stochastic modeling required relates to the Brownian motion σW_t . Here we can use a standard “symmetric random walk” approximation: divide the time interval $[0, T]$ into n intervals of length $\delta = T/n$ and take a space step of length $h = \sigma\sqrt{\delta}$. At each discrete time point, the random walk (denoted X_i) takes a step of $\pm h$ with probability 1/2 each—this is just a binomial tree with equal up and down probabilities. For a single step $Z = X_i - X_{i-1} = \pm h$ we have $E[e^Z] = \cosh h$, so if we define $\alpha = \log(\cosh h)$ then $M_i^{(n)} = \exp(X_i - \alpha i)$ is a positive discrete-time martingale with $E[M_i^{(n)}] = 1$. It is a standard result that the sequence $M^{(n)}$ (suitably interpreted) converges weakly to M given by equation (17) as $n \rightarrow \infty$. This gives us a discrete-time model

$$S_i^{(n)} = F_{0,i\delta} M_i^{(n)} \quad (18)$$

such that $E[S_i^{(n)}] = F_{0,i\delta}$ holds *exactly* at each i . At node (i, j) in the tree the corresponding price is $F_{0,i\delta} \exp((n-j)h - i\alpha)$. Essentially, we have replaced the original multiplicative random walk representing the price $S(t)$ by an additive random walk representing the return process $\log S(t)$. The advantages of this are (i) all the yield curve aspects are bundled up in the model-free function F , and (ii) the stochastic model is “universal” (and very simple).

The decisive drawback of any binomial model is the absolute inflexibility with respect to volatility: it is impossible to maintain a recombining tree while allowing time-varying volatility. This means that the model cannot be calibrated to more than a single option price, making it useless for real pricing applications. The trinomial tree gets around this: we can adjust the local volatility by changing the transition probabilities while maintaining the tree geometry (i.e., the constant spatial step h).

American Options

An American option is a contract between the seller and the buyer. It is characterized by a nonnegative random function of time Z and a maturity. The option can be exercised at any time t between the initial date and the maturity. If the buyer exercises the option at time t , he/she receives the amount of money $Z(t)$ at time t . The buyer may exercise the option only once before the maturity. The price of an American option is always greater than or equal to the price of the corresponding European option (see **Black–Scholes Formula**). Indeed, the buyer of an American option gets more rights than the one who holds a European option, as he/she may exercise the option at any time before the maturity. This is the right of early exercise, and the difference between the American and European options prices is called the *early exercise premium*. The basic American options are American call and put options (see **Call Options**): they allow the buyer to sell or buy a financial asset at a price K (the strike price) and before a date (maturity) agreed before. The function Z associated to the call (respectively put) option is then $Z(t) = (S_t - K)^+$ (respectively $Z(t) = (K - S_t)^+$), where S_t is the value at time t of the underlying financial asset.

The study of American options began in 1965 with McKean [41] who considered the pricing problem as an optimal stopping problem and reduced it to a free boundary problem. The option value is then computable if one knows the free boundary called the *optimal exercise boundary*. In 1976, Van Moerbeke [48] exhibited some properties of this boundary. The formalization of the American option pricing problem as an optimal stopping problem was done in the two pioneering works of Benssoussan and Karatzas [5, 32].

They have proved that, under no arbitrage and completeness assumptions (see **Complete Markets**), the value process of an American option is the Snell envelope of the pay-off process, that is, the smallest supermartingale greater than the pay-off process. From previous works on these processes [23], we can derive some properties of the value process. Especially, we obtain characterization of optimal exercise times. In the section American Option and Snell Envelope, we present the main results and some

numerical methods based on this characterization of the option value process.

We can adopt a complementary point of view to study an American option. If we specify the evolution model for the underlying assets of the option, we could characterize the option value as the solution of a variational inequality. This method, introduced by Benssoussan and Lions [6], was applied to American options by Jaillet *et al.* [31]. We present this variational approach in the section Analytic Properties of American Options. We conclude this survey by giving results on exercise regions. In particular, we recall a formula linking the European and the American option prices known as the early exercise premium formula (see the section Exercise Region).

American Option and Snell Envelope

To price and hedge an American option, we have to choose a model for the financial market. We consider a filtered probability space $(\Omega, \mathbb{F} = (\mathcal{F}_t)_{0 \leq t \leq T}, \mathbb{P})$, where T is the maturity of our investment, $\mathcal{F}_t$ the information available at time t , and $\mathbb{P}$ the historical probability. We assume that the market is composed of $d + 1$ assets: $S^0, S^1, \dots, S^d$. S^0 is a deterministic process representing the time value of money. The others are risky assets such that S_t^i is the value of asset i at time t . In this section, we assume that the market does not offer arbitrage opportunities and is complete (see **Complete Markets**). Harisson and Pliska [28] observed that the no arbitrage assumption is equivalent to the existence of a probability measure equivalent to the historical one under which the discounted asset price processes are martingales. In a complete market, such a probability measure is unique and called the *risk-neutral probability measure* (see **Risk-neutral Pricing**). We will denote it by $\mathbb{P}^*$.

American Option Pricing

We present the problems linked to the American option study. The first one is the option pricing. An American option is characterized by an adapted and nonnegative process $(Z_t)_{t \geq 0}$, which represents the option pay-off if its owner exercises it at time t . We generally define Z as a function of one or several underlying assets. For instance, for a call option with strike price K , we have $Z_t = (S_t - K)^+$

or for a put option on the minimum of two assets, we have $Z_t = (K - \min(S_t^1, S_t^2))^+$. There also exist options, called *Amerasian options*, where the pay-off depends on the whole path of the assets, for instance, $Z_t = \left(K - \frac{1}{t} \int_0^t S_u du\right)^+$.

Using arbitrage arguments, Benssoussan and Karatzas [5, 32] have shown that the discounted American option value at time t is the Snell envelope of the discounted pay-off process [19, 43]. For the definition and general properties on the Snell envelope, we refer to [23] for continuous time and to [44] for discrete time. We can then assert that the price at time t of an American option with pay-off process Z and maturity T is

$$P_t = \text{esssup}_{\tau \in \mathcal{T}_{t,T}} \mathbb{E}_{\mathbb{P}^*} \left[\frac{S_t^0}{S_\tau^0} Z_\tau \mid \mathcal{F}_t \right] \quad (1)$$

where $\mathcal{T}_{t,T}$ is the set of $\mathbb{F}$ -stopping times with values in $[t, T]$.

The second problem appearing in the option theory consists in determining a hedging strategy for the option seller (*see Hedging*). The solution follows directly from the Snell envelope properties. Indeed, if X is a process, we will denote the discounted process by $\tilde{X} = \frac{X}{S^0}$ and we have the following result ([35, Corollary 10.2.4]).

Proposition 1 *The process $(\tilde{P}_t)_{0 \leq t \leq T}$ is the smallest right-continuous super martingale that dominates $(\tilde{Z}_t)_{0 \leq t \leq T}$.*

As $(\tilde{P}_t)_{0 \leq t \leq T}$ is a super martingale, it admits a Doob decomposition (*see Doob–Meyer Decomposition*). There exist a unique right-continuous martingale $(M_t)_{0 \leq t \leq T}$ and a unique nondecreasing, continuous, adapted process $(A_t)_{0 \leq t \leq T}$ such that $A_0 = 0$ and $\tilde{P}_t = M_t - A_t$ for all $t \in [0, T]$. This decomposition of P is very useful to determine a surreplication strategy for an American option (*see Superhedging*). A strategy is defined as a predictable process $(\phi_t)_{0 \leq t \leq T}$ such that the value, at time t , of the portfolio associated with this strategy is $V_t(\phi) = \sum_{i=0}^d \phi_t^i S_t^i$. In a complete market, each contingent claim is replicable; then there exists a self-financing strategy ϕ such that $V_T(\phi) = S_T^0 M_T$. As $\tilde{V}(\phi)$ is a martingale under the risk-neutral probability, we get $\tilde{V}_t(\phi) = M_t$ for all $t \in [0, T]$. In conclusion, we have constructed a self-financing strategy such that

$$\forall t \in [0, T], \quad V_t(\phi) = P_t + S_t^0 A_t \geq P_t \quad (2)$$

This is a surreplication strategy for American options. Moreover, for this strategy, the initial wealth for hedging the option is minimum because we have $V_0(\phi) = P_0$.

The third problem arising in the American option theory is linked to early exercise opportunity. Contrary to European options, for the American option holder, knowing the arbitrage price of his/her option is not enough. He/she has to know when it is optimal for him/her to exercise the option. The tool to study this problem is the optimal stopping theory.

Optimal Exercise

We recall some useful results of the optimal stopping theory and apply them to the American put option in the famous Black–Scholes model. These results are proved in [23] in a larger setting and their financial applications have been developed in [35]. An optimal stopping time for an American option holder is a stopping time that maximizes his/her gain. Consequently, a stopping time ν is optimal if we have

$$\mathbb{E}_{\mathbb{P}^*}[\tilde{Z}_\nu] = \text{esssup}_{\tau \in \mathcal{T}_{0,T}} \mathbb{E}_{\mathbb{P}^*}[\tilde{Z}_\tau \mid \mathcal{F}_t] \quad (3)$$

We have a characterization of optimal stopping times, thanks to the following theorem.

Theorem 1 *Let $\tau^* \in \mathcal{T}_{0,T}$. τ^* is an optimal stopping time if and only if $P_{\tau^*} = Z_{\tau^*}$ and the process $(\tilde{P}_{t \wedge \tau^*})_{0 \leq t \leq T}$ is a martingale.*

It follows from this result that the stopping time

$$\tau^* = \inf\{t \geq 0 : P_t = Z_t\} \wedge T \quad (4)$$

is an optimal stopping time and, obviously, it is the smallest one. We can easily determine the largest optimal stopping time by using the Doob decomposition of super martingale. We introduce the following stopping time:

$$\nu^* = \inf\{t \geq 0 : A_t > 0\} \wedge T \quad (5)$$

and it is easy to see that ν^* is the largest optimal stopping time.

We then apply these results to an American put option in Black–Scholes framework (*see Black–Scholes Formula*). We assume that the

underlying asset S of the option is solution, under the risk-neutral probability, to the following equation:

$$dS_t = S_t (r dt + \sigma dW_t) \quad (6)$$

with $r, \sigma > 0$ and W a standard Brownian motion.

From the Markov property of S , we can deduce that the option price at time t is $P(t, S_t)$, where

$$P(t, x) = \sup_{\tau \in T_{0, T-t}} \mathbb{E}_{\mathbb{P}^*} [e^{-r\tau} (K - S_\tau)^+ | S_0 = x] \quad (7)$$

It is easy to see that $t \rightarrow P(t, x)$ is nonincreasing for all $x \in [0, +\infty)$. Moreover, for $t \in [0, T]$, the function $x \rightarrow P(t, x)$ is convex [24, 29, 30]. From the convexity of P , we deduce that there exists a unique optimal stopping time: $\tau^* = \inf\{t \geq 0 : P(t, S_t) = (K - S_t)^+\} \wedge T$. We introduce the so-called critical price or free boundary $s(t) = \inf\{x \in [0, +\infty) : P(t, x) > (K - x)^+\}$ and can write that

$$\begin{aligned} \tau^* &= \inf\{t \geq 0 : S_t \leq s(t)\} \wedge T \\ &= \inf\{t \geq 0 : W_t \leq \alpha(t)\} \wedge T \\ \text{with } \alpha(t) &= \frac{1}{\sigma} \left(\ln \left(\frac{s(t)}{S_0} \right) - \left(r - \frac{\sigma^2}{2} \right) t \right) \end{aligned} \quad (8)$$

Hence, τ^* is the reaching time of α by a Brownian motion. If α was known, we could compute τ^* and then P . However, the only way to get the law of τ^* explicitly is to reduce the dimension by considering options with infinite maturity (also known as *perpetual options*). In this case, we have the following result ([37, Proposition 4.5]).

Proposition 2 *The value function of an American perpetual put option is*

$$\begin{aligned} P^\infty(x) &= \sup_{\tau \in T_{0, +\infty}} \mathbb{E}_{\mathbb{P}^*} [e^{-r\tau} (K - S_\tau)^+ \\ &\quad \times \zeta_{\tau < +\infty} | S_0 = x] \end{aligned} \quad (9)$$

and is given by

$$\begin{aligned} P^\infty(x) &= \begin{cases} K - x & \text{if } x \leq s^* \\ (K - s^*) \left(\frac{s^*}{x} \right)^\gamma & \text{if } x > s^* \end{cases} \\ \text{where } \gamma &= \frac{2r}{\sigma^2} \text{ and } s^* = \frac{K\gamma}{1 + \gamma} \end{aligned} \quad (10)$$

is the critical price.

Another technique to reduce the dimension of the problem is the randomization of the maturity applied in [9, 13], but only approximations of the option price can be obtained in this way. In the following section, we present methods to approximate P based on the discretization of the problem.

Approximation of the American Option Value

To approximate P_t , it is natural to restrict the set of exercise dates to a finite one. We then introduce a subdivision $\mathcal{S} = \{t_1, \dots, t_n\}$ of the interval $[0, T]$ and assume that the option owner can exercise only at a date in $\mathcal{S}$. Such options are called *Bermuda options* and their price at time t is given by

$$P_t^n = \text{esssup}_{\tau \in T_{t, T}^n} \mathbb{E}[S_t^0 \tilde{Z}_\tau | \mathcal{F}_t] \quad (11)$$

where $T_{t, T}^n$ is the set of $\mathbb{F}$ -stopping times with values in $\mathcal{S} \cap [t, T]$. We obviously have $\lim_{n \rightarrow +\infty} P^n = P$ and some estimates of the error have been given in [1, 15]. For perpetual put options, Dupuis and Wang [21] have obtained a first-order expansion of the error on the value function and on the critical prices. In the case of finite maturity, this problem is still open; we just know that the error is proportional to $\frac{1}{n}$ for the value function and to $\frac{1}{\sqrt{n}}$ for the critical prices [18].

We have to determine $P_{t_i}^n$ for all $i \in \{1, \dots, n\}$. For this, we use the so-called dynamic programming equation:

$$\begin{cases} P_T^n = Z_T \\ P_{t_i}^n = \max \left(Z_{t_i}, \mathbb{E}_{\mathbb{P}^*} \left[\frac{S_{t_i}^0}{S_{t_{i+1}}^0} P_{t_{i+1}}^n | \mathcal{F}_{t_i} \right] \right) \end{cases} \quad (12)$$

This equation is easy to understand with financial arguments. At maturity of the option, it is obvious that the option price P_T^n is equal to the pay-off Z_T . At time $t_i < T$, the option holder has two choices: he/she exercises and then earns Z_{t_i} ; else he/she keeps the option and then would have the option value at time $n+1$, $P_{t_{i+1}}^n$. Hence, using the no arbitrage assumption, one can prove that at time t_i the option seller should receive

$$\max \left(Z_{t_i}, \mathbb{E}_{\mathbb{P}^*} \left[\frac{S_{t_i}^0}{S_{t_{i+1}}^0} P_{t_{i+1}}^n | \mathcal{F}_{t_i} \right] \right) \quad (13)$$

Computing the Bermuda option price consists now in calculating the expectations in the dynamic

programming equation. On the one hand, Monte Carlo techniques have been applied to solve this problem (see **Monte Carlo Simulation for Stochastic Differential Equations; Bermudan Options** and [11]). More precisely, we can quote some regression methods based on projections on Hilbert space base [40, 47], quantization algorithms proposed in [1, 2], and some Monte Carlo methods based on Malliavin calculus [3, 8]. On the other hand, we can use a discrete approximation of the underlying assets process. A widely used model is the Cox, Ross, and Rubinstein model (see **Binomial Tree**). We introduce a family of independent and identically distributed Bernoulli variables $(U_n)_{1 \leq n \leq N}$ with values in $\{b, h\}$, where $-1 < b < h$. We then consider only two assets S^0 and S whose respective initial values are 1 and S_0 such that

$$S_n^0 = (1+r)^n \quad \text{and} \quad S_n = S_{n-1}(1+U_n) \\ \forall n \in \{1, \dots, N\} \quad (14)$$

where $r > 0$ is the constant interest rate of the market. From the no arbitrage assumption, it follows that $b < r < h$ and that, under the risk-neutral probability $\mathbb{P}^*$, we have $p := \mathbb{P}^*(U_1 = h) = \frac{r-b}{h-b}$. Hence, using the Markov property of S , we can price an American option on S . For instance, for a call option with exercise price K , we get $P_n = F(n, S_n)$, where F is the solution to the following equation:

$$\left\{ \begin{array}{l} F(N, x) = (K - x)^+ \\ F(n, x) = \max \left\{ K - x, \frac{1}{1+r} \right. \\ \quad \times (pF(n+1, x(1+h)) \\ \quad \left. + (1-p)F(n+1, x(1+b))) \right\} \end{array} \right. \quad (15)$$

The convergence of binomial approximations was first studied in a general setting in [34]. The rate of convergence is difficult to get, but some estimates are given in [36, 38].

In conclusion, for some simple models, one can numerically solve the option pricing problem. However, only the time variable is discretized. Analytical methods have been developed and provide a better understanding of the links between time and space variables. In particular, we can characterize the option value as a solution to a variational inequality and get an approximation of its solution, thanks to finite difference methods. This characterization has many

consequences from the theoretical point of view and on practical aspects.

Analytic Properties of American Options

In this section, we assume that the assets prices process follows a model called *local volatility model* (see **Local Volatility Model**). This model is complete and takes into account the smile of volatility observed when one calibrates the Black–Scholes model (see **Model Calibration; Implied Volatility Surface** and [20]). We suppose that the assets prices process is solution to the following stochastic differential equation:

$$dS_t^i = S_t^i \left(b_i(t, S_t) dt + \sum_{j=1}^d \sigma_{i,j}(t, S_t) dW_t^j \right) \quad (16)$$

where W is a standard Brownian motion on $\mathbb{R}^d$, b a function mapping $[0, T] \times [0, +\infty)^d$ into $\mathbb{R}^d$, and σ a function mapping $[0, T] \times [0, +\infty)^d$ into $\mathbb{R}^{d \times d}$. Moreover, we assume that b is bounded and Lipschitz continuous, that σ is Lipschitz continuous in the space variable, and that there exists $\alpha \geq 1/2$ and σ_H such that $\forall x \in [0, +\infty)^d$, $(t, s) \in [0, T]^2$, $|\sigma(t, x) - \sigma(s, x)| \leq \sigma_H |t - s|^\alpha$. Moreover, to ensure the completeness of the market and the nondegeneracy of the partial differential equation satisfied by European option price functions, we assume that there exist $m > 0$ and $M > 0$ such that

$$\forall (t, x, \xi) \in [0, T] \times [0, +\infty)^d \times \mathbb{R}^d, \\ m^2 \|\xi\|^2 \leq \xi^* \sigma^* \sigma(t, x) \xi \leq M^2 \|\xi\|^2 \quad (17)$$

From the Markov property of the process S , at time t , the price of an American option with maturity T and pay-off process $(f(S_t))_{0 \leq t \leq T}$ is $P(t, S_t)$, where

$$P(t, x) = \sup_{\tau \in T_{t,T}} \mathbb{E} \left[e^{-r(\tau-t)} f(S_\tau) \mid S_t = x \right] \quad (18)$$

The Value Function

To compute the option price, we now have to study the option value function P . From its definition, we can derive immediate properties:

- $\forall x \in [0, +\infty)^d$, $P(T, x) = f(x)$

- $\forall(t, x) \in [0, T] \times [0, +\infty)^d$, $P(t, x) \geq f(x)$
- If the coefficients σ and b do not depend on time, we can write

$$P(t, x) = \sup_{\tau \in \mathcal{T}_0, T-t} \mathbb{E} [e^{-r\tau} f(S_\tau) \mid S_0 = x] \quad (19)$$

then the function $t \rightarrow P(t, x)$ is nonincreasing on $[0, T]$.

Up to imposing some assumptions on the regularity of the pay-off function, we can derive some important continuity properties of P . In this section, we assume that f is nonnegative and continuous on $[0, +\infty)$ such that

$$\begin{aligned} \exists(M, n) \in [0, +\infty) \times \mathbb{N}, \quad \forall x \in [0, +\infty)^d, \\ |f(x)| + \sum_{i=1}^d \left| \frac{\partial f}{\partial x_i}(x) \right| \leq M(1 + |x|^n) \end{aligned} \quad (20)$$

These assumptions are generally satisfied by the pay-off functions appearing in finance, especially by the pay-off functions of put and call options. In this setting, we have the following result [31].

Proposition 3 *There exists a constant $C > 0$ such that*

$$\begin{aligned} \forall t \in [0, T], \quad \forall(x, y) \in [0, +\infty)^{2d}, \\ |P(t, x) - P(t, y)| \leq C |x - y| \\ \forall x \in [0, +\infty)^d, \quad \forall(t, s) \in [0, T]^2, \\ |P(t, x) - P(s, y)| \leq C \left| (T - t)^{\frac{1}{2}} - (T - s)^{\frac{1}{2}} \right| \end{aligned} \quad (21)$$

(22)

As a consequence of this result, we can assert that the first-order derivatives of P in the sense of distributions are locally bounded on the open set $(0, T) \times (0, +\infty)^d$. This plays a crucial role in the characterization of P as a solution to a variational inequality.

Variational Inequality

In a more general setting, Benssoussan and Lions [6] have studied existence and uniqueness of solutions of variational inequalities and linked these solutions to those of optimal stopping problems. Applying

this method to the American option problem, Jaillet *et al.* have proved that the value function P can be characterized as the unique solution, in the sense of distribution, of the following variational inequality [31]:

$$\begin{cases} \mathcal{D}P \leq 0, & f \leq P, & (P - f)\mathcal{D}P = 0 & \text{a.e.} \\ P(x, T) = f(x) & \text{on } [0, +\infty) \end{cases} \quad (23)$$

where we set

$$\begin{aligned} \mathcal{D}h(t, x) = \frac{\partial h}{\partial t} + \frac{1}{2} \sum_{i,j=1}^d (\sigma \sigma^*)_{i,j}(t, x) x_i x_j \frac{\partial^2 h}{\partial x_i \partial x_j} \\ + \sum_{i=1}^d b_i(t, x) x_i \frac{\partial h}{\partial x_i} - rh \end{aligned} \quad (24)$$

This inequality directly derives from the properties of the Snell envelope. Indeed, the condition $\mathcal{D}P \leq 0$ is the analytic translation of the super martingale property of $\tilde{P}$, $f \leq P$ corresponds to $Z \leq P$, and the fact that one of this two inequalities has to be an equality follows from the martingale property of $(P_{t \wedge \tau^*})_{0 \leq t \leq T}$.

From the variational inequality, we can use numerical methods, such as finite difference methods, to compute the option price (see **Finite Difference Methods for Early Exercise Options** and [31]). From a theoretical point of view, we can deduce some analytic properties of P . If we add the condition that second-order derivatives of the pay-off function are bounded from below, we have the following result.

Proposition 4 *Regularity of P*

1. *Smooth fit property: For $t \in [0, T)$, the function $x \rightarrow P(t, x)$ is continuously differentiable and its first derivatives are uniformly bounded on $[0, T] \times [0, +\infty)^d$.*
2. *There exists a constant $C > 0$ such that for all $(t, x) \in [0, T) \times [0, +\infty)^d$, we have*

$$\left| \frac{\partial P}{\partial t}(t, x) \right| + |D^2 P(t, x)| \leq \frac{C}{(T - t)^{\frac{1}{2}}} \quad (25)$$

where $D^2 P$ is the Hessian matrix of P .

The *smooth fit property* has equally been established with probabilistic arguments, using the early

exercise premium formula presented in the section Exercise Region [30, 43]. In connection with free boundary problems, some analytic methods have been developed in [26] from which we can deduce the continuity of $\frac{\partial P}{\partial t}$ on $[0, T) \times [0, +\infty)^d$.

Thanks to the variational inequality, we can establish the so-called robustness of Black–Scholes formula [24]. The two main results obtained are the following.

Proposition 5 *We assume that $d = 1$. If the pay-off function is convex, then the value function P is equally convex. Moreover, if there exist $\sigma_1, \sigma_2 > 0$ such that $\sigma_1 \leq \sigma \leq \sigma_2$, then we have*

$$P^{\sigma_1} \leq P \leq P^{\sigma_2} \quad (26)$$

where P^{σ_i} is the value function of the American option on an underlying asset with volatility σ_i .

The propagation of convexity has been proved with probabilistic arguments in [29] and can be extended to the case $d > 1$. The robustness of Black–Scholes formula is equally useful from a practical point of view because it allows to construct surreplication and subreplication strategies using a constant volatility.

When there is only one risky asset modeled as a geometric Brownian motion, the analytic properties presented in this section can be used to transform, thanks to Green’s theorem, the variational inequality in an integral equation (see **Integral Equation Methods for Free Boundaries**). This point of view has been adopted to provide new numerical methods [16] to get theoretical results such as the convexity of the critical price for the put option [22] or its behavior near maturity [16, 25].

Integro-differential Equation

The integro-differential approach can be extended to the American option on jump diffusions (see **Partial Integro-differential Equations (PIDEs)**). In 1976, Merton (see **Merton, Robert C.** and [42]) introduced a model including some discontinuities in the assets value process. He considered a risky asset whose value process is solution to the following equation:

$$dS_t = S_{t-} \left(\mu dt + \sigma dW_t + d \left(\sum_{i=1}^{N_t} U_i \right) \right) \quad (27)$$

where $\mu \in \mathbb{R}$, $\sigma > 0$, W is a standard Brownian motion, N is a Poisson process with intensity $\lambda > 0$, and the U_i are independent and identically distributed variables with values in $(-1, +\infty)$ such that $\mathbb{E}[U_i^2] < +\infty$.

This model is not complete but up to a change of probability measure, we can suppose that $\mu = r - \lambda \mathbb{E}[U_1]$, where $r > 0$ is the constant interest rate of the market. Hence, $\tilde{S}$ is a martingale with respect to the filtration generated by W , N , and $(U_i \mathbb{1}_{\{i \leq N_t\}})_{0 \leq t \leq T}$. The option price is then determined as the initial wealth of a replication portfolio, which minimizes the quadratic risk. Merton obtained closed formulas to calculate the European options price. In this model, Zhang [50] extended the variational inequality approach to evaluate the American options price and he got a characterization of the value function as solution to the following integro-differential equation:

$$\begin{cases} \mathcal{D}P + \mathcal{I}P \leq 0, & f \leq P, \\ (\mathcal{D}P + \mathcal{I}P)(P - f) = 0 & \text{a.e.} \\ P(x, T) = f(x) & \text{on } [0, +\infty) \end{cases} \quad (28)$$

with

$$\begin{aligned} \mathcal{D}h(t, x) &= \frac{\partial h}{\partial t} + \frac{\sigma^2 x^2}{2} \frac{\partial^2 h}{\partial x^2} + \mu x \frac{\partial h}{\partial x} - rh \\ \mathcal{I}h(t, x) &= \lambda \int (h(t, x + z) - h(t, x)) \nu(dz) \end{aligned} \quad (29)$$

where ν is the law of $\ln(1 + U_1)$. Zhang used this equation to derive numerical schemes for approximating P . However, he could not obtain a description of the optimal exercise strategies. This was studied by Pham [46] who obtained a pricing decomposition formula and some properties of the exercise boundary.

In conclusion, analytic properties of the American option value function have been used to build numerical methods of pricing and to get some theoretical properties. Although the variational point of view is better for understanding the discretization of American options, it is less explicit than the probabilistic methods. We can remark that a specific region of $[0, T] \times [0, +\infty)^d$ appears in these two approaches: the so-called exercise region

$$\mathcal{E} = \{(t, x) \in [0, T) \times [0, +\infty)^d : P(t, x) = f(x)\} \quad (30)$$

If we knew $\mathcal{E}$, on the one hand, we would be able to determine the law of optimal stopping times and, on the other hand, the option pricing problem would be reduced to solving a partial differential equation in the complementary set of $\mathcal{E}$. In the following section, we recall some results on exercise regions and in particular we give a price decomposition, known as the *early exercise premium formula*, which involves the exercise region.

Exercise Region

Description

In the section Optimal Exercise, we have already presented a brief description of the exercise region of an American put option on a single underlying following the Black–Scholes model. These results are still true in the local volatility model introduced in the section Analytic Properties of American Options. Hence, for a put option with maturity T and strike price K , we have

$$\mathcal{E} = \{(t, x) \in [0, T) \times [0, +\infty); x \leq s(t)\} \text{ with} \\ s(t) = \inf\{x \in [0, +\infty) : P(t, x) = f(x)\} \quad (31)$$

Using the integral equation satisfied by P in the Black–Scholes model, we can apply general results proved in [27] for free boundary problems and assert that s is continuously differentiable on $[0, T)$. It has been shown that this is still true in the local volatility model using some blow-up techniques and monotonicity formulas [7, 12]. Moreover, Kim [33] proved that $\lim_{t \rightarrow T} s(t) = \min(K, \frac{rK}{\delta})$ if S is solution to $dS_t = S_t((r - \delta)dt + \sigma(t, S_t)dW_t)$. We will see that the behavior of s near maturity has been extensively studied.

The description of exercise region for options on several assets is more interesting because in high dimension numerical methods are less efficient and it helps to have a better understanding of these products. Broadie and Detemple were the first to investigate this problem [10]. They give precise descriptions of the exercise region shapes for the most traded options on several assets. Their results were completed by Villeneuve [49]. In particular, he gives a characterization of the nonemptiness of the exercise region. We just quote here the main results concerning a call option on the maximum on two

assets but the same kinds of results exist for many others options.

We denote by $\mathcal{E}_t$ the temporal section of the exercise region. For a call option on the maximum of two assets, S^1 and S^2 $\mathcal{E}_t$ can be decomposed in two regions: $\mathcal{E}_t^1 = \mathcal{E}_t \cap \{(x_1, x_2) \in [0, +\infty)^2 : x_2 \leq x_1\}$ and $\mathcal{E}_t^2 = \mathcal{E}_t \cap \{(x_1, x_2) \in [0, +\infty)^2 : x_1 \leq x_2\}$. These two regions are convex and can be rewritten as follows:

$$\mathcal{E}_t^1 = \{(x_1, x_2) \in [0, +\infty)^2 : s_1(t, x_2) \leq x_1\} \text{ and} \\ \mathcal{E}_t^2 = \{(x_1, x_2) \in [0, +\infty)^2 : s_2(t, x_1) \leq x_2\} \quad (32)$$

where s_1 and s_2 are the respective continuous boundaries of $\mathcal{E}_1(t)$ and $\mathcal{E}_2(t)$.

To compute these boundaries, we can use the early exercise premium formula given in the following section.

Early Exercise Premium Formula

About the same time, many authors have exhibited a decomposition formula for the American option price [14, 30, 43]. This formula is very enlightening from a financial point of view because it consists in writing that $P_t = P_t^e + a_t$ where P_t^e is the corresponding European option price and a is a nonnegative function of time corresponding to the premium the option buyer has to pay to get the right of early exercise. If the exercise region is known, a closed formula allows us to compute this premium. We recall this formula for a put option on a dividend-paying asset following the Black–Scholes model:

$$P(t, x) = P^e(t, x) + \int_t^T \mathbb{E}_{\mathbb{P}^*} [e^{-r(u-t)} (\delta S_u - rK) \\ \times \mathbb{1}_{\{S_u \geq s(u)\}} | S_t = x] du \quad (33)$$

where $\delta > 0$ is the dividend rate and $P^e(t, x) = \mathbb{E}_{\mathbb{P}^*} [e^{-r(T-t)} (K - S_T)^+ | S_t = x]$. This formula is equally interesting from a theoretical point of view as it leads to an integral equation for the critical price:

$$K - s(t) = P^e(t, s(t)) + \int_t^T \mathbb{E}_{\mathbb{P}^*} [e^{-ru} (\delta S_u - rK) \\ \times \mathbb{1}_{\{S_u \geq s(u)\}} | S_t = s(t)] du \quad (34)$$

This formula has been extended in [10] to American options on several assets. For the call on the maximum on two assets, we get

$$\begin{aligned}
 P(t, x) = & P^e(t, x) + \int_t^T \mathbb{E}_{\mathbb{P}^*} [e^{-r(u-t)} (\delta_1 S_u^1 - rK) \\
 & \times \zeta_{\{S_u^1 \geq s_1(u, S_u^2)\}} | S_t = x] du \\
 & + \int_t^T \mathbb{E}_{\mathbb{P}^*} [e^{-r(u-t)} (\delta_2 S_u^2 - rK) \\
 & \times \zeta_{\{S_u^2 \geq s_2(u, S_u^1)\}} | S_t = x] du \quad (35)
 \end{aligned}$$

Once again an integral equation could be derived for (s_1, s_2) .

We can also use this formula and the integral equation satisfied by the free boundary to study the behavior of the exercise region for short maturity. This is a crucial point for numerical methods. Indeed, we have seen that both the value function and the free boundary present irregularities near maturity, which implies instability in numerical methods.

Behavior Near Maturity

The behavior of the exercise region near maturity has been extensively studied when there is only one underlying asset. In his pioneering work, Van Moerbeke conjectured a parabolic behavior for the boundary near maturity [48]. However, when the asset does not distribute dividends, it has been shown that there is an extra logarithmic factor [4]. Lamberton and Vileneuve have then proved that, in the Black–Scholes model, the free boundary has a parabolic behavior if its limit is a point of regularity for the pay-off function, else a logarithmic factor appears [39]. This result has been extended to local volatility model in [17]. In a recent paper [16], new approximations are provided for the location of the free boundary by using integral equation satisfied by P and s . However, this technique cannot be extended to the case of options on several assets. When there are several underlying assets, the behavior of the exercise boundary near maturity has been studied by Nyström [45], who has proved that the convergence rate, when time to maturity goes to 0, is faster than parabolic.

Asian Options

An Asian option is also known as a *fixed-strike Asian option* or an *average price* or *average rate option*. These options have a payoff based on the average of an underlying asset price over a specified time period. The Asian option has a payoff dependent on the average of the asset price and a strike that is fixed in advance. The other type of Asian option is the average strike option (or floating strike), where the payoff is determined by the difference between the underlying asset price and its average (see **Average Strike Options**). Asian options are path-dependent options as their payoff depends on the asset price path rather than just on the terminal value.

If the average is computed using a finite sample of asset price observations taken at a set of regularly spaced time points, we have a discrete Asian option. A continuous time Asian option is obtained by computing the average *via* the integral of the price path over an interval of time. In reality, contracts are based on discrete averaging; however, if there are a large number of averaging dates, there are advantages in working in continuous time. The average itself can be defined to be geometric or arithmetic. When the geometric average is used, the Asian option has a closed-form solution for the price, whereas the option with arithmetic average does not have a known closed-form solution.

One of the reasons Asian options were invented was to avoid price manipulation toward the end of the option's life. By making the payoff depend on the average price rather than on the price itself, such manipulations have little effect on the option value. For this reason, Asian options are usually of European style. The possibility of exercise before the expiration date would make the option more vulnerable to price manipulation; see [11]. The payoff of an Asian option cannot be obtained by combining other instruments such as vanilla options, forwards, or futures.

Asian options are commonly used for currencies, interest rates, and commodities, and more recently in energy markets. They are useful in corporate hedging situations, for instance, a company exchanging foreign currency for domestic currency at regular intervals. Each transaction could be hedged separately with derivatives or a single Asian option could hedge the "average" rate over the period during which the currency is transferred.

An advantage for the buyer of an Asian option is that it is often less expensive than an equivalent vanilla option. This is because the volatility of the average is lower than the volatility of the asset itself. Another advantage in thinly traded markets is that the payoff does not depend only on the price of the asset on a particular day.

Consider the standard Black–Scholes economy with a risky asset (stock) and a money market account. We also assume the existence of a risk-neutral probability measure Q (equivalent to the real-world measure P) under which discounted asset prices are martingales. Under measure Q we denote the expectation by E , and under Q , the stock price follows:

$$\frac{dS_t}{S_t} = (r - \delta) dt + \sigma dW_t \quad (1)$$

where r is the constant continuously compounded interest rate, δ is a continuous dividend yield, σ is the instantaneous volatility of asset return, and W is a Q -Brownian motion. The reader is referred to **Black–Scholes Formula** for details on the Black–Scholes model and **Risk-neutral Pricing** for a discussion of risk-neutral pricing.

The Asian contract is written at time 0 and expires at $T > t_0$. The averaging begins at time $0 \leq t_0$ and occurs over the period $[t_0, T]$. (It is possible to have contracts where the averaging period finishes before maturity T , but this case is not covered here.) It is of interest to calculate the price of the option at the current time t , where $0 \leq t \leq T$. The position of t compared to the start of the averaging, t_0 , may vary. If $t \leq t_0$, the option is "forward starting". The special case $t = t_0$ is called a *starting option* here. If $t > t_0$, the option is termed *in progress* as the averaging has begun.

We consider an Asian contract that is based on the value A_t^l , where we denote $l = c$ for continuous averaging and $l = d$ for discrete averaging. The continuous arithmetic average is given as

$$A_t^c = \frac{1}{t - t_0} \int_{t_0}^t S_u du, \quad t > t_0 \quad (2)$$

and by continuity, we define $A_{t_0}^c = S_{t_0}$. For the discrete arithmetic average, denote $0 \leq t_0 < t_1 < \dots < t_n = T$, and for current time $t_m \leq t < t_{m+1}$ (for integer $0 \leq m \leq n$),

$$A_t^d = \frac{1}{m+1} \sum_{0 \leq i \leq m} S_{t_i} \quad (3)$$

The corresponding geometric average $G_t^l; l = c, d$ is defined to be

$$G_t^c = \exp\left(\frac{1}{t-t_0} \int_{t_0}^t \ln S_u du\right) \quad (4)$$

for continuous averaging and

$$G_t^d = (S_{t_0} S_{t_1} \dots S_{t_m})^{1/(m+1)} \quad (5)$$

for discrete averaging.

The payoff of an Asian call with arithmetic averaging is given as

$$(A_T^l - K)^+ \quad (6)$$

and the payoff of an Asian put with arithmetic averaging is given as

$$(K - A_T^l)^+ \quad (7)$$

where K is the fixed strike. Option payoffs depending on the geometric average are identical with A_T^l replaced by G_T^l .

By standard arbitrage arguments, the time- t price of the Asian call is

$$e^{-r(T-t)} \mathbb{E}[(A_T^l - K)^+ | \mathcal{F}_t] \quad (8)$$

and the price of the put is

$$e^{-r(T-t)} \mathbb{E}[(K - A_T^l)^+ | \mathcal{F}_t] \quad (9)$$

It is worth noting that in pricing the Asian option, we need to consider only those cases where $t \leq t_0$. For $t > t_0$, the option is in progress, and we can write $e^{-r(T-t)} \mathbb{E}[(A_T - K)^+ | \mathcal{F}_t]$ as

(documented in many papers including Levy [13]), so it is enough to consider the call option and derive the price of the put from this.

The main difficulty in pricing and hedging the Asian option is that the random variable A_T does not have a lognormal distribution. This makes the pricing very involved, and an explicit formula does not exist to date. This is an interesting mathematical problem and many research papers have been and still are written on the topic. The first of these was by Boyle and Emmanuel [3] in 1980.

Early methods for pricing the Asian option with arithmetic average involved replacing the arithmetic average A_T with the geometric average G_T , which is lognormally distributed; see [5, 10, 11, 15, 17]. This gives a simple formula, but it underprices the call significantly. However, it is worth noting that the formula leads to a scaling known as the $1/\sqrt{3}$ rule, since for $t > t_0$, the volatility is scaled down by this factor. That is, the formula involves the term $\sigma \frac{1}{\sqrt{3}} \sqrt{T-t}$. This is a particularly useful observation if the averaging period is quite short relative to the life of the option. See [12], among others, for a description and more details.

The second class of methods used is to approximate the true distribution of the arithmetic average using an approximate distribution, usually lognormal with appropriate parameters. True moments for A_T are equated with those implied by a lognormal model, so

$$\mathbb{E}A_T^n = e^{n\alpha + 1/2n^2v^2} \quad (11)$$

for any integer n and α, v are the mean and standard deviation of a normally distributed variable. This idea was used in a number of papers including

$$\begin{aligned} & e^{-r(T-t)} \mathbb{E}_t \left[\left(\frac{1}{T-t_0} \int_{t_0}^T S_u du + \frac{t-t_0}{T-t_0} A_t - K \right)^+ \right] \\ &= \frac{T-t}{T-t_0} e^{-r(T-t)} \mathbb{E}_t \left[\left(\frac{1}{T-t} \int_t^T S_u du - \left(\frac{T-t_0}{T-t} K - \frac{t-t_0}{T-t} A_t \right) \right)^+ \right] \end{aligned} \quad (10)$$

where $\mathbb{E}_t$ denotes the expectation conditional on information at time t . This is now the time t price of $\frac{T-t}{T-t_0}$ times an Asian option with averaging beginning at time t , with modified strike $\left(\frac{T-t_0}{T-t} K - \frac{t-t_0}{T-t} A_t \right)$. The prices of Asian options also satisfy a put-call parity

[13]. Turnbull and Wakeman [19] also corrected for skew and kurtosis by expanding about the lognormal. The practical advantage of such approximations is their ease of implementation; however, typically these

methods work well for some parameter values but not for others.

A further analytical technique in approximating the price of the Asian option is to establish price bounds. Curran [6] and Rogers and Shi [16] used conditioning to obtain a two-dimensional integral, which proves to be a tight lower bound for the option.

Much work has been done on pricing the Asian option using quasi-analytic methods. Geman and Yor [8] derived a closed-form solution for an “in-the-money” Asian call and a Laplace transform for “at-the-money” and “out-of-the-money” cases. Their methods are based on a relationship between geometric Brownian motion and time-changed Bessel processes. To price the option, one must invert the Laplace transform numerically; see [7]. Shaw [18] demonstrated that the inversion can be done quickly and efficiently for all reasonable parameter choices in Mathematica, making this a fast and effective approach. Linetsky [14] produced a quasi-analytic pricing formula using eigenfunction methods, with highly accurate results, also employing a package such as Mathematica.

Direct numerical methods such as Monte Carlo or quasi-Monte Carlo simulation and finite-difference partial differential equation (PDE) methods can be used to price the Asian option (see **Lattice Methods for Path-dependent Options**). In fact, given the popularity of such techniques, these methods were probably amongst the first used by practitioners (and remain popular today). Monte Carlo simulation was used to price Asian options by Broadie and Glasserman [4] and Kemna and Vorst [11], among many other more recent researchers. Simulation methods have the advantage of being widely used by practitioners to price derivatives, so no “new” method is required. Additional practical features such as stochastic volatility or interest rates can be incorporated without a significant increase in complexity. Control variates can often be used (e.g., using a geometric Asian option when pricing an arithmetic option). Additionally, simulation is often used as a benchmark price against which other methods are tested. The disadvantages are that it is computationally expensive, even when variance reduction techniques are used. Lapeyre and Temam [12] showed that Monte Carlo simulation can be competitive under the more advanced schemes they propose and with variance reduction techniques.

The Asian option is an exotic path-dependent option since the value at any point in time depends on the history of the underlying asset price. Specifically, the value of the option at t depends on the current level of the underlying asset S_t , time to expiry $T - t$, and the average level of the underlying up to t , A_t . Zvan *et al.* [21] presented numerical methods for solving this PDE. It turns out that the problem can be reduced to two variables (one state and the other time). Rogers and Shi [16], Alziary *et al.* [1], and Andreasen [2] formulated a one-dimensional PDE. The PDE approach is flexible in that it can handle market realities, but it is difficult to solve numerically as the diffusion term is very small for values of interest on the finite-difference grid. Vecer [20] reformulated the problem using analogies to passport options [9] to obtain an unconditionally stable PDE, which is more easily solved.

Methods based on discrete sampling become more appropriate when there are relatively few averaging dates. One simplistic approach is a scaling correction to volatility as described. Other possibilities include a Monte Carlo simulation or numerical solution of a sequence of PDEs [2]. Monte Carlo simulation can be quite efficient when there are only a small number of averaging dates, since the first “step” can take one straight to the averaging period (under the usual exponential Brownian motion model). Andreasen [2] priced discretely sampled Asian options using finite-difference schemes on a sequence of PDEs. This is particularly efficient if the averaging period is short and hence there are only a small number of PDEs to solve. He compared his PDE results to that of Monte Carlo simulation and showed that the finite-difference schemes get within a penny accuracy of the Monte Carlo simulation in less than a second of CPU time.

To conclude, there has been ongoing research into the methods for pricing the Asian option. It seems, however, the current-state-of-the-art pricing methods (good implementation of inversion of Laplace transform, eigenfunction and other expansions, stable PDE, and Monte Carlo simulation where appropriate) are fast, accurate, and adequate for most uses.

Arbitrage Bounds

A key question in option pricing concerns how to incorporate information about the prices of existing, liquidly traded options into the prices of exotic options. In the classical **Black–Scholes model**, where there is only one parameter to choose, this question becomes: what do existing prices tell us about the volatility? Since the Black–Scholes model lacks the flexibility to capture all the market information, a wide variety of pricing models have been proposed. Rather than specifying a model and pricing with respect to this model, an alternative approach is to construct model-free *arbitrage* bounds on the price of exotic options. Arbitrage bounds are constraints on the price of an option, due to the absence of **arbitrage strategies**. These strategies are typically derived from relationships between the payoff of an option, and the payoff of a simple trading strategy constructed from other related derivatives—for example, the strategy might be a buy-and-hold strategy. If such a simple trading strategy can be shown to be worth at least as much as the corresponding option at maturity in every possible outcome, then the initial cost of the trading strategy must be more than the cost of the option, or else there exists a simple arbitrage. An important feature of these bounds is that they are often valid for a very wide class of models.

Arbitrage Bounds for Call Prices

Perhaps the earliest and simplest example of arbitrage bounds are the following inequalities, which are described in the seminal paper [29]:

$$\max\{0, S_0 - B(T)K\} \leq C(K, T) \leq S_0 \quad (1)$$

where $C(K, T)$ is the time-0 price of a *European call* option on the asset $(S_t)_{t \geq 0}$ with strike K and maturity T , and $B(T)$ is the time-0 price of a bond that is worth \$1 at time T . These bounds can be derived from the following simple arbitrages:

1. Suppose $C(K, T) > S_0$. Then we can construct an arbitrage by selling the call option and buying the asset. We receive an initial positive cash flow, while at maturity the option is worth $(S_T - K)_+$, which is less than S_T , the value of the asset we hold.
2. Suppose $C(K, T) < S_0 - B(T)K$. Then we can construct an arbitrage by buying the call option with strike K , selling short the asset, and buying K units of the bond that pays \$1 at time T . At time 0, we receive the cash amount

$$S_0 - B(T)K - C(K, T) \quad (2)$$

which, by assumption, is strictly positive. At maturity, writing $x_+ = \max\{x, 0\}$, we hold a portfolio whose value is

$$(S_T - K)_+ - (S_T - K) \quad (3)$$

which is positive.

3. Finally, it is clear that the call option must have a positive value (i.e., $C(T, K) \geq 0$), but this can also be considered a consequence of the arbitrage strategy of “buying” the derivative (for a negative price), and hence receiving positive cash flows both initially and at maturity.

There are some key features of the above example that are repeated in other similar applications. Note, first of all, that the inequalities make no modeling assumptions—the final value of the arbitrage portfolios will be larger/smaller than the call option for any final value of the asset, so these bounds are truly independent of any model for the underlying asset. Secondly, the bounds are the best we can do in the following sense: it can be shown that there are arbitrage-free models for the asset price under which the bounds are tight. For example, if the interest rates are deterministic, and the asset price satisfies $S_t = S_0 B(t)$, then the lower bounds hold for all strikes, and there is no arbitrage in the market. Alternatively, the upper and lower bounds can be shown to be the Black–Scholes price of an option in the limit as $\sigma \rightarrow \infty$ and $\sigma \rightarrow 0$, respectively.

In practice, these bounds are far too wide for most practical purposes, although they can be useful as a check that a pricing algorithm is producing sensible numerical results. Part of the reason for this wide range of values concerns the relatively small amount of information that is being used in deriving the bound. In general, one would expect to have some information about the behavior of the market. A natural place to look for further information is in the market prices of other vanilla options: in model-specific pricing, this information is commonly used for calibration of the model. However, the

information contained in these prices can also be used to provide arbitrage bounds on the prices of other exotic derivatives through the formulation of appropriate portfolios.

Breeden–Litzenberger Formula

One of the initial works to consider the pricing implications of vanilla options on exotic options is [6]. Here, the authors suppose that the value of calls at all strikes and a given maturity are known, and observe that

$$p(x) = \frac{1}{B(T)} \frac{\partial^2 C(K, T)}{\partial K^2} \Big|_{K=x} \quad (4)$$

can be thought of as the density of a random variable. The value at time-0 of an option whose payoff is only a function of the terminal value of the asset, $f(S_T)$, can then be shown to be

$$B(T) \int f(x) p(x) dx \quad (5)$$

or, intuitively, the discounted expectation under the density implied by the call prices. We can see this by noting that (at least for twice-differentiable functions f), we have

$$f(S) = f(0) + Sf'(0) + \int_0^\infty f''(K)(S - K)_+ dK \quad (6)$$

and therefore may replicate the contract $f(S)$ exactly by holding $f(0)$ in cash, buying $f'(0)$ units of the asset, and “holding” a continuous portfolio of calls consisting of $f''(K) dK$ units of call options with strikes in $[K, K + dK]$. Since this portfolio replicates the exotic option exactly, by an arbitrage argument, the prices must agree. The price of the portfolio of calls can be shown to be equation (5). In practice, some discrete approximation of such a portfolio is necessary, and this is generally possible provided the calls trade at a suitably large range of strikes.

One of the interesting consequences of this result is that we have a representation for the price of the exotic option as a discounted expectation. A key result in modern mathematical finance is the **fundamental theorem of asset pricing**, which allows us to deduce from the assumption of no arbitrage

that the price of an option may be written as a discounted expectation under a suitable probability measure. However, an assumption of the fundamental theorem of asset pricing is that there is a (known) model for the underlying asset. In the situation we wish to consider, there is no such measure. It is therefore not immediate that we can say anything about any probabilistic structure that might help us. One of the interesting consequences of this result is that it does provide some information about the underlying probabilistic structure: namely, that the call prices “imply” a risk-neutral distribution for the asset price, and that there are arbitrage relationships that ensure that any other option whose payoff depends only on the final value of the asset also has the price implied by this probability measure.

Arbitrage Bounds for Exotic Options

A general approach that is implied by the above examples is the following: suppose we know the prices of (and can trade in) a set of “vanilla” derivatives. Consider also an exotic option, for example, a **barrier option**. Without making any (strong) assumptions about a model for the underlying asset, what does arbitrage imply about the price of the barrier option? Through a suitable set of trades in the underlying and vanilla options, we should be able to construct portfolios and self-financing trading strategies that either dominate, or are dominated by, the payoff of the exotic option. If we can find a portfolio that dominates the exotic option, then the initial cost of this portfolio (which is known) must be at least as much as the price of the exotic option, or else there will be an arbitrage from buying the portfolio and selling the exotic option. The price of this portfolio therefore provides an upper bound on the price of the option. In a similar manner, we may also find a lower bound for the price of the option by looking for portfolios and trading strategies in the underlying and vanilla options that result in a terminal value that is always dominated by the exotic option. Note that we are, in general, interested in the least upper bound and also the greatest lower bound that can be attained, since these will give the tightest possible bounds.

We have been vague about two concepts here: first, we said that we would not want to make any “strong” assumptions about the model of the underlying asset.

The exact assumptions that different examples make about the underlying models vary from case to case, but typically we might assume, perhaps, that the underlying asset price is continuous (or at least, that it continuously crosses a barrier), or that the price process satisfies some symmetry assumption. Secondly, we have not specified what types of trading strategies we wish to consider: this is because, in part, this depends heavily on the assumptions on the price process—for example, trading strategies that involve a trade when the asset first crosses a barrier often assume that the underlying crosses the barrier continuously; the assumption on the symmetry of the asset price results in identities connecting the prices of call and put options. However, the important point to note here is that we work typically in a class of price processes that are too large to be able to hedge dynamically in any meaningful way, so that continuously rebalancing the portfolio is not an option. Two important classes of strategies are *static* strategies, which involve purchasing an initial portfolio of the underlying and vanilla options, and holding this to maturity (see **Static Hedging**), and *semistatic* strategies, which involve a fixed position in the options, and some trading in the underlying asset, often at hitting times of certain levels or sets.

Consistency of Vanilla Options

Since we are looking for arbitrage in the market when we add an exotic option, it is important that the initial prices of the vanilla options do include an arbitrage. In the case of equity markets, where the underlying vanilla options are call options, written on a given set of strikes and maturities, this is a question that has been studied by a number of authors [9, 11, 13, 15, 18]. The fundamental conclusion that may be arrived at from all these works is the following: the prices of calls are arbitrage free if and only if there exists a model under which the prices agree with the discounted expectation under the model. Moreover, the existence of the model has a relatively straightforward characterization in terms of the properties of the call prices, so that for a given set of call prices, the conditions may be checked with relative ease. Moreover, some practical concerns can be included in the models: [15] allows the inclusion of default of the asset, while [18] also allows for the inclusion of dividends.

Of course, not all markets fit naturally into this framework, and so other settings should also be considered, as, for example, in [27], where arbitrage bounds for fixed income markets are considered.

Barrier Options

One of the simplest classes of options that can be considered are the various types of barrier options, and one of the simplest of these options is the *one-touch* barrier option: this is an option that pays \$1 at maturity if the barrier is breached during the lifetime of the contract, and expires worthless if the barrier is not hit before maturity. Suppose that the price process is continuous, and suppose further that the riskless interest rate is zero. Then [7] provides an upper bound on the price of the option, $OT(R, T)$, where R is the level of the barrier, $R > S_0$, and T is the maturity of the option. The bound that is derived in [7] is

$$OT(R, T) \leq \inf_{x \leq R} \frac{C(x, T)}{R - x} \quad (7)$$

The bound can be most clearly seen by noting the corresponding arbitrage strategy: suppose that the bound does not hold, then we can find an x for which

$$OT(R, T) > \frac{C(x, T)}{R - x} \quad (8)$$

We sell the one-touch option, and buy $\frac{1}{R-x}$ units of the call with strike x and maturity T . If the barrier at R is not hit, the one-touch option expires worthless, and our call option may have positive value. Alternatively, suppose that at some time, the barrier is hit. At this time, we enter into a forward contract on the asset. Specifically, we sell $\frac{1}{R-x}$ units of a forward struck at R . Since the current value of the asset is R , and we have assumed that the interest rates are zero, we may enter into such a contract for free. At maturity, the value of our position in the forward will be $\frac{R-S_T}{R-x}$, and the total value of our position in the call and the forward is

$$\begin{aligned} & \frac{1}{R-x}(S_T - x)_+ + \frac{R - S_T}{R-x} = \frac{1}{R-x} \\ & \times [(S_T - x) + (x - S_T)_+ + (R - S_T)] \\ & = -1 + \frac{(x - S_T)_+}{R-x} \end{aligned} \quad (9)$$

where we write $x_+ = \max\{x, 0\}$. Since the value of the portfolio is now greater than the value of the one-touch option, we have an arbitrage.

It can also be shown that the bound here is the best that can be attained: specifically, it can be shown that there exists a model under which there is equality in the identity (7). By considering the form of the hedge, we can also say something about the extremal model. For equality to be there in equation (7), we must always have equality between the payoff of the one-touch option, and the value of the hedging portfolio. The case where the barrier is not hit requires that

$$0 = \frac{(S_T - x)_+}{R - x} \quad (10)$$

or, equivalently, that S_T is always below x . The case where the barrier is struck requires that

$$1 = 1 + \frac{(x - S_T)_+}{R - x} \quad (11)$$

or that S_T is always above x . In other words, in the extremal model, the paths that hit the barrier will, at maturity, finish above the minimizing value of x , while those that do not hit the barrier will always end up below x .

A similar approach allows us to find a lower bound. In this case, the hedging portfolio consists of a digital call struck at the barrier, so that the payoff of this option is simply \$1 if the asset ends up above the barrier, and put options are struck at the barrier, at some $y < R$. Note that the digital call can, in theory at least, be arbitrarily closely approximated by buying a suitably large number of calls just below the strike, and selling the same number of calls at the strike, so that we can deduce the price of the digital call from the prices of the vanilla call options. The prices of the puts can be deduced from **put-call parity**. In a manner similar to the above, we can find the “best” bound by finding the value of y that corresponds to the most expensive portfolio. Again, the bound is tight, in the sense that there exists a model under which we attain equality. We can also describe the behavior in this model: the paths that hit the barrier will end up either below y or above R . Those that do not hit the barrier will finish between y and R .

Using extensions of these ideas, similar bounds can be found for other common barrier options, for example, down-and-in calls. Full details can be found in [7].

There are a number of observations that we can make about the solution to the above problem, and which extend more generally. First, the extension to nonzero interest rates is nontrivial—one of the assumptions that was made in constructing the trading strategy was that, when the barrier is struck, we would be able to enter into a forward contract with a strike at the barrier. If there are nonzero interest rates, we will not be able to enter into such a contract at no cost. Consequently, these results are only generally valid in cases where there is zero cost of carry, for example, where the underlying is a forward price, in foreign exchange markets where both currencies have the same interest rate, or commodities where the interest rate is the same as the convenience yield. Secondly, recall that the only assumption we made on the paths was continuity. This assumption is key to knowing that we can sell forward as we hit the barrier. In fact, the upper bound will still hold if the path is not continuous, provided we sell forward the first time that we go above the barrier, at which point, we can enter into a forward contract that is at least as good for our purposes. Note, however, that under the model for which the bound is tight, we must cross the barrier continuously. The same is not true of the lower bound, which fails if the asset price does not cross the barrier continuously. If the path is not assumed continuous, a new bound can be derived, which corresponds to the asset jumping immediately to its final value. The third aspect to note about these constructions is that there is a natural extension to the case where calls are available at finitely many strikes. Consider the upper bound on the one-touch option, and suppose that calls trade at a finite set of strikes $K_1, K_2, \dots, K_n$. Rather than taking the infimum over x where $x < R$, to get an upper bound, we can take the minimum over the strikes at which calls are available

$$OT(R, T) \leq \min_{i: K_i < R} \frac{C(K_i, T)}{R - K_i} \quad (12)$$

The previous arguments can be applied directly to show that this is an upper bound. It can also be shown that there is a model that fits with the call prices, and under which this bound is attained, so the resulting bounds are the best possible. Details of this extension can be found in [7].

Put–Call Symmetry

An alternative approach to the pricing of barrier options using the above techniques is to introduce the concept of “put–call symmetry”. Following [5], we say that put–call symmetry holds if the value of a call struck at $K > S_t$, and a put struck at $H < S_t$, satisfy

$$C(K)K^{-1/2} = P(H)H^{-1/2} \quad (13)$$

where the current asset price S_0 is the geometric mean of H and K : $(KH)^{1/2} = S_0$. While this is a more general concept, in the context of a **local volatility model**, this assumption can be interpreted in terms of a symmetry condition on the volatility: $\sigma(S_t, t) = \sigma(S_0^2/S_t, t)$. In particular, this is an assumption that is satisfied whenever the volatility is a deterministic function of time. Alternatively, if we graph the **implied volatility** smile against $\log(K/S_t)$, the smile should be symmetric. Note that, as above, we still require either the interest rate to be zero, or, for example, to be working with a forward price.

Under the assumption that put–call symmetry holds at all future times, we can construct replicating portfolios for many types of barrier options. Consider the case of a down-and-in call (see **Barrier Options**), with a barrier at R and strike K , so $R < S_0$. Then we may hedge the option simply by purchasing initially K/R puts at H , where $H = R^2/K$. If the asset never reaches the barrier, both the down-and-in call and the put expire worthless, so we consider the behavior at the barrier. When the asset is at the barrier, put–call symmetry implies

$$C(K) = \frac{K}{R} P(H) \quad (14)$$

and so we may sell the puts and buy a call with strike K . Thus this portfolio exactly replicates the down-and-in call.

The results described above were initially introduced in [5], where, in addition to considering knock-in and knockout calls, and the one-touch option above, the authors also included the **lookback** option by expressing it as a portfolio of suitable down-and-in options. Further developments can be found in [10], which considers the replication of more general options in this framework, and [12], which extends to double knockout calls, rolldown calls, and ratchet calls. Further extensions to these ideas, where the volatility is assumed to be a known function of the

underlying and time, can be found in [2]. A different approach to static hedging is given in [20].

Arbitrage Bounds via Skorokhod Embeddings

As shown by Dupire [21], if prices of calls at all strikes *and* all maturities are known, there is a unique diffusion model, the **local volatility model**, which matches those call prices. If we drop the diffusion assumption, we are led to follow the line of reasoning from [6]. One of the conclusions from this work is that knowing the call prices at all strikes at a fixed future maturity implies the law of the asset price under the risk-neutral measure at this fixed future date. Further, as a consequence of the assumption of no arbitrage, we believe that under the risk-neutral measure, the discounted asset price should be a martingale. In this manner, we should be able to restrict the class of possible (discounted, risk-neutral) price processes to the class of martingales that have a given terminal distribution. If we now also wish to infer information about the price of an exotic option, we can ask the question: what is the largest/smallest price implied by the martingale price processes in this class? Moreover, we might hope to find an arbitrage if the option trades outside this range.

One of the simplest examples to consider is the one-touch option above: under the risk-neutral measure, the price of the call is the discounted probability that the price process goes above the barrier before the expiry date. By restricting ourselves to the class of martingales with a given terminal law, we should be able to deduce some information about the possible values of this probability, and thus of the price of the option. The key to using this approach efficiently is to find a suitable representation of the set of martingales with the given terminal distribution.

A classical result from probability theory, the Dambis–Dubins–Schwartz Theorem, states that any continuous martingale may be written as the time change of a Brownian motion (see, for example, [33, Chapter V]), and this is essentially true if the martingale is only right continuous [30]. Hence, if the discounted asset price is a martingale, one would expect it to be a time change of a Brownian motion—that is, we would expect to be able to write

$$B(t)S_t = W_{\tau(t)} \quad (15)$$

where W_t is a Brownian motion, $\tau(t)$ is increasing in t and is a stopping time for all t . As a consequence, any martingale price process should be a time change of a Brownian motion. If, in addition, we know that the law of S_T under the risk-neutral measure is implied by the call prices, we also know that $W_{\tau(T)}$ has a given law. Finally, suppose that the time change is continuous (as it will be if the price process is continuous), then many of the properties in which we are interested remain unaffected by the exact form of the time change. For example, consider the probability of whether the discounted asset price goes above a barrier R before time T . This is the same as the probability that the Brownian motion W_t with $W_{\tau(t)} = B(t)S_t$ goes above the barrier before time $\tau(T)$. Moreover, consider two time changes $\tau(t)$ and $\tilde{\tau}(t)$, such that we always have $\tau(T) = \tilde{\tau}(T)$. Then the probability of whether the barrier has been breached will be the same for the price processes corresponding to the time change τ and the time change $\tilde{\tau}$. Consequently, if we are concerned with such path properties of the underlying price process, when we look in the Brownian setting, we need only differentiate between different final stopping times $\tau(T)$, and not different time changes.

The argument then goes as follows: suppose we know call prices at all strikes at time T . From this information, we may deduce the law of the discounted asset price $B(T)S_T$, which we assume to be a time change of a Brownian motion, and whose value at some stopping time τ therefore has the same law. Since the time change in the intermediate time is assumed to be continuous, and its exact form will not impact the quantities of interest, we get a one-to-one correspondence between possible price processes and the class of stopping times of a Brownian motion that have a given law. This line of reasoning is of interest, since the problem of finding a stopping time with a given terminal law has a long history in the probabilistic literature, where it is known as the **Skorokhod embedding problem**. In particular, given a distribution μ , we say that a stopping time τ is a (Skorokhod) embedding of μ , if W_τ has law μ . The recent survey paper [31] contains a comprehensive survey of the probabilistic literature on the Skorokhod embedding problem.

Getting back to the one-touch option, we see that the upper bound will correspond to the stopping time that maximizes the probability of being larger than the barrier within the class of embeddings,

and the minimum will correspond to stopping time that minimizes the probability within this class. The construction of arbitrage bounds for the price of the option is therefore equivalent to the identification of extremal Skorokhod embeddings for the law implied by the call prices at maturity, as seen in [7]. The construction that attains this maximum is due to Azema and Yor [3], while the construction that attains the minimum is due to Perkins [32], and it can be shown that these embeddings do indeed have the behavior that was hypothesized previously: for the upper bound, those paths that hit the barrier remain above the level x derived in the bound, while in the lower bound, those paths that hit the barrier all either finish above the barrier, or stop below y .

The Skorokhod embedding approach was initially explored in [23]. In this work, it is shown that the upper bound on the price of a lookback option can be computed in terms of the available call prices. Moreover, Hobson [23] has constructed a trading strategy that will result in an arbitrage should the lookback option trade above the given bound. In this case, the strategy involves constructing an initial portfolio of calls (purchased at the specified prices) and then selling these calls appropriately as the price process sets new maxima. The price at which the calls can be sold will be at least the intrinsic value of the call, and it can be shown that the profit from selling off the calls appropriately will be at least the payoff from the lookback option. A simple lower bound is also derived, but without assuming any continuity. For discontinuous asset prices, the lower bound is attained by the price process that jumps immediately to its final value. In terms of the corresponding Skorokhod embeddings, the upper bound has close connections with the embedding due to Azema and Yor [3]; this can be shown to maximize the law of the maximum over the class of embeddings. Further, it can be shown that if we use the price process that corresponds to the stopping time constructed in [3], then the trading strategy dominating the lookback option actually attains equality demonstrating that the upper bound is the best possible. This connection between an extremal Skorokhod embedding and a corresponding bound on the price of a connected exotic option has been exploited a number of times: in [8], these techniques are used to generalize the above results to the case where the call prices at an intermediate time are also known; in [24] the embedding due to Perkins [32] is generalized to

provide a lower bound on the price of a forward start digital option, under the assumption that the price process is continuous; in [16] the embedding of Vallois [35] is used to provide an upper bound on products related to corridor variance options.

A related development of these ideas is considered in [28], wherein the problem of fitting martingales to marginal distributions specified at all maturities is presented, and some solutions corresponding to the different Skorokhod embedding approaches, the local volatility models of Dupire [21], and processes with independent increments are discussed.

Advantages and Disadvantages

From a theoretical point of view, the results described above provide a clear, satisfactory picture: for a relatively large class of options, a range of model-free prices, or even exact prices, can be established. Where there is a range of prices, the upper and lower bounds can usually be shown to be tight, and trading strategies produced that result in arbitrages, should the bounds be violated.

However, the results have often been produced under strong restrictions on the mechanics of the market—typically, the cost of carry has been assumed to be zero, and factors such as transaction costs have been ignored. To some extent, these factors can be added into the bounds, although this is at the expense of wider bounds. Moreover, the bounds that result from the model-free techniques have a tendency to be rather wide. Figure 1 illustrates the resulting bounds for the one-touch option, comparing the upper and lower bounds described earlier, with the actual price derived from a Black–Scholes model. The range of the bounds is, for interesting values, of the order of 5% of the final payoff above the Black–Scholes price, and as much as 15% below the Black–Scholes price. These ranges are of much too high an order to be helpful for pricing purposes.

How else might these techniques be of use in practice? One important feature is the tendency to produce simple hedging portfolios. These allow a trader to cover a position in a derivative with a portfolio that needs little or no ongoing management, and through which they have a guaranteed lower bound on any possible hedging error. Several authors, for example, [22, 34], have produced comparisons between static or semistatic and dynamic

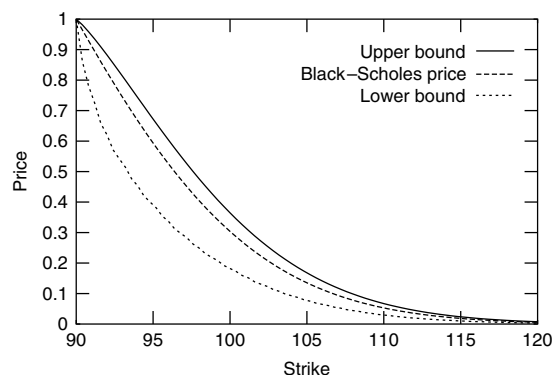

Figure 1 Upper and lower model-free bounds on the price of a one-touch option, as a function of the strike, compared with the Black–Scholes price. The interest rate is 0, the asset price is \$90, and $\sigma = 15\%$

hedging. In [34], there is no clear outperformance by either strategy, but in some circumstances the static or semistatic hedging strategy outperforms the dynamic strategy. In [22], the authors consider barrier options, and find that some static hedging strategies for barrier options appear to outperform dynamic strategies. Another useful observation is that by identifying the extremal models, one can identify the key model properties that influence the price of the option: for example, in finding bounds for the one-touch barrier, the extremal models were identified as those models that either hit the barrier and stay close, or those models that hit the barrier and end up far away. Knowledge of these extremes might help in deciding where the real price might lie in relation to the arbitrage bounds, or how prices of the option might react to large structural changes to the market. Finally, arbitrage bounds can also be considered as a special case of the **good-deal bounds** of [14]. Good-deal bounds provide a range of prices, outside of which there exists a trading strategy whose payoff may be considered a “good deal”, which is not necessarily an arbitrage, but is sufficiently close to one to be very desirable for an investor.

Additional Resources

There are a number of papers [17, 25, 26] that consider deriving bounds on the price of **basket options**, where the payoff of the option depends

on the value of a weighted sum of a number of assets, and where calls are traded on each of the underlying assets. There are also connections to [1], where bounds on the prices of **Asian options** are derived.

Another class of options where similar hedging techniques have been considered are installment options [19], which are options similar to a European call, but where the holder pays for the option in a set number of installments, and has the option to stop paying the installments at any point before maturity, thereby losing the final payoff for the contract.

A common complication that arises in constructing many of the bounds and their respective hedging portfolios is that there can be some nontrivial optimization problems, typically, large linear programming problems [4, 17, 25].

Average Strike Options

An average strike option is also known as an *Asian option* with floating strike. These options have a payoff based on the difference between the terminal asset price and the average of an underlying asset price over a specified time period. The other type of Asian option is the fixed-strike option, where the payoff is determined by the average of an underlying asset price and a fixed strike set in advance (*see Asian Options*).

If the average is computed using a finite sample of asset price observations taken at a set of regularly spaced time points, we have a discrete average strike option. A continuous time option is obtained by computing the average *via* the integral of the price path over an interval of time. The average itself can be defined to be geometric or arithmetic. As for the fixed strike Asian option, when the geometric average is used, the average strike option has a closed-form solution for the price, whereas the option with arithmetic average does not have a known closed-form solution.

We concentrate on the continuous time, average strike option of European style with arithmetic averaging. A discussion of the uses and rationale for introducing Asian contracts is given in **Asian Options**. Average strike options are closely related to these options, but are less commonly used in practice.

Consider the standard Black–Scholes economy with a risky asset (stock) and a money market account. We also assume the existence of a risk-neutral probability measure Q (equivalent to the real-world measure P) under which discounted asset prices are martingales. We denote expectation under measure Q by E , and the stock price follows

$$\frac{dS_t}{S_t} = (r - \delta) dt + \sigma dW_t \quad (1)$$

where r is the constant continuously compounded interest rate, δ is a continuous dividend yield, σ is the instantaneous volatility of asset return, and W is a Q -Brownian motion. The reader is referred to **Black–Scholes Formula** for details on the Black–Scholes model and **Risk-neutral Pricing** for a discussion of risk-neutral pricing.

We consider a contract that is based on the value A_T , where $(A_t)_{t \geq t_0}$ is the arithmetic average

$$A_t = \frac{1}{t - t_0} \int_{t_0}^t S_u du, \quad t > t_0 \quad (2)$$

and by continuity, we define $A_{t_0} = S_{t_0}$. The corresponding geometric average G_t is defined as

$$G_t = \exp \left(\frac{1}{t - t_0} \int_{t_0}^t \ln S_u du \right) \quad (3)$$

The contract is written at time 0 (with $0 \leq t_0$) and expires at $T > t_0$. It is of interest to calculate the price of the option at the current time t , where $0 \leq t \leq T$. The position of t compared to the start of the averaging, t_0 may vary, as described in **Asian Options**.

The payoff of an average strike call with arithmetic averaging is given as

$$(S_T - A_T)^+ \quad (4)$$

and the payoff of an average strike put with arithmetic averaging is

$$(A_T - S_T)^+ \quad (5)$$

Average strike option payoffs with geometric averaging are identical, with A_T replaced by G_T . The buyer of an average strike call is able to exchange the terminal asset price for the average of the asset price over a given period. For this reason, it is sometimes referred to as a *lookback* on the average (*see Lookback Options* for a discussion of the lookback option).

By standard arbitrage arguments, the time- t price of the average strike call is

$$e^{-r(T-t)} \mathbb{E}[(S_T - A_T)^+ | \mathcal{F}_t] \quad (6)$$

and the price of the put is

$$e^{-r(T-t)} \mathbb{E}[(A_T - S_T)^+ | \mathcal{F}_t] \quad (7)$$

It turns out that we need to consider only the case $t \geq t_0$, where the option is “in progress”. The forward starting case ($t < t_0$) can be rewritten as a modified option with averaging starting at t , today. This is in contrast to the Asian option with fixed strike, where the difficult case was when the option was forward

starting. As for the Asian option, the average strike option satisfies a put–call parity; see [1] for details.

The average strike option is an exotic path-dependent option, as the price depends on the path of the underlying asset *via* the average. The distribution of the average A_T is not lognormal, if the asset price is lognormal, and pricing is difficult because the joint law of A_T and S_T is needed. This is in contrast to the Asian option, which required only the law of the average. Perhaps because of this increased complexity, or their lesser popularity in practice, fewer methods exist for the pricing of average strike options. Just as for the Asian option, there are no closed-form solutions for the price of the average strike option.

Many of the methods that we discuss here for pricing are similar to those used to price the Asian option. An early technique to give an approximate price for the average strike option was to replace the arithmetic average A_T with the geometric average G_T . Since G_T has a lognormal distribution, the (approximate) pricing problem becomes (for a call)

$$e^{-r(T-t)} \mathbb{E}[(S_T - G_T)^+ | \mathcal{F}_t] \quad (8)$$

We recognize that this is exactly an exchange option (*see Exchange Options*), which can be priced *via* a change of measure, as in [9]. Levy and Turnbull [8] mentioned this connection to exchange options, but it was Conze and Viswanathan [3] who presented the results of this computation.

Other analytical approximations can be obtained by approximating the true joint distribution of the arithmetic average and asset price using an approximate distribution, usually jointly lognormal with appropriate parameters. Chung *et al.* [2] extended the linear approximations of Bouaziz *et al.* [1], Levy [7], and Ritchken *et al.* [10] (approximating distribution of $\{A_T, S_T\}$ by joint lognormal) to include quadratic terms. Their approximation is no longer based on a geometric-type approximation.

Recently, symmetries of a similar style to that of the put-call symmetry have been found between fixed strike Asian options and average strike options. For forward starting average strike options, Henderson *et al.* [4] gave a symmetry with a starting Asian option. If the average strike option is starting, the special case of Henderson and Wojakowski [5] is recovered. If the average strike option is in progress, it cannot be rewritten as an Asian option, and Henderson *et al.* [4] derived an upper bound for the

price of the average strike option. This bound is in terms of an Asian option with fixed strike and a vanilla option. The method gives an “exact” bound for forward starting and starting options and when expiry is reached.

Numerical methods can be used to price the average strike option. The discussion of Monte Carlo simulation in **Asian Options** is also relevant here, as simulation is often used as a benchmark price. Ingersoll [6] was the first to recognize that it is possible to reduce the dimension of the pricing problem for the average strike option using a transformation of variables. Despite the value of the average strike option at t depending on the current asset price, current value of the average, and time to expiry, a one-dimensional partial differential equation (PDE) can be derived by using Ingersoll’s reduction of variables. However, the drawback is that the Dirac delta function appears as a coefficient of the PDE, making it prone to instabilities. Vecer’s [12] PDE method for Asian options with fixed strike also applies to average strike options and gives a stable one-dimensional PDE. Some testing of this method for the average strike option is given in [11].

To conclude, research into pricing the average strike option is ongoing, with current PDE and bound methods being very efficient.

Foreign Exchange Markets

The foreign exchange (FX) market has two major functionalities, one related to hedging and the other to investment.

In the age of globalization, it is essential for corporates and multinationals to hedge their FX exposure due to export/import activities. In addition, fund managers (institutional) need to hedge their FX risk in stocks or bonds if the stocks/bonds are quoted in a foreign currency. With hedging instruments, the FX exposure can be reduced and one can even benefit from certain market scenarios. This kind of participation brings us to the important class of investor-oriented products where the coupon depends on an FX rate or, at maturity, the pay-off (amount, currency) will be determined by an FX rate. This kind of product can be issued as a note, certificate, or bond.

For the major currencies such as USD, EUR, JPY, GBP, CHF, AUD, CAD, and NZD, the market has become more transparent over the last few years. For plain vanilla options, market data, especially volatilities for maturities below 1 year, are published by brokers or banks and are shown on Reuters pages (e.g., TTKLINDEX10, ICAPFXOP, GFIVOLS). For exotic products, new pricing tools, such as Superderivatives, LPA, Bloomberg, ICY, Fenics, and so on, are available for users, but the premium of the option will depend on the pricing model and the adjustments used. For the emerging market currencies such as PLN (Polish zloty), HUF (Hungarian forint), ZAR (South African rand), and so on, which are freely tradable but less liquid, the market data are less transparent. Currencies that are not freely tradable (the currency cannot be cash-settled offshore) such as BRL (Brazilian real) or CNY (Chinese yuan renmimbi) can be traded as a nondeliverable forward (NDF) or as a nondeliverable option (NDO) against a tradable currency. The NDF is a cash-settled product without exchange of notionals, which means that the intrinsic value at maturity will be paid in the free tradable currency based on a fixing source. The underlying of an NDO is the NDF, meaning that exercising the NDO results in an NDF, which will also be cash-settled. Another class of currencies is that of the fully cash-settled pegged ones, which means that their

exchange rate is 100% correlated to a major currency, mostly the USD. If one expects that this peg will continue, hedges should be done in the correlated major currency. In the case of SAR (Saudi riyal) or AED (United Arab Emirates dirham), discussion has been ongoing about depegging the currencies. In case this is done, there could be an increasing interest in SAR- or AED-linked investments. This opens an increasing interest in SAR- or AED-linked investments to participate in the case that these currencies are depegged. For the “more exotic currencies” such as the GHC (Ghanaian cedi), there is no options market.

Quotation

The exchange rate can be defined as the amount of domestic currency one gets if one sells one unit of foreign currency. If we take a look at an example of the EUR/USD exchange rate, the default quotation is EUR-USD, where USD is the domestic currency and EUR is the foreign currency. The terms *domestic* and *foreign* are not related to the location of the trader or any country, but it is more a question of the definition. Domestic and base are synonyms as are foreign and underlying. The common way is to denote the currency pair with a slash (/) and the quotation with a dash (–). The slash (/) does not mean a division.

For example, the currency pair EUR/USD can be quoted either in EUR-USD, which means how many USD one gets for selling one EUR, or in USD-EUR, which then means how many EUR one gets for selling one USD. There are certain market standard quotations; some of them are listed in Table 1.

In the FX market, two currencies are involved, which means that one needs to specify on which currency a particular call or put option is written. For

Table 1 Market convention of some major currency pairs with sample spot price

Currency pair	Quotation	Quote
EUR/USD	EUR-USD	1.4400
GBP/USD	GBP-USD	1.9800
USD/JPY	USD-JPY	114.00
USD/CHF	USD-CHF	1.1500
EUR/CHF	EUR-CHF	1.6600
EUR/JPY	EUR-JPY	165.00
EUR/GBP	EUR-GBP	0.7300
USD/CAD	USD-CAD	0.9800

instance, in the currency pair EUR/USD, there can be a EUR call, which is equivalent to a USD put, or a EUR put, which is equivalent to a USD call.

FX Terminology

In the FX market, a million is called a *buck* and a billion a *yard*. This is because the word “billion” has different meanings in different languages. In French and German, it represents 10^{12} and in English it stands for 10^9 .

Certain currency pairs have their own names in the market. For instance, GBP/USD is called a *cable*, because the exchange rate information used to be sent between England and America through a telephone cable in the Atlantic Ocean. EUR/JPY is called the *cross*, because it is the cross rate of the more liquidly traded USD/JPY and EUR/USD.

Some currency pairs also have their own names to make them short and unique in communication. New Zealand dollar, which is NZD/USD, is called *Kiwi*, and the Australian dollar, which is AUD/USD, is called *Aussie*. Among the Scandinavian currencies, NOK (Norwegian krone) is called *Noki*, SEK (Swedish krona) is called *Stoki*, and in combination with DKK (Danish krone) the three are called *Scandies*.

The exchange rates are usually quoted in five relevant figures, for example, in EUR-USD we would get a quote of 1.4567. Sometimes one can get a quote up to six figures, but for the time being we focus on five figures. The last digit “7” is called the *pip* and the middle digit “5” is called the *big figure*, because the interbank spot trading tools show this digit in bigger size since it is the most important information. The figure to the left of the big figure is known anyway and the pips to the right of the big figures are sometimes “negligible”. For example, a rise of EUR-JPY 165.00 by 40 pips is 165.40 or a rise by 3 big figures would be 168.00.

Quotation of Option Prices

Plain vanilla option prices are usually quoted in terms of implied volatility. If an option is priced in volatility, a delta exchange is necessary. The advantage is that the volatility does not usually move as quickly as the spot rate and one has the chance to

Table 2 Standard market quotation types for option premiums

Symbol	Description of symbol	Result of example
d pips	Domestic per unit foreign	208.42 USD pips per EUR
f pips	Foreign per unit domestic	97.17 EUR pips per USD
$\%f$	Foreign per unit foreign	1.4575% EUR
$\%d$	Domestic per unit domestic	1.3895% USD
d	Domestic amount	20 842 USD
f	Foreign amount	14 575 EUR

Foreign = EUR, domestic = USD, $S_0 = 1.4300$, $r_d = 5.0\%$, $r_f = 4.5\%$, volatility = 8.0%, $K = 1.5000$, $T = 365$ days, EUR call USD put, notional = 1 000 000 EUR = 1 500 000 USD

compare the prices, especially in the broker market. On the basis of the spot rate on which the delta exchange is done, the premium of the plain vanilla option is calculated *via* the Black–Scholes formula. For exotic options, a price in volatility is not possible because each bank has its own pricing model for these.

The premium, value, or prices of options can be quoted in six different ways (Table 2). The Black–Scholes formula quotes in domestic pips per one unit of foreign notional. The others can be retrieved in the following manner:

$$d \text{ pips} \xrightarrow{\times \frac{1}{SK}} f \text{ pips} \xrightarrow{\times K} \%f \xrightarrow{\times \frac{S}{K}} \%d \quad (1)$$

Delta and Premium Convention

The spot delta of a plain vanilla option can be retrieved in a straightforward way by using the Black–Scholes formula. It is called the *raw spot delta*, δ_{raw} . One retrieves it in percentage of the foreign currency, but the delta in the second involved currency $\delta_{\text{raw}}^{\text{opposite}}$ can be computed in the following manner:

$$\delta_{\text{raw}}^{\text{opposite}} = -\frac{S}{K} \delta_{\text{raw}} \quad (2)$$

The delta multiplied with the corresponding notional determines the amount that has to be bought

or sold to hedge the spot risk of the option up to the first order.

An important question is whether the premium of the option needs to be included in the delta or not? An example, EUR-USD, for investigation is considered here. In this quotation, USD is the domestic currency and EUR is the foreign one. The Black–Scholes formula calculates the premium in domestic per 1 unit foreign currency, which in our example is in USD per 1 EUR. This premium is denoted by p . If the premium is paid in EUR, which means in the foreign currency, it includes an FX risk. The premium p in USD is equivalent to $\frac{p}{S}EUR$, which means that the amount of EUR that has to be bought to hedge the option needs to be reduced by this EUR premium and is given as

$$\delta_{\text{raw}} - \frac{p}{S}EUR \quad (3)$$

We denoted USD as domestic currency and EUR as foreign currency, but do all banks or trading places have this notion? What is the notional currency of the option and what is the premium currency? In the interbank market, there exists a fixed notion of the delta of the currency pair. Normally, it is the LHS delta in Fenics^a if the option is traded in the LHS premium, which is mostly used, for example, for EUR/USD, USD/JPY, and EUR/JPY, and the RHS delta if it is the RHS premium, for example, for GBP/USD and AUD/USD. Most of the options traded in the market are out-of-the-money; therefore, the premium does not create a critical FX risk for the trader.

For the banks where the base currency is considered the risk-free currency, the market value of the option is in the base currency, and if the premium is in the risky currency, the premium needs to be included in the hedge. If the premium is in the risk-free (or the base) currency, the premium will be offset by the market value of the option. In the opposite case, where the risk-free currency is the underlying currency, if the premium is in the risky currency, the premium will be offset by the market value of the option. Only in the case of premium in risk-free currency, the amount needs to be included in the hedge.

Therefore, the delta hedge is invariant with respect to the risky currency notion of the bank; for example, for both banks, one is based in USD and the other in EUR, and the delta is the same.

Table 3 One-year EUR call USD put, the strike is 1.4300 for a EUR-based bank

Delta currency	Premium currency	Fenics	Hedge	Delta
%EUR	EUR	LHS	$\delta_{\text{raw}} - P$	48.35
%EUR	USD	RHS	δ_{raw}	51.64
%USD	EUR	RHS + F4	$-(\delta_{\text{raw}} - P) \frac{S}{K}$	-48.35
%USD	USD	LHS + F4	$-\delta_{\text{raw}} S/K$	-51.64

$S = 1.4300$, $r_d = 5.0\%$, $r_f = 4.5\%$, volatility = 8.0%, $K = 1.4300$

Table 4 One-year EUR call USD put, the strike is 1.5000 for a EUR-based bank

Delta currency	Premium currency	Fenics	Hedge	Delta
%EUR	EUR	LHS	$\delta_{\text{raw}} - P$	28.22
%EUR	USD	RHS	δ_{raw}	29.69
%USD	EUR	RHS + F4	$-(\delta_{\text{raw}} - P) \frac{S}{K}$	-26.91
%USD	USD	LHS + F4	$-\delta_{\text{raw}} S/K$	-28.30

$S = 1.4300$, $r_d = 5.0\%$, $r_f = 4.5\%$, volatility = 8.0%, $K = 1.5000$

Examples

To see the different deltas used in practice, consider two examples discussed in Tables 3 and 4.

Implied Volatility and Delta for a Given Strike

Implied volatility is not constant across strikes (*see Foreign Exchange Smiles*). The volatility σ depends on the corresponding delta of the option, but the delta depends on the price of the option and therefore on the used volatility. How can we retrieve the correct volatility for a given strike? For sure it is an iterative process. Initially, one uses the at-the-money (ATM) volatility σ_0 and calculates the delta Δ_1 . On the basis of Δ_1 , a new volatility σ_1 can be retrieved from the volatility matrix. This new volatility leads to a new delta and so on. Now one can define a convergence criterion to stop the iteration. In practice, a fixed number of iterations is used, usually five steps.

4 Foreign Exchange Markets

Table 5 Vega matrix for standard maturities and delta values, expressed in percent of foreign notional

Mat/ Δ	50%	45%	40%	35%	30%	25%	20%	15%	10%	5%
<i>O/N</i>	0.02	0.02	0.02	0.02	0.02	0.02	0.02	0.01	0.01	0.01
1W	0.06	0.06	0.05	0.05	0.05	0.04	0.04	0.03	0.02	0.01
1M	0.11	0.11	0.11	0.10	0.10	0.09	0.08	0.07	0.05	0.03
2M	0.16	0.16	0.15	0.15	0.14	0.13	0.11	0.09	0.07	0.04
3M	0.20	0.02	0.19	0.19	0.17	0.16	0.14	0.12	0.09	0.05
6M	0.28	0.28	0.27	0.26	0.25	0.23	0.20	0.17	0.13	0.07
9M	0.33	0.33	0.33	0.32	0.30	0.28	0.24	0.20	0.15	0.09
1Y	0.38	0.38	0.38	0.37	0.35	0.32	0.28	0.24	0.18	0.10
2Y	0.51	0.51	0.51	0.50	0.48	0.44	0.40	0.33	0.25	0.15
3Y	0.60	0.60	0.60	0.60	0.57	0.54	0.48	0.40	0.31	0.18

The matrix shows, for example, that 2Y EUR call USD put 35 delta can be hedged with two times 6M EUR call USD put 30 delta

Mapping of Delta on Vega

From the Black–Scholes formula, it is clear that for a fixed delta, the vega P_σ does not depend on volatility or r_d , and P_σ is therefore a function of only r_f , maturity, and delta. This gives the trader the advantage of a moderately stable vega matrix. Such a matrix is shown in Table 5, with $r_f = 4.5\%$.

FX Smile

The FX smile surface has a different setup or construction in comparison to equity.

Plain vanilla options with different maturities have different implied volatilities. This is called the *term structure* of a currency pair.

Plain vanilla options are quoted in terms of volatility for a given delta. The smile curve is usually set up on some fixed pillars and the points between these pillars are interpolated to get a smooth surface. In the direction of the term structure, the easiest way is to interpolate linearly in the variance. In addition, weights are introduced to highlight or lower the importance of some dates, for example, the release of nonfarm payrolls, local holiday, or a day before or after a weekend. In the direction of the moneyness or delta, one method of interpolation is the cubic spline. The pillars in that direction are 10-delta put, 25-delta put, ATM, 25-delta call, and 10-delta call. Sometimes the 35-delta put and 35-delta call are also used. Unlike equity, in the FX market, the smile surface is decomposed into the symmetric part by using butterflies or strangles and the skew part by using the risk reversals for the fixed deltas. This is

because of the liquidity of these products in the FX market.

Risk Reversal (RR)

For instance, a 25-delta risk reversal is a combination of buying a 25-delta call and selling a 25-delta put. The payout profile is shown in Figure 1.

Butterfly (BF)

In the case of a 25-delta butterfly, it is the combination of buying 25-delta put, buying 25-delta call, selling ATM put, and selling ATM put (alternatively, 25-delta strangle is a 25-delta put and a 25-delta call). Payout profiles are shown in Figure 2.

The decomposition of a smile curve inspired by these products is shown in Figure 3.

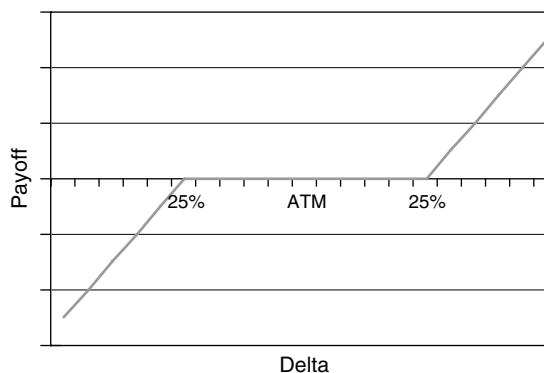

Figure 1 Payout profile of a risk reversal

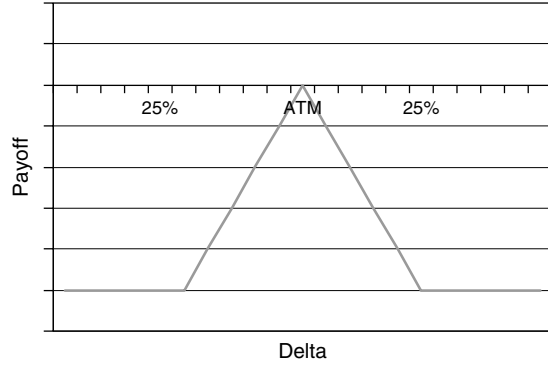

Figure 2 Payout profile of a butterfly

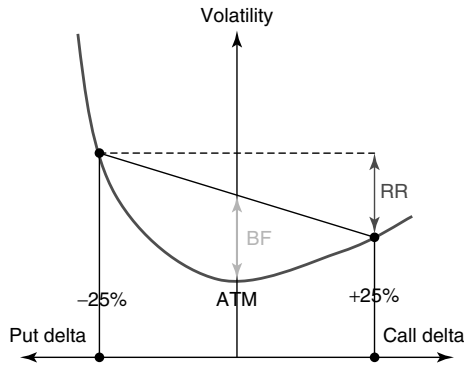

Figure 3 Decomposition of a smile curve

If we denote the ATM volatility by σ_0 , the 25-delta put volatility by σ_- , and the 25-delta call volatility by σ_+ , we get the following relationships:

$$RR = \sigma_+ - \sigma_- \quad (4)$$

$$BF = \frac{1}{2}(\sigma_+ + \sigma_-) - \sigma_0 \quad (5)$$

$$\sigma_+ = ATM + BF + \frac{1}{2}RR \quad (6)$$

$$\sigma_- = ATM + BF - \frac{1}{2}RR \quad (7)$$

It should be noted that the values RR and BF given above have nothing to do with the prices of actual risk reversal and butterfly contracts: rather they provide a convenient representation of the implied volatility smile in terms of its level (σ_0), convexity (BF), and skewness (RR).

Table 6 EUR/USD 25-delta risk reversal (in %)

Date	1 month	3 months	1 year
Dec 3, 2007	-0.6	-0.6	-0.6
Dec 4, 2007	-0.525	-0.55	-0.525
Dec 5, 2007	-0.525	-0.55	-0.525

Dec 7, 2007	-0.6	-0.6	-0.6
Dec 10, 2007	-0.6	-0.6	-0.6

Table 7 EUR/USD 25-delta butterfly (in %)

Date	1 month	3 months	1 year
Dec 3, 2007	0.225	0.425	0.460
Dec 4, 2007	0.225	0.425	0.460
Dec 5, 2007	0.225	0.425	0.460
Dec 6, 2007	0.225	0.425	0.460
Dec 7, 2007	0.227	0.425	0.463
Dec 10, 2007	0.227	0.425	0.463

Table 6 shows the 25-delta risk reversal in EUR/USD on different trading dates and the corresponding butterflies are listed in Table 7.

For the setup of the smile surface in a risk management or pricing tool, it is important to know which convention is used for a certain currency pair in the option market to define the notion of ATM.

At-the-money Definition

There exist several definitions of ATM:

- ATM spot: Strike is equal to the spot.
- ATM forward: Strike is equal to the forward.
- Delta parity: The absolute value of the delta call is equal to the absolute value of the delta put.
- Fifty delta: Put delta is 50% and the call delta is 50%.
- Value parity: The premium of the delta put is equal to the delta call.

The most widely used one in the interbank market is the delta parity up to 1 year for the most liquid currencies. In emerging markets, (at-the-money-forward) (ATMF) is used. For long-term options such as USD/JPY 15 years, the ATMF convention is used, but since this results in a delta position, a forward delta exchange will be done.

End Notes

^aFenics is an FX option pricing tool owned by the broker GFI and used in the interbank market (www.fenics.com).

Foreign Exchange Options

Market Overview

The importance of foreign exchange (FX) options for risk management and directional trades is gaining more and more recognition from companies and investors. Various banks have been adapting their products to this situation during the past years. Different risk and profit profiles can be generated with plain vanilla or exotic options as individual products, as well as in combination with various products such as structured products. Financial engineers call this as *playing with Lego bricks*. Linear combinations of basic products are used to build structured products. To price plain vanilla or exotic options and show their risk, many professional trading systems have been introduced and are being continuously developed. With these systems, the traders are able to evaluate the positions in the individual currency pair or in currency portfolios at any time. In the FX options market, options trading systems such as *Fenics*, *Murex*, or *SuperDerivates* are used. Owing to the very rapid development in this sector, some banks started developing and using systems of their own.

To comply with various customer requests, a successful trading desk in the interbank market is essential. This is mostly plain volatility trade. The market risk of a short-term FX options trading desk consists of changes in spot, volatility, and interest rates. Since spot risk is easily eliminated by **delta hedging** and the effect of rates is small compared to the risk of changing volatility in the short term up to two years, managing volatility risk is the main task of the trader. Since the relationship of volatility and price of call or put options is monotone, it is equivalent to quote the price of an option either by the price itself or by the volatility implied by the **Black–Scholes formula**. The established market standard is quoting this implied volatility, which is why it is often viewed as a traded quantity. In the case of plain vanilla options, a **vega** long position is given when buying (call or put); conversely, a vega short position is given when selling. Volatility difference between call and put with same expiry and same deltas is called a *risk reversal*. If the risk reversal is positive, the market is willing to pay more for calls than for puts; if the risk reversal is negative, the

market favors put options. The butterfly measures the convexity of the “smile” of the volatility, that is, the volatility for the out-of-the-money and the in-the-money-options (*see Foreign Exchange Markets* for details).

If the **delta hedge** is done with an interbank partner at the same time the option is traded, the trader can focus on the vega position in his book. The **delta hedge** neutralizes the change of the option price caused by changes of the underlying. For long-term options with an expiry longer than two years or options with high interest rate sensitivity, the **delta hedge** should be replaced by a forward hedge, as the risk of interest rate sensitivity is mostly higher than the volatility risk in this case. This means that instead of neutralizing spot risk by trading in the spot market, one would trade a forward contract with maturities matching those of the cash flows of the option. This would simultaneously take care of the spot and the rate risk.

First-generation Exotic Options

First-generation exotic options are all options beyond plain vanilla options that started trading in the 1990s, in particular, barrier options, digital and touch products, average rate or Asian options, and lookback and compound options. There is no strict separation between first- and second-generation exotics as the viewpoint on what is first and second varies by the person in charge. Exotic options are traded live in currency trading as opposed to plain vanilla options, which mostly trade through automated systems. Trading exotic options is done by quoting the bid and ask price of the product rather than the corresponding volatility, because the monotone relationship of volatility and price is often not guaranteed. When asking for a quote, the spot reference level is agreed upon at which the option is calculated and priced. This allows comparing quotes of the exotic options and is also the basis of the **delta hedge**. To keep the **vega** risk low when fixing a deal, a vega hedge can be done with the partner. In this case, plain vanilla options (calls/puts, at-the-money ATM straddles) are traded to offset the vega of the exotic option. The default vega hedge is done with a straddle—an out-of-the-money call and an out-of-the-money put—the reason being that this product does not have any delta, so one offsets the vega position without touching

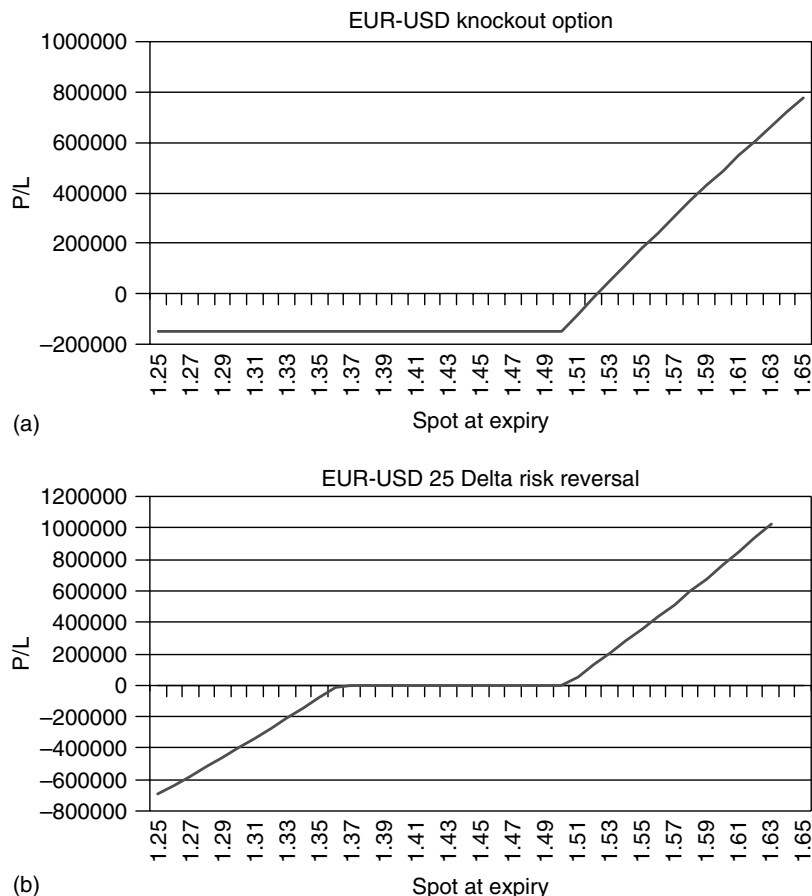

Figure 1 (a) Payoff profile of a EUR-USD knockout option that is not knocked out during its lifetime; (b) payoff profile of the EUR-USD risk reversal at expiry

the delta position. Normally, during the lifetime of the option, the risk is hedged dynamically across the entire option book.

The quoting bank (market maker) is the calculation agent. It stipulates the regulations under which predefined triggers are reached or how often the underlying is traded in certain predefined ranges. The market maker informs the market user about the trigger event.

Barrier Options

Barrier options are vanilla put and call options with additional barriers. In case of a knockout, the option expires worthless, if the spot ever trades at or beyond the prespecified barrier. In case of a knockin option,

the option is only activated if the spot ever trades at or beyond the prespecified barrier. The barrier is valid at all times between inception of the trade and the maturity time of the option.

One can further distinguish regular barrier options, where the barrier is out-of-the-money, and reverse-barrier options, where the barrier is in-the-money.

A regular knockout barrier option can basically be priced and semistatically hedged by a risk reversal (Lego-brick principle).

Figure 1 illustrates the example: EUR-USD Spot 1.4600 expiry six months, strike 1.5000, EUR CALL with regular knockout trigger at 1.4300.

Hedging a short regular knockout EUR call, we can go long a vanilla EUR call with the same strike and the same expiry and go short a vanilla EUR put

with a strike such that the value of the hedge portfolio is zero if the spot is at the barrier. The long call and short put is called a *risk reversal* and its market price can be used as a proxy for the price of the regular knockout call. In our example, it would be a 1.3650 EUR put. If the trigger is not reached, then the put expires worthless and the call offsets the knockout call payoff. If the trigger is reached, the risk reversal can be canceled with approximately zero value. The delta of a knockout option is higher than the delta of the corresponding plain vanilla option, and the higher it is, the closer the trigger is to the underlying spot.

Reverse knockout and reverse knockin are more difficult to price and hedge as the risk profile of these options is difficult to replicate with other options. In this case, the trigger is in the money. The volatility risk of first and second order arising from these options can be hedged dynamically with risk reversals and butterflies (see **Vanna–Volga Pricing**). However, all sensitivities take extreme values when getting closer to the trigger and closer to maturity. Delta positions can be a multiple of the notional amount. Therefore, it is difficult for the trader to perform dynamic hedging strategies. To manage these risks, short-term reverse knockout barrier options are often removed from the global books and are matched as individual positions, or are closed two to three weeks before expiry. The risk surcharge paid in this case is often smaller than the cost of keeping to such positions and hedging them individually.

Modifications and Extensions of Barrier Options

Standard extensions of barrier options are *double-barrier options*, where there is a barrier above and below the current spot. A double knockout option expires worthless if any of the two barriers are ever touched or crossed. A double knockin option only becomes a vanilla option if at least one of the two barriers is touched or crossed in the underlying.

A further modification of barrier options is called the *knockin/knockout (KIKO)* option. This option can knockout at any time; however, it must knockin to become alive. A short KIKO option can be statically hedged with a long knockout option and a short double knockout option, if the spot value is between the triggers, and with a long knockout option and a

short knockout option, if the spot value is above both triggers (Lego-brick principle).

Window barriers (partial barriers) are additional modifications of barrier options. In case of a window-barrier option, the trigger is valid only within a certain period of time. Commonly, this period of time is from inception of the trade until a specific date (*early ending*) or from a specific date during validity until expiry date of the option (*deferred start*). Arbitrary time intervals are possible.

For *European barrier options*, the triggers are only valid at maturity. They can be statically hedged with plain vanilla options and European digital options (Lego-brick principle).

Binary Options/Digital Options

Digital or binary options pay a fixed amount in a currency to be specified if the spot trades at or beyond a prespecified barrier or trigger. For European digitals, the trigger is valid only at maturity, whereas for American digitals, the trigger is valid during the entire lifetime of the trade. In FX-interbank trade American digitals are also called *one-touch* (if the fixed amount is paid at maturity) or *instant one-touch* (if the fixed amount is paid at first hitting time) options. Further touch options are the so-called *no-touch* options, *double no-touch* options, and *double one-touch* options. A no-touch pays only if the spot never touches or crosses the prespecified trigger. A double no-touch pays only if neither the upper trigger nor the lower trigger is ever touched or crossed during the lifetime of the contract. A double one-touch pays only if at least one of the upper or the lower triggers is touched. When buying a double no-touch option, a vega short position is generated. This means that double no-touch options are cheap in phases of high volatility.

European digital options can be replicated with bull or bear spreads with large amounts. Their market price can thus be approximated by liquid vanilla options. However, this type of option is difficult to hedge as the delta hedge close to expiry is zero almost everywhere.

General Features When Pricing Exotic Options

Most commercial software packages calculate the “theoretical value (TV)” of the exotic options, which

is the value of the product in a **Black–Scholes model** with constant parameters.

Knowing the TV is important for trading partners as it serves as a checksum to ensure that both parties talk about the same product. The market value, however, often deviates from this value because of so-called overhedge costs, which arise when hedging the exotic option. Every trader must be aware of the risk arising from these options and should be able to control this risk dynamically in his books via the Greeks (price sensitivity with respect to market and model parameters). If a gain is generated by performing this hedge, the price of an exotic option must be higher than the TV. Conversely, if the hedge leads to a loss, the market price of the exotic option should be above TV.

A very important issue when trading exotic options is placing automatic spot orders at spot levels that could lead to a knockout or expiry of the option. This order eliminates the **delta hedge** of the option automatically when reaching the trigger. This explains the occasional very heavy spot movements during specific trigger events in the market.

The following vega structure is often found in options books as it stems from most of the **structured products** offered today in the FX range: ATM vega long and wing vega short. This is the reason for a long phase of low volatility and high butterflies for the past years. See also **Foreign Exchange Smiles**.

Second-generation Exotic Options

We consider every exotic option as second generation if it is not a vanilla and not a first-generation product.

Some of the common examples in FX markets are *range accruals* and *faders*.

A range accrual is a sum of digital call spreads and pays an amount of a prespecified currency that depends on the number of currency fixings that come to fall inside a prespecified range. A fader is any basic option product like a vanilla or barrier option, whose notional amount depends on the number of currency fixings that come to fall inside a prespecified range. We distinguish fade-in products, where the notional grows with each fixing inside the range and fade-out products, where the notional decreases with each fixing inside the range.

Further extensions are target redemption products, whose notional amount increases until a certain gain is reached. A common example is a **target redemption forward** (TRF). We provide a description and an example here: We consider a TRF in which a counterpart sells EUR and buys USD at a much higher rate than current spot or forward rates. The key feature in this product is that counterpart has a total target profit that, once hit, knocks out all future settlements (in the example below, all weekly settlements), locking the gains registered until then.

The idea is to place the strike over 5.5 big figures above spot to allow the counterpart to quickly accumulate profits and have the trade knocked out after five or six weeks. The counterpart will start losing money if EUR-USD starts fixing above the strike. On a spot reference of 1.4760, consider a one year TRF, in which the counterpart sells 1 EUR 1 million per week at 1.5335, subject to a knockout condition: if the sum of the counterpart profits reaches the target, all future settlements are canceled. We let the target be 0.30 (i.e., 30 big figures), measured weekly as $\text{Profit} = \text{Max}(0, 1.5335 - \text{EUR-USD Spot Fixing})$. As usual, this type of forward is also traded at zero cost:

Week 1 Fixing = 1.4800 Profit = 0.0535 Max (1.5335–1.4800, 0)

Week 2 Fixing = 1.4750 Profit = 0.0585 Accumulated profit = 0.1120

Week 3 Fixing = 1.4825 Profit = 0.0510 Accumulated profit = 0.1630

Week 4 Fixing = 1.4900 Profit = 0.0435 Accumulated profit = 0.2065

Week 5 Fixing = 1.4775 Profit = 0.0560 Accumulated profit = 0.2625

Week 6 Fixing = 1.4850 Profit = 0.0485 Accumulated profit = 0.3110

The profit is capped at 0.30, so the counterpart only accumulates the last 3.75 big figures and the trade knocks out.

Each forward will be settled physically every week until trade knocks out (if the target is reached).

Another popular FX product is the *time option*, which is essentially a forward contract of American style, that is, the buyer is entitled and obliged to trade a prespecified amount at a prespecified strike, but can choose the time within a prespecified time interval.

The market is likely to continue to develop fast. Besides *Bermudan style options*, where early exercise is allowed at certain prespecified times, **basket options** and the corresponding structures are very much in demand in the market. Hybrid structures are exotic options whose payoff depends on underlying spots across different market sectors. We refer the reader to [1].

Currency Forward Contracts

Executive Summary

Structured forwards use combinations of options to replicate forwards like payout profiles. The main use of structured forwards is for corporate and institutional clients trying to hedge their foreign exchange exposures. While standard forwards lock in a fixed exchange rate, structured forwards give the user the advantage of the possibility of an improved exchange rate, while still guaranteeing a worst-case rate. As standard forwards, structured forwards usually have no upfront premium requirements (zero-cost strategies). Having the chance of an improved exchange rate for no upfront premium suggests that structured forwards must have a guaranteed worst-case exchange rate that is worse than the prevailing forward rate. This is the risk involved when entering into structured forward transactions.

Forward Contract

A foreign exchange forward transaction involves two parties, who enter into a contract, whereby one counterparty agrees to sell a specified amount of a currency A in exchange for a specified amount of another currency B on a specified date. The other counterparty agrees to buy the specified amount of that currency A in exchange of the other currency B.

The Characteristics of Forward Contracts

Both counterparties have the obligation to fulfill the contract (as opposed to an option transaction where only one of the parties has the obligation, the option seller, while the other counterparty, the option buyer, has the right, but no obligation). As both currency amounts are fixed on the day the contract is entered into, the exchange rate between the two currencies is fixed. Hence, the parties to the contract know from the beginning at what exchange rate they are obliged to buy or sell the specified currency.

For corporate and institutional clients, this can be a useful information, as they can use this exchange rate to calculate the cost of production of a given product

or service. Another positive feature of forwards is that there is no upfront premium to be paid by either party. As both parties to the contract have an obligation to deliver and the contract is struck at the prevailing market forward rate, the transaction is by definition a zero-cost strategy. This is because the definition of the market forward rate is a future exchange rate of two currencies at a rate that demands no upfront payment from either party.

How can one calculate this market forward rate and what are the influencing factors?

Calculating the Market Forward Rate

The following example helps to determine the forward exchange rate of a given currency pair.

Market Information.

- Company X: London-based manufacturer exporting to the United States.
- The importing company: New York-based company importing from the United Kingdom.
- The bank: it is the other counterparty to the forward transaction.
- Company X sells its goods to the importing company. The sale is agreed in USD, and the payment of USD 100 000 is expected six months after the contract is signed. Therefore, the London-based company X has a foreign exchange exposure, as the change in the foreign exchange rate has an effect on its income in GBP.
- Current GBP/USD exchange rate: 2.0000. This means that 1 GBP is worth 2 USD.
- Current GBP interest rate: 6% per annum. This is the interest rate company X can borrow and lend in GBP.
- Current USD interest rate: 3% per annum. This is the interest rate company X can borrow and lend in USD.

What can company X do to eliminate its foreign exchange exposure? We know that company X will receive USD 100 000 in six months time. In fact they could already sell this USD 100 000 at the prevailing market rate (spot rate), but they don't have it yet. The solution is to go to the bank and borrow the USD 100 000. To be precise, they need to borrow less than USD 100 000, because they need to pay interest on the loan to the bank. So the exact amount to borrow

2 Currency Forward Contracts

is the net present value (NPV) of USD 100 000. To calculate this, we use the following formula:

$$NPV = \frac{N}{1 + r^*d/dc} \quad (1)$$

where

- N is the amount for which one wants to calculate the NPV. In this example, it is USD 100 000.
- r is the interest rate, expressed as percentage per annum, for the currency in which N is denominated.
- d is the duration of the deposit or loan in days. In this example, it is 180 days (i.e., six months).
- dc is the day-count fraction. This is usually 360, except for GBP deposits or loans where it is 365.

We are now able to calculate the amount company X has to borrow: $\text{USD } 100\,000 / (1 + 0.03 \times 180/360) = \text{USD } 98,522.17$. If they borrow this money, they have to pay back exactly USD 100 000 in six months time including the interest charge. This is the amount company X is due to receive in six months time from the sales of its goods to the import-export company.

If company X now sells the borrowed USD in the spot market and buys GBP, they receive GBP 49 261.08. This is calculated by dividing the borrowed USD amount by the current GBP/USD exchange rate (2.0000 in this example).

Company X now has the GBP and has eliminated the foreign exchange exposure. They can take GBP and deposit it with their bank at the current interest rate (6% in this example). The amount they get back after six months is equal to GBP 50 718.67—this is calculated as follows: $\text{GBP } 49\,261.08 \times (1 + 0.06 \times 180/365)$.

After these series of transactions company X is left with no cash position at the beginning of the transaction. They receive GBP 50 718.67 after six months and have to pay USD 100 000 in exchange. The exchange rate that is implied from the above-mentioned two amounts is 1.9717 (calculated as USD 100 000 divided by GBP 50 718.67).

What happens when a forward transaction is entered into? Exactly the same:

- At the beginning of the transaction:
 - company X has no cash position;
 - company X agrees to sell USD 100 000 for GBP at the market forward rate.

- At the end of the transaction:
 - company X pays USD 100 000 for the GBP amount exchanged at the agreed forward rate.

Because the two approaches described earlier have the same outcome, the GBP amount received for the USD 100 000 has to be the same; otherwise there would be an arbitrage opportunity. Therefore, the market forward rate in this example has to be 1.9717.

Generally, the forward rate can be calculated with a single and easy formula:

$$F_{\text{GBP/USD}} = S_{\text{GBP/USD}} \frac{1 + r_{\text{USD}}^*d/dc_{\text{USD}}}{1 + r_{\text{GBP}}^*d/dc_{\text{GBP}}} \quad (2)$$

where $F_{\text{GBP/USD}}$, forward rate for GBP/USD; $S_{\text{GBP/USD}}$, spot exchange rate for GBP/USD; r_{USD} , USD interest rate expressed in percentage per annum; r_{GBP} , GBP interest rate expressed in percentage per annum; d , duration of the deposit or loan in days; dc_{USD} , day-count fraction for USD (360); and dc_{GBP} , day-count fraction for GBP (365).

As the formula suggests, the market forward rate is a function of only the current (spot) exchange rate and the interest rates of the two currencies for the specified forward period. Hence, it is not market expectations, or any other factor that determines the arbitrage-free forward rate.

Structured Forwards

The previous section helped us to understand how a foreign exchange exposure resulting from a cross-border transaction can be eliminated and hedged through a forward transaction. It showed that the forward exchange rate was fixed right at the beginning of the contract and hence the uncertainty about exchange rate movements was turned into a known rate with which companies can calculate their cost of production. The example also demonstrated that there is no cash flow at the beginning of a forward transaction and there is no premium or any other fee associated with it. A forward transaction is by definition a zero-cost strategy.

The Difference between Forwards and Structured Forwards

The disadvantage of forwards is that favorable exchange rate moves are also eliminated when the

exchange rate is fixed. In the previous example, the forward rate was calculated to be 1.9717. This is the rate at which company X has to buy GBP and sell the USD. If in six months time the GBP/USD exchange rate falls below 1.9717, company X would be better off without hedging the GBP purchase through a forward.

Structured forwards allow just this. They are more flexible, because favorable exchange rate moves, and, in fact, any market view can be incorporated into the transaction to enhance the rate at which a currency is exchanged for another.

As with forwards, structured forwards offer the worst-case exchange rate. This rate is fixed at the beginning of the contract and similar to a regular forward, it offers the benefit of certainty about the exchange rate that can be used for financial planning.

Similar to standard forward contracts, most structured forward contracts are zero-cost strategies, that is, no upfront premium is required.

We all know that there is no such a thing as a “free lunch”. Therefore, to have the benefit of an improved exchange rate, a fixed worst-case rate, and a zero-cost strategy, the company entering into a structured forward transaction needs to take on certain risks. This risk is usually structured so that the guaranteed worst-case exchange rate is set at a rate that is worse than the prevailing market forward rate. The hedging counterparty accepts this worse guaranteed rate for the chance of receiving a better rate, in case a predefined condition is met. As the examples in the following section demonstrate, these predefined conditions can take many forms and may incorporate the market view of the counterparty entering into the structured forward transaction.

Examples of Structured Forwards

As mentioned in the previous section, structured forwards offer the possibility to incorporate one’s market view into a forward transaction. This view might be the appreciation or depreciation of a currency or even the view that a currency pair remains in a certain range over a given period of time. The following examples demonstrate how these different market views can be expressed with currency options that can be structured into the forward transaction. As a reminder: all examples follow the basic assumptions that the structured forward has a worst-case buying

(or selling) rate and no upfront premium must enter into the transaction.

Forward Plus. The forward plus is the simplest of all structured forwards. It offers the possibility to take advantage of favorable market movements up to a certain point, while still having a certain worst-case hedged rate.

How does it work: by accepting a worst-case hedge rate that is less favorable than the prevailing market forward rate, we create excess cash. Remember, trading at the market forward rate is zero cost by definition. If one trades on a rate that is worse than the market rate, one can expect some compensation. The cash generated is used to buy an option that pays out, if the underlying currency pair moves favorably. To make this a zero-cost strategy, we need to introduce a barrier, or knockout. This has the effect that options cease to exist (are knocked out) if the barrier is reached. For our strategy, it means that we can participate in a favorable market move, but only up to a certain point, namely, the predefined barrier level. If the barrier is reached we are locked into a forward transaction with a rate equal to the worst-case rate.

Let us continue the previous example with company X: We calculated the market forward rate to purchase GBP against USD in six months time to be 1.9717. A forward plus could have a worst-case buying rate of 1.9850. This rate is 0.0133 worse than the market forward rate. As compensation for accepting this hedge rate, company X has the opportunity to buy GBP at the prevailing spot rate in six months time as long as the barrier of 1.8875 is not reached or breached during the life of the contract. As the barrier is observed continuously during the entire life of the transaction, we call this barrier an American style barrier (this is not to be confused with an American style option that is exercisable during the life of the option). So what does this right to buy the GBP at the prevailing market spot rate in six months time give to company X? Imagine that the barrier was never reached and the spot rate in six months time is at 1.9000. In this case, company X may buy the GBP at 1.9000 and it will outperform the forward transaction that would have forced it to buy the GBP at 1.9717. However, if the spot rate ever trades at or below the barrier of 1.8875, company X has to buy the GBP at the worst-case rate of 1.9850.

Table 1 and Figure 1 demonstrate possible scenarios with assumed spot rates after six months.

4 Currency Forward Contracts

Table 1 Forward plus scenario analysis

Spot rate in six months time	Forward plus buying rate		Market forward rate
	Barrier never reached	Barrier reached	
2.0200	1.9850	1.9850	1.9717
2.0100	1.9850	1.9850	1.9717
2.0000	1.9850	1.9850	1.9717
1.9900	1.9850	1.9850	1.9717
1.9850	1.9850	1.9850	1.9717
1.9750	1.9750	1.9850	1.9717
1.9700	1.9700	1.9850	1.9717
1.9650	1.9650	1.9850	1.9717
1.9600	1.9600	1.9850	1.9717
1.9550	1.9550	1.9850	1.9717
1.9500	1.9500	1.9850	1.9717
1.9450	1.9450	1.9850	1.9717
1.9400	1.9400	1.9850	1.9717
1.9350	1.9350	1.9850	1.9717
1.9300	1.9300	1.9850	1.9717
1.9250	1.9250	1.9850	1.9717
1.9200	1.9200	1.9850	1.9717
1.9150	1.9150	1.9850	1.9717
1.9100	1.9100	1.9850	1.9717
1.9050	1.9050	1.9850	1.9717
1.9000	1.9000	1.9850	1.9717
1.8950	1.8950	1.9850	1.9717
1.8876	1.8876	1.9850	1.9717
1.8875	1.9850	1.9850	1.9717
1.8800	1.9850	1.9850	1.9717
1.8750	1.9850	1.9850	1.9717
1.8700	1.9850	1.9850	1.9717

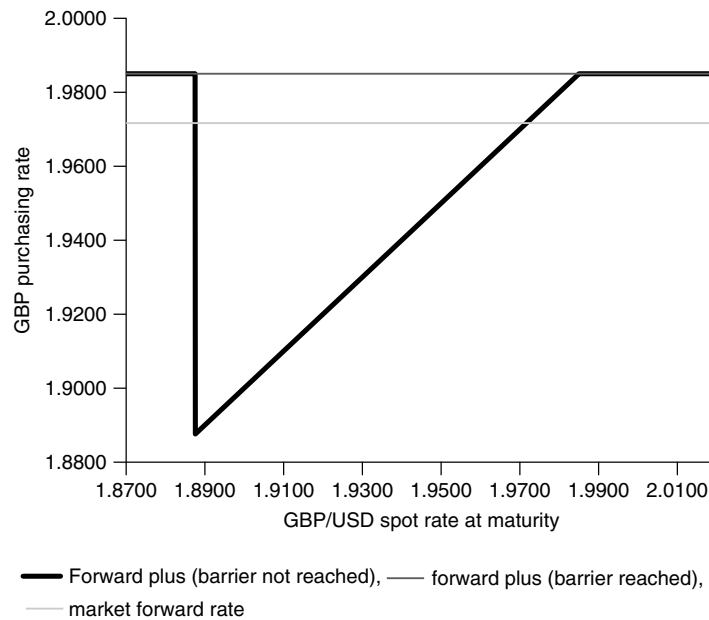

Figure 1 Forward plus scenario analysis

As Figure 1 demonstrates, the forward plus outperforms the market forward rate, if the barrier is never reached and the GBP/USD spot rate at maturity is below 1.9717.

If we set the worst-case scenario even higher than 1.9850, we can set the barrier further down. Taking advantage of this flexibility, each company entering into a forward plus can create a product that suits its risk appetite.

Range Forward. The following example uses another market view to try to outperform the forward rate. In this case, we expect the underlying currency pair to trade within a predefined range during the life of the contract.

Like with the forward plus (and with nearly all other structured forwards), the worst-case hedge rate is less favorable than the prevailing market forward rate. The generated excess cash is spent on an option

that pays out if the range holds. The payout of the option is then used to improve the worst-case rate.

Here is an example: we calculated the market forward rate to purchase GBP against USD in six months time to be 1.9717. A range forward could have a worst-case buying rate of 1.9850. This rate is 0.0133 worse than the market forward rate. In compensation for accepting this hedge rate, company X can buy GBP at 1.8850 (0.0867 better than the forward rate), if the GBP/USD exchange rate remains within the 2.0700–1.9400 range during the entire six-month period. If at any time during the life of the contract, the underlying currency pair trades outside the range, company X has to buy the GBP at the worst-case rate of 1.9850.

Table 2 and Figure 2 demonstrate possible scenarios with assumed spot rates after six months.

As Figure 2 demonstrates, the range forward outperforms the market forward rate, if the range holds, even if spot rate closes above the forward rate.

Table 2 Range forward scenario analysis

Spot rate in six months time	Range forward buying rate		Market forward rate
	Barriers never reached	Barrier reached	
2.1000	1.9850	1.9850	1.9717
2.0700	1.9850	1.9850	1.9717
2.0699	1.8850	1.9850	1.9717
2.0500	1.8850	1.9850	1.9717
2.0300	1.8850	1.9850	1.9717
2.0250	1.8850	1.9850	1.9717
2.0200	1.8850	1.9850	1.9717
2.0150	1.8850	1.9850	1.9717
2.0100	1.8850	1.9850	1.9717
2.0050	1.8850	1.9850	1.9717
2.0000	1.8850	1.9850	1.9717
1.9950	1.8850	1.9850	1.9717
1.9900	1.8850	1.9850	1.9717
1.9850	1.8850	1.9850	1.9717
1.9800	1.8850	1.9850	1.9717
1.9750	1.8850	1.9850	1.9717
1.9700	1.8850	1.9850	1.9717
1.9650	1.8850	1.9850	1.9717
1.9600	1.8850	1.9850	1.9717
1.9550	1.8850	1.9850	1.9717
1.9500	1.8850	1.9850	1.9717
1.9450	1.8850	1.9850	1.9717
1.9401	1.8850	1.9850	1.9717
1.9400	1.9850	1.9850	1.9717
1.9300	1.9850	1.9850	1.9717
1.9250	1.9850	1.9850	1.9717
1.9200	1.9850	1.9850	1.9717

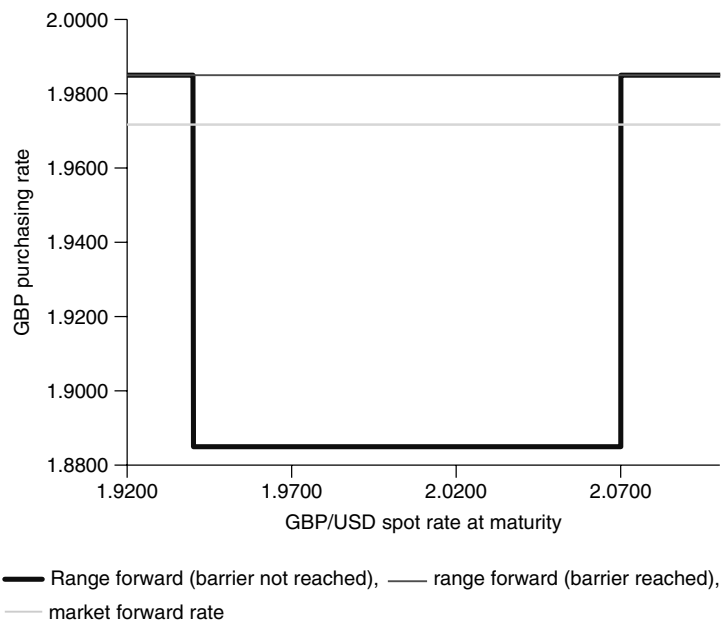

Figure 2 Range forward scenario analysis

If we set the worst-case scenario even higher than 1.9850, we can widen the range or improve the best-case buying rate. Taking advantage of this flexibility, each company entering into a range forward can create a product that suits its risk appetite.

Pricing Formulae for Foreign Exchange Options

The foreign exchange options market is highly competitive, even for products beyond vanilla call and put options. This means that pricing and risk management systems always need to have the fastest possible method to compute values and sensitivities for all the products in the book. Only then can a trader or risk manager know the current position and risk of his book. The ideal solution is to use pricing formulae in closed form. However, this is often only possible in the **Black–Scholes model**.

General Model Assumptions and Abbreviations

Throughout this article, we denote the current value of the spot S_t by x and use the abbreviations listed in Table 1.

The pricing follows the usual procedures of **Arbitrage pricing theory** and the **Fundamental theorem of asset pricing**. In a foreign exchange market, this means that we model the underlying exchange rate by a *geometric Brownian motion*

$$dS_t = (r_d - r_f)S_t dt + \sigma S_t dW_t \quad (1)$$

where r_d denotes the domestic interest rate, σ the volatility, and W_t the standard Brownian motion; see **Foreign Exchange Symmetries** for details. Most importantly, we note that there is a foreign interest rate r_f . As in **Option Pricing: General Principles**, one can compute closed-form solutions for many options types with payoff $F(S_T)$ at maturity T directly via

$$\begin{aligned} v(t, x) &= e^{-r_d T} \mathbb{E}[F(S_T) | S_t = x] \\ &= e^{-r_d T} \mathbb{E} \left[F \left(x e^{(r_d - r_f - \frac{1}{2}\sigma^2)\tau + \sigma\sqrt{\tau}Z} \right) \right] \end{aligned} \quad (2)$$

where $v(t, x)$ denotes the value of the derivative with payoff F at time t if the spot is at x . The random variable Z represents the continuous returns, which are modeled as standard normal in the **Black–Scholes model**. In this model, we can proceed as

Table 1 Abbreviations used for the pricing formulae of FX options

$\tau \triangleq T - t$	$\theta_{\pm} \triangleq \frac{r_d - r_f}{\sigma} \pm \frac{\sigma}{2}$
$D_d \triangleq e^{-r_d \tau}$	$d_{\pm} \triangleq \frac{\ln\left(\frac{x}{K}\right) + \sigma\theta_{\pm}\tau}{\sigma\sqrt{\tau}}$
$D_f \triangleq e^{-r_f \tau}$	$x_{\pm} \triangleq \frac{\ln\left(\frac{x}{B}\right) + \sigma\theta_{\pm}\tau}{\sigma\sqrt{\tau}}$
$n(t) \triangleq \frac{1}{\sqrt{2\pi}} e^{-\frac{t^2}{2}}$	$z_{\pm} \triangleq \frac{\ln\left(\frac{B^2}{xK}\right) + \sigma\theta_{\pm}\tau}{\sigma\sqrt{\tau}}$
$\mathcal{N}(x) \triangleq \int_{-\infty}^x n(t) dt$	$y_{\pm} \triangleq \frac{\ln\left(\frac{B}{x}\right) + \sigma\theta_{\pm}\tau}{\sigma\sqrt{\tau}}$
$\phi = +1$ for call options	$\phi = -1$ for put options
t : current time	T : maturity time
K : strike	B, L, H : barriers

$$\begin{aligned} v(t, x) &= e^{-r_d \tau} \int_{-\infty}^{+\infty} F \left(x e^{(r_d - r_f - \frac{1}{2}\sigma^2)\tau + \sigma\sqrt{\tau}z} \right) n(z) dz \\ &= D_d \int_{-\infty}^{+\infty} F \left(x e^{\sigma\theta_{-}\tau + \sigma\sqrt{\tau}z} \right) n(z) dz \end{aligned} \quad (3)$$

The rest is working out the integration. In other models, one would replace the normal density by another density function such as a t -density. However, in many other models densities are not explicitly known, or even if they are, the integration becomes cumbersome.

For the resulting pricing formulae, there are many sources, for example, [7, 11, 17]. Many general books on **Option Pricing** also contain formulae in a context outside the foreign exchange, for example, [8, 18]. Obviously, we cannot cover all possible formulae in this section. We give an overview of several relevant examples and refer to **Foreign Exchange Basket Options; Margrabe Formula; Quanto Options** for more. FX vanilla options are covered in **Foreign Exchange Symmetries**.

Barrier Options

We consider the payoff for single-barrier knock-out options

$$\begin{aligned} & [\phi(S_T - K)]^+ \mathbb{I}_{\{\eta S_t > \eta B, 0 \leq t \leq T\}} \\ &= [\phi(S_T - K)]^+ \mathbb{I}_{\{\min_{t \in [0, T]}(\eta S_t) > \eta B\}} \end{aligned} \quad (4)$$

where the binary variable η takes the value +1 if the barrier B is approached from above (down-and-out) and -1 if the barrier is approached from below (up-and-out).

To price knock-in options paying

$$[\phi(S_T - K)]^+ \mathbb{I}_{\{\min_{t \in [0, T]}(\eta S_t) \leq \eta B\}} \quad (5)$$

we use the fact that

$$\text{knock-in} + \text{knock-out} = \text{vanilla} \quad (6)$$

Computing the value of a barrier option in the Black–Scholes model boils down to knowing the joint density $f(x, y)$ for a Brownian motion with drift and its running extremum ($\eta = +1$ for a minimum and $\eta = -1$ for a maximum),

$$\left(W(T) + \theta_- T, \eta \min_{0 \leq t \leq T} [W(t) + \theta_- t] \right) \quad (7)$$

which is derived, for example, in [15], and can be written as

$$\begin{aligned} & f(x, y) \\ &= -\eta e^{\theta_- x - \frac{1}{2}\theta_-^2 T} \frac{2(2y - x)}{T\sqrt{2\pi T}} \exp \left\{ -\frac{(2y - x)^2}{2T} \right\}, \quad (8) \\ & \quad \eta y \leq \min(0, \eta x) \end{aligned}$$

Using the density (8), the value of a barrier option can be written as the following integral

$$\begin{aligned} & \text{barrier}(S_0, \sigma, r_d, r_f, K, B, T) \\ &= e^{-r_d T} \mathbb{E} \left[[\phi(S_T - K)]^+ \mathbb{I}_{\{\eta S_t > \eta B, 0 \leq t \leq T\}} \right] \quad (9) \\ &= e^{-r_d T} \int_{x=-\infty}^{x=+\infty} \int_{\eta y \leq \min(0, \eta x)} [\phi(S_0 e^{\sigma x} - K)]^+ \\ & \quad \times \mathbb{I}_{\left\{ \eta y > \eta \frac{1}{\sigma} \ln \frac{B}{S_0} \right\}} f(x, y) dy dx \quad (10) \end{aligned}$$

Further details on how to evaluate this integral can be found in [15]. It results in four terms. We provide the four terms and summarize, in Table 2, how they are used to find the value function (see also [13] or [14]).

$$A_1 = \phi x D_f \mathcal{N}(\phi d_+) - \phi K D_d \mathcal{N}(\phi d_-) \quad (11)$$

$$A_2 = \phi x D_f \mathcal{N}(\phi x_+) - \phi K D_d \mathcal{N}(\phi x_-) \quad (12)$$

$$\begin{aligned} A_3 &= \phi \left(\frac{B}{x} \right)^{\frac{2\theta_-}{\sigma}} \\ & \quad \times \left[x D_f \left(\frac{B}{x} \right)^2 \mathcal{N}(\eta z_+) - K D_d \mathcal{N}(\eta z_-) \right] \quad (13) \end{aligned}$$

$$\begin{aligned} A_4 &= \phi \left(\frac{B}{x} \right)^{\frac{2\theta_-}{\sigma}} \\ & \quad \times \left[x D_f \left(\frac{B}{x} \right)^2 \mathcal{N}(\eta y_+) - K D_d \mathcal{N}(\eta y_-) \right] \quad (14) \end{aligned}$$

Table 2 The summands for the value of single barrier options

Option type	ϕ	η	In/Out	Reverse	Combination
Standard up-and-in call	+1	-1	in	$K > B$	A_1
Reverse up-and-in call	+1	-1	in	$K \leq B$	$A_2 - A_3 + A_4$
Reverse up-and-in put	-1	-1	in	$K > B$	$A_1 - A_2 + A_4$
Standard up-and-in put	-1	-1	in	$K \leq B$	A_3
Standard down-and-in call	+1	+1	in	$K > B$	A_3
Reverse down-and-in call	+1	+1	in	$K \leq B$	$A_1 - A_2 + A_4$
Reverse down-and-in put	-1	+1	in	$K > B$	$A_2 - A_3 + A_4$
Standard down-and-in put	-1	+1	in	$K \leq B$	A_1
Standard up-and-out call	+1	-1	out	$K > B$	0
Reverse up-and-out call	+1	-1	out	$K \leq B$	$A_1 - A_2 + A_3 - A_4$
Reverse up-and-out put	-1	-1	out	$K > B$	$A_2 - A_4$
Standard up-and-out put	-1	-1	out	$K \leq B$	$A_1 - A_3$
Standard down-and-out call	+1	+1	out	$K > B$	$A_1 - A_3$
Reverse down-and-out call	+1	+1	out	$K \leq B$	$A_2 - A_4$
Reverse down-and-out put	-1	+1	out	$K > B$	$A_1 - A_2 + A_3 - A_4$
Standard down-and-out put	-1	+1	out	$K \leq B$	0

Digital and Touch Options

Digital Options

Digital options have a payoff

$$v(T, S_T) = \mathbb{I}_{\{\phi S_T \geq \phi K\}} \text{ domestic paying} \quad (15)$$

$$w(T, S_T) = S_T \mathbb{I}_{\{\phi S_T \geq \phi K\}} \text{ foreign paying} \quad (16)$$

In the domestic paying case, the payment of the fixed amount is in domestic currency, whereas in the foreign paying case the payment is in foreign currency. We obtain for the value functions

$$v(t, x) = D_d \mathcal{N}(\phi d_-) \quad (17)$$

$$w(t, x) = x D_f \mathcal{N}(\phi d_+) \quad (18)$$

of the digital options paying one unit of domestic and paying one unit of foreign currency, respectively.

One-touch Options

The payoff of a one-touch is given by

$$R \mathbb{I}_{\{\tau_B \leq T\}} \quad (19)$$

$$\tau_B \triangleq \inf\{t \geq 0 : \eta S_t \leq \eta B\} \quad (20)$$

This type of option pays a domestic cash amount R if a barrier B is hit any time before the expiration time. We use the binary variable η to describe whether B is a lower barrier ($\eta = 1$) or an upper barrier ($\eta = -1$). The stopping time τ_B is called the *first hitting time*. In FX markets, an option with this payoff is usually called a *one-touch (option)*, *one-touch-digital*, or *hit option*. The modified payoff of a *no-touch (option)*, $R \mathbb{I}_{\{\tau_B \geq T\}}$ describes a rebate, which is paid if a knock-in-option is not knocked-in by the time it expires and can be valued similarly by exploiting the identity

$$R \mathbb{I}_{\{\tau_B \leq T\}} + R \mathbb{I}_{\{\tau_B > T\}} = R \quad (21)$$

Furthermore, we distinguish the time at which the rebate is paid and let

$$\omega = 0, \text{ if the rebate is paid at first hitting time } \tau_B \quad (22)$$

$$\omega = 1, \text{ if the rebate is paid at maturity time } T \quad (23)$$

where the former is also called *instant one-touch* and the latter is the default in FX options markets. It is important to mention that the payoff is one unit of the domestic currency. For a payment in the foreign currency EUR, one needs to exchange r_d and r_f , replace x and B by their reciprocal values, and change the sign of η ; see **Foreign Exchange Symmetries**.

For the one-touch, we use the abbreviations

$$\begin{aligned} \vartheta_- &\triangleq \sqrt{\theta_-^2 + 2(1-\omega)r_d} \quad \text{and} \\ e_{\pm} &\triangleq \frac{\pm \ln \frac{x}{B} - \sigma \vartheta_- \tau}{\sigma \sqrt{\tau}} \end{aligned} \quad (24)$$

The theoretical value of the one-touch turns out to be

$$\begin{aligned} v(t, x) &= R e^{-\omega r_d \tau} \\ &\times \left[\left(\frac{B}{x} \right)^{\frac{\theta_- + \vartheta_-}{\sigma}} \mathcal{N}(-\eta e_+) + \left(\frac{B}{x} \right)^{\frac{\theta_- - \vartheta_-}{\sigma}} \mathcal{N}(\eta e_-) \right] \end{aligned} \quad (25)$$

Note that $\vartheta_- = |\theta_-|$ for rebates paid-at-end ($\omega = 1$).

The risk-neutral probability of knocking out is given by

$$\mathbb{P}[\tau_B \leq T] = \mathbb{E}[\mathbb{I}_{\{\tau_B \leq T\}}] = \frac{1}{R} e^{r_d T} v(0, S_0) \quad (26)$$

Properties of the First Hitting Time τ_B . As derived, for example, in [15], the first hitting time

$$\tilde{\tau} \triangleq \inf\{t \geq 0 : \theta t + W(t) = x\} \quad (27)$$

of a Brownian motion with drift θ and hit level $x > 0$ has the density

$$\begin{aligned} \mathbb{P}[\tilde{\tau} \in dt] \\ = \frac{x}{t \sqrt{2\pi t}} \exp \left\{ -\frac{(x - \theta t)^2}{2t} \right\} dt, \quad t > 0 \end{aligned} \quad (28)$$

the cumulative distribution function

$$IP[\tilde{\tau} \leq t] = \mathcal{N}\left(\frac{\theta t - x}{\sqrt{t}}\right) + e^{2\theta x} \mathcal{N}\left(\frac{-\theta t - x}{\sqrt{t}}\right), \quad t > 0 \quad (29)$$

the Laplace transform

$$IEe^{-\alpha \tilde{\tau}} = \exp\left\{x\theta - x\sqrt{2\alpha + \theta^2}\right\}, \quad \alpha > 0, \quad x > 0 \quad (30)$$

and the property

$$IP[\tilde{\tau} < \infty] = \begin{cases} 1 & \text{if } \theta \geq 0 \\ e^{2\theta x} & \text{if } \theta < 0 \end{cases} \quad (31)$$

For upper barriers $B > S_0$, we can now rewrite the first passage time τ_B as

$$\begin{aligned} \tau_B &= \inf\{t \geq 0 : S_t = B\} \\ &= \inf\left\{t \geq 0 : W_t + \theta_- t = \frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right)\right\} \end{aligned} \quad (32)$$

The density of τ_B is hence

$$\begin{aligned} IP[\tilde{\tau}_B \in dt] &= \frac{\frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right)}{t\sqrt{2\pi t}} \\ &\times \exp\left\{-\frac{\left(\frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right) - \theta_- t\right)^2}{2t}\right\}, \quad t > 0 \end{aligned} \quad (33)$$

Derivation of the value function. Using the density (33), the value of the paid-at-end ($\omega = 1$) upper rebate ($\eta = -1$) option can be written as the following integral:

$$\begin{aligned} v(T, S_0) &= Re^{-r_d T} IE\left[\mathbb{I}_{\{\tau_B \leq T\}}\right] \\ &= Re^{-r_d T} \int_0^T \frac{\frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right)}{t\sqrt{2\pi t}} \\ &\times \exp\left\{-\frac{\left(\frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right) - \theta_- t\right)^2}{2t}\right\} dt \end{aligned} \quad (34)$$

To evaluate this integral, we introduce the notation

$$e_{\pm}(t) \triangleq \frac{\pm \ln \frac{S_0}{B} - \sigma \theta_- t}{\sigma \sqrt{t}} \quad (35)$$

and list the properties

$$e_-(t) - e_+(t) = \frac{2}{\sqrt{t}} \frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right) \quad (36)$$

$$n(e_+(t)) = \left(\frac{B}{S_0}\right)^{-\frac{2\theta_-}{\sigma}} n(e_-(t)) \quad (37)$$

$$\frac{\partial e_{\pm}(t)}{\partial t} = \frac{e_{\mp}(t)}{2t} \quad (38)$$

We evaluate the integral in equation (34) by rewriting the integrand in such a way that the coefficients of the exponentials are the inner derivatives of the exponentials using properties (36)–(38).

$$\begin{aligned} &\int_0^T \frac{\frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right)}{t\sqrt{2\pi t}} \exp\left\{-\frac{\left(\frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right) - \theta_- t\right)^2}{2t}\right\} dt \\ &= \frac{1}{\sigma} \ln\left(\frac{B}{S_0}\right) \int_0^T \frac{1}{t^{(3/2)}} n(e_-(t)) dt \\ &= \int_0^T \frac{1}{2t} n(e_-(t)) [e_-(t) - e_+(t)] dt \\ &= - \int_0^T n(e_-(t)) \frac{e_+(t)}{2t} + \left(\frac{B}{S_0}\right)^{\frac{2\theta_-}{\sigma}} n(e_+(t)) \frac{e_-(t)}{2t} dt \\ &= \left(\frac{B}{S_0}\right)^{\frac{2\theta_-}{\sigma}} \mathcal{N}(e_+(T)) + \mathcal{N}(-e_-(T)) \end{aligned} \quad (39)$$

The computation for lower barriers ($\eta = 1$) is similar.

Double-no-touch Options

A double-no-touch with payoff function

$$\mathbb{I}_{\{L < \min_{t \in [0, T]} S_t \leq \max_{t \in [0, T]} S_t < H\}} \quad (40)$$

pays one unit of domestic currency at maturity T , if the spot *never* touches any of the two barriers, where the lower barrier is denoted by L , the higher

barrier by H . A *double-one-touch* pays one unit of domestic currency at maturity, if the spot either touches or crosses any of the lower or higher barrier at least once between inception of the trade and maturity. This means that a portfolio of a double-one-touch and a double-no-touch is equivalent to a certain payment of one unit of domestic currency at maturity.

To compute the value, let us introduce the stopping time

$$\tau_{L,H} \triangleq \min \{ \inf \{ t \in [0, T] | S_t = L \text{ or } S_t = H \}, T \} \quad (41)$$

and the notation

$$\tilde{h} \triangleq \frac{1}{\sigma} \ln \frac{H}{S_t} \quad (42)$$

$$\tilde{l} \triangleq \frac{1}{\sigma} \ln \frac{L}{S_t} \quad (43)$$

$$\tilde{\theta}_{\pm} \triangleq \theta_{\pm} \sqrt{\tau} \quad (44)$$

$$h \triangleq \tilde{h} / \sqrt{\tau} \quad (45)$$

$$l \triangleq \tilde{l} / \sqrt{\tau} \quad (46)$$

$$\epsilon_{\pm} \triangleq \epsilon_{\pm}(j) = 2j(h-l) - \tilde{\theta}_{\pm} \quad (47)$$

$$n_T(x) \triangleq \frac{1}{\sqrt{2\pi T}} \exp \left(-\frac{x^2}{2T} \right) \quad (48)$$

At any time $t < \tau_{L,H}$, the value of the double-no-touch is

$$v(t) = \mathbb{E}^t \left[D_d \mathbb{I} \{ L < \min_{u \in [t, T]} S_u \leq \max_{u \in [t, T]} S_u < H \} \right] \quad (49)$$

and for $t \in [\tau_{L,H}, T]$,

$$v(t) = D_d \mathbb{I} \{ L < \min_{u \in [t, T]} S_u \leq \max_{u \in [t, T]} S_u < H \} \quad (50)$$

The joint distribution of the maximum and the minimum of a Brownian motion can be taken from [12] and is given by

$$\mathbb{P} \left[\tilde{l} < \min_{[0, T]} W_t \leq \max_{[0, T]} W_t < \tilde{h} \right] = \int_{\tilde{l}}^{\tilde{h}} k_T(x) dx \quad (51)$$

with

$$k_T(x) = \sum_{j=-\infty}^{\infty} \left[n_T(x + 2j(\tilde{h} - \tilde{l})) - n_T(x - 2\tilde{h} + 2j(\tilde{h} - \tilde{l})) \right] \quad (52)$$

One can use Girsanov's theorem (see **Equivalent Martingale Measures**) to deduce that the joint density of the maximum and the minimum of a Brownian motion with drift θ , $W_t^{\theta} \triangleq W_t + \theta t$, is then given by

$$k_T^{\theta}(x) \triangleq k_T(x) \exp \{ \theta x - \frac{1}{2} \theta^2 T \} \quad (53)$$

We obtain for the value of the double-no-touch at any time $t < \tau_{L,H}$

$$\begin{aligned} v(t, S_t) &= D_d \mathbb{E} \mathbb{I} \{ L < \min_{u \in [t, T]} S_u \leq \max_{u \in [t, T]} S_u < H \} \\ &= D_d \mathbb{E} \mathbb{I} \{ \tilde{l} < \min_{u \in [t, T]} W_u^{\theta_-} \leq \max_{u \in [t, T]} W_u^{\theta_-} < \tilde{h} \} \\ &= D_d \int_{\tilde{l}}^{\tilde{h}} k_{(T-t)}^{\theta_-}(x) dx \\ &= D_d \cdot \sum_{j=-\infty}^{\infty} \left[e^{-2j\tilde{\theta}_-(h-l)} \right. \\ &\quad \times \{ \mathcal{N}(h + \epsilon_-) - \mathcal{N}(l + \epsilon_-) \} \\ &\quad - e^{-2j\tilde{\theta}_-(h-l) + 2\tilde{\theta}_-h} \\ &\quad \times \{ \mathcal{N}(h - 2h + \epsilon_-) - \mathcal{N}(l - 2h + \epsilon_-) \} \left. \right] \end{aligned} \quad (54)$$

and for $t \in [\tau_{L,H}, T]$

$$v(t, S_t) = D_d \mathbb{I} \{ L < \min_{u \in [t, T]} S_u \leq \max_{u \in [t, T]} S_u < H \} \quad (55)$$

Of course, the value of the double-one-touch is given by

$$D_d - v(t, S_t) \quad (56)$$

To obtain a formula for a double-no-touch paying foreign currency, see **Foreign Exchange Symmetries**.

Lookback Options

Lookback options are path dependent. At expiration, the holder of the option can “look back” over the lifetime of the option and exercise based upon the optimal underlying value (extremum) achieved during

that period. Thus, lookback options (like **Asian options**) avoid the problem of European options that the underlying performed favorably throughout most of the option's lifetime but moves into a nonfavorable direction toward maturity. Moreover, (unlike **American Options**) **lookback options** optimize the market timing, because the investor gets, by definition, the most favorable underlying price. As summarized in Table 3, **lookback options** can be structured in two different types with the extremum representing either the strike price or the underlying value. Figure 1 shows the development of the payoff of **lookback options** depending on a sample price path. In detail, we define

$$M_T \triangleq \max_{0 \leq u \leq T} S(u) \quad \text{and} \quad m_T \triangleq \min_{0 \leq u \leq T} S(u) \quad (57)$$

Variations of lookback options include *partial lookback options*, where the monitoring period for the underlying is shorter than the lifetime of the option. Conze and Viswanathan [2] present further variations like *limited risk* and *American lookback options*.

In theory, Garman pointed out in [4], that lookback options can also add value for risk managers, because floating (fixed) strike lookback options are good means to solve the timing problem of market entries (exits) (see [9]). For instance, a minimum strike call is suitable for avoiding missing the best

Table 3 Types of lookback options. The contract parameters T and X are the time to maturity and the strike price, respectively, and S_T denotes the spot price at expiration time. Fixed strike lookback options are also called *hindsight options*

Payoff	Lookback type	Parameter used below in valuation
$M_T - S_T$	Floating strike put	$\phi = -1, \bar{\eta} = +1$
$S_T - m_T$	Floating strike call	$\phi = +1, \bar{\eta} = +1$
$(M_T - X)^+$	Fixed strike call	$\phi = +1, \bar{\eta} = -1$
$(X - m_T)^+$	Fixed strike put	$\phi = -1, \bar{\eta} = -1$

exchange rate in currency-linked security issues. However, this right is very expensive. Since one buys a guarantee for the best possible exchange rate ever, lookback options are generally too expensive and hardly ever trade. Exceptions are performance notes, where lookback and average features are mixed, for example, performance notes paying say 50% of the best of 36 monthly average gold price returns.

Valuation

We consider the example of the floating strike lookback call. Again, the value of the option is given by

$$\begin{aligned} v(0, S_0) &= \mathbb{E} [e^{-r_d T} (S_T - m_T)] \\ &= S_0 e^{-r_f T} - e^{-r_d T} \mathbb{E} [m_T] \end{aligned} \quad (58)$$

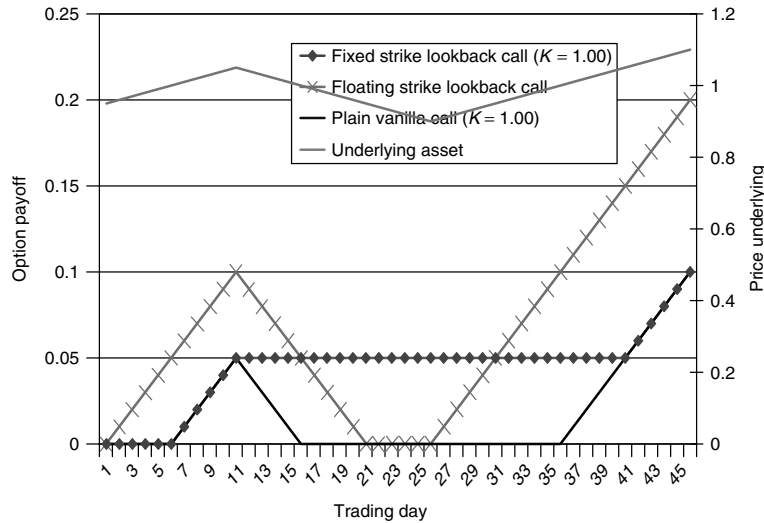

Figure 1 Payoff profile of lookback calls (sample underlying price path, $m = 20$ trading days)

In the standard Black–Scholes model (1), the value can be derived using the reflection principle and results in

$$v(t, x) = \phi \left\{ x D_f \mathcal{N}(\phi d_+) - K D_d \mathcal{N}(\phi d_-) \right. \\ \left. + \frac{1-\eta}{2} \phi D_d [\phi(R-X)]^+ \right. \\ \left. + \eta x D_d \frac{1}{h} \left[\left(\frac{x}{K} \right)^{-h} \mathcal{N}(-\eta \phi(d_+ - h\sigma\sqrt{\tau})) \right. \right. \\ \left. \left. - e^{(r_d - r_f)\tau} \mathcal{N}(-\eta \phi d_+) \right] \right\} \quad (59)$$

This value function has a removable discontinuity at $h = 0$ where it turns out to be

$$v(t, x) = \phi \left\{ x D_f \mathcal{N}(\phi d_+) - K D_d \mathcal{N}(\phi d_-) \right. \\ \left. + \frac{1-\eta}{2} \phi D_d [\phi(R-X)]^+ \right. \\ \left. + \eta x D_d \sigma \sqrt{\tau} [-d_+ \mathcal{N}(-\eta \phi d_+) \right. \\ \left. + \eta \phi n(d_+)] \right\} \quad (60)$$

The abbreviations we use are

$$h \triangleq \frac{2(r_d - r_f)}{\sigma^2} \quad (61)$$

$$R \triangleq \begin{array}{l} \text{running extremum: extremum observed} \\ \text{until valuation time} \end{array} \quad (62)$$

$$K \triangleq \begin{cases} R & \text{floating strike lookback} \\ -\phi \min(-\phi X, -\phi R) & \text{fixed strike lookback} \end{cases} \quad (63)$$

$$\eta \triangleq \begin{cases} +1 & \text{floating strike lookback} \\ -1 & \text{fixed strike lookback} \end{cases} \quad (64)$$

Note that this formula basically consists of that for a **call option** (the first two terms) plus another term. Conze and Viswanathan also show closed-form solutions for fixed strike lookback options and the variations mentioned above in [2]. Heynen and Kat develop equations for *partial fixed and floating strike*

Table 4 Sample values for lookback options. For the input data, we used spot $S_0 = 0.9800$, $r_d = 3\%$, $r_f = 6\%$, $\sigma = 10\%$, $\tau = 1/12$, running min $R = 0.9500$, running max $R = 0.9900$, and number of equidistant fixings $m = 22$

Payoff sampled	Discretely sampled Equations (67) and (68)	Continuously Equations (59) or (60)
$M_T - S_T$	0.0231	0.0255
$S_T - m_T$	0.0310	0.0320
$(M_T - 0.99)^+$	0.0107	0.0131
$(0.97 - m_T)^+$	0.0235	0.0246

lookback options in [10]. We list some sample results in Table 4.

Discrete Sampling

In practice, one cannot take the average over a continuum of exchange rates. The standard is to specify a *fixing calendar* and take only a finite number of fixings into account. Suppose there are m equidistant sample points left until expiration at which we evaluate the extremum. In this case, the value function v_m can be determined by an approximation described by Broadie *et al.* [1]. We set

$$\beta \triangleq -\zeta(1/2)/\sqrt{2\pi} \\ = 0.5826 \quad (\zeta \text{ being Riemann's } \zeta\text{-function}) \quad (65)$$

$$\alpha \triangleq e^{\phi\beta\sigma\sqrt{\tau/m}} \quad (66)$$

and obtain for fixed strike lookback options

$$v_m(t, x, r_d, r_f, \sigma, R, X, \phi, \eta) \\ = v(t, x, r_d, r_f, \sigma, \alpha R, \alpha X, \phi, \eta)/\alpha \quad (67)$$

and for floating strike lookback options

$$v_m(t, x, r_d, r_f, \sigma, R, X, \phi, \eta) \\ = av(t, x, r_d, r_f, \sigma, R/\alpha, X, \phi, \eta) - \phi(\alpha - 1)x D_f \quad (68)$$

Forward Start Options

Product Definition

A forward start vanilla option is just like a vanilla option, except that the strike is fixed on some future date $t_f \in (0, T)$, specified in the contract. The strike is fixed as αS_{t_f} , where $\alpha > 0$ is some contractually defined factor (very common one) and S_{t_f} is the spot at time t_f . It pays off

$$[\phi(S_T - \alpha S_{t_f})]^+ \quad (69)$$

The Value of Forward Start Options

Using the abbreviations

$$d_{\pm}(x) \triangleq \frac{\ln \frac{x}{K} + \sigma \theta_{\pm}(T - t_f)}{\sigma \sqrt{T - t_f}} \quad (70)$$

$$d_{\pm}^{\alpha} \triangleq \frac{-\ln \alpha + \sigma \theta_{\pm}(T - t_f)}{\sigma \sqrt{T - t_f}} \quad (71)$$

we recall the value of a vanilla option with strike K at time t_f as

$$\begin{aligned} & \text{vanilla}(t_f, x; K, T, \phi) \\ &= \phi [x e^{-r_f(T-t_f)} \mathcal{N}(\phi d_+(x)) - K e^{-r_d(T-t_f)} \mathcal{N}(\phi d_-(x))] \end{aligned} \quad (72)$$

For the value of a forward start vanilla option, we obtain

$$\begin{aligned} & v(0, S_0) \\ &= e^{-r_d t_f} \mathbb{E}[\text{vanilla}(t_f, S_{t_f}; K = \alpha S_{t_f}, T, \phi)] \\ &= \phi S_0 [e^{-r_f T} \mathcal{N}(\phi d_+^{\alpha}) - \alpha e^{(r_d - r_f)t_f} e^{-r_d T} \mathcal{N}(\phi d_-^{\alpha})] \end{aligned} \quad (73)$$

Noticeably, the value computation is easy here, because the strike K is set as a *multiple* of the future spot. If we were to choose to set the strike as a constant *difference* of the future spot, the integration would not work in closed form, and we would have to use numerical integration.

Table 5 Value of a forward start vanilla in USD on EUR/USD—spot of 0.9000, $\alpha = 99\%$, $\sigma = 12\%$, $r_d = 2\%$, $r_f = 3\%$, maturity $T = 186$ days, and strike set at $t_f = 90$ days

	Call	Put
Value	0.0251	0.0185

Example

We consider an example in Table 5.

Compound and Instalment Options

An instalment call option allows the holder to pay the premium of the **call option** in instalments spread over time. A first payment is made at the inception of the trade. On the following payment days, the holder of the instalment call can decide to prolong the contract, in which case, he has to pay the second instalment of the premium, or to terminate the contract by simply not paying any more. After the last instalment payment, the contract turns into a plain vanilla call.

Valuation in the Black–Scholes Model

The intention of this section is to obtain a closed-form formula for the n -variate instalment option in the **Black–Scholes model**. For the cases $n = 1$ and $n = 2$, the Black–Scholes formula and Geske’s compound option formula (see [5]) are well-known special cases.

Let $t_0 = 0$ be the instalment option inception date and $t_1, t_2, \dots, t_n = T$ a schedule of decision dates in the contract on which the option holder has to pay the premiums $k_1, k_2, \dots, k_{n-1}$ to keep the option alive. To compute the price of the instalment option, which is the upfront payment V_0 at t_0 to enter into the contract, we begin with the option payoff at maturity T

$$V_n(s) \triangleq [\phi_n(s - k_n)]^+ \triangleq \max[\phi_n(s - k_n), 0] \quad (74)$$

where $s = S_T$ is the price of the underlying asset at T and as usual $\phi_n = +1$ for a call option, $\phi_n = -1$ for a put option.

At time t_i , the option holder can either terminate the contract or pay k_i to continue. This means that the instalment option can be viewed as an option with strike k_1 on an option with strike $k_2 \cdots$ on an option with strike k_n . Therefore, by the **risk-neutral pricing** theory, the holding value is

$$e^{-r_d(t_{i+1}-t_i)} \mathbb{E}[V_{i+1}(S_{t_{i+1}}) | S_{t_i} = s],$$

for $i = 0, \dots, n-1$ (75)

where

$$V_i(s) = \begin{cases} [e^{-r_d(t_{i+1}-t_i)} \mathbb{E}[V_{i+1}(S_{t_{i+1}}) | S_{t_i} = s] - k_i]^+ & \text{for } i = 1, \dots, n-1 \\ V_n(s) & \text{for } i = n \end{cases}$$

(76)

Then the unique arbitrage-free time-zero value is

$$P \triangleq V_0(s) = e^{-r_d(t_1-t_0)} \mathbb{E}[V_1(S_{t_1}) | S_{t_0} = s] \quad (77)$$

Figure 2 illustrates this context.

One way of pricing this instalment option is to evaluate the nested expectations through multiple numerical integration of the payoff functions *via* backward iteration. Alternatively, one can derive a solution in closed form in terms of the n -variate cumulative normal, which is described in the following.

The Curnow and Dunnett Integral Reduction Technique

Denote the n -dimensional multivariate normal integral with upper limits $h_1, \dots, h_n$ and correlation

matrix $R_n \triangleq (\rho_{ij})_{i,j=1,\dots,n}$ by $\mathcal{N}_n(h_1, \dots, h_n; R_n)$. Let the correlation matrix be nonsingular and $\rho_{11} = 1$.

Under these conditions, Curnow and Dunnett [3] derived the following reduction formula for multivariate normal integrals:

$$\begin{aligned} \mathcal{N}_n(h_1, \dots, h_n; R_n) &= \int_{-\infty}^{h_1} \mathcal{N}_{n-1}\left(\frac{h_2 - \rho_{21}y}{(1 - \rho_{21}^2)^{1/2}}, \dots, \frac{h_n - \rho_{n1}y}{(1 - \rho_{n1}^2)^{1/2}}; R_{n-1}^*\right) n(y) dy, \\ R_{n-1}^* &\triangleq (\rho_{ij}^*)_{i,j=2,\dots,n}, \\ \rho_{ij}^* &\triangleq \frac{\rho_{ij} - \rho_{i1}\rho_{j1}}{(1 - \rho_{i1}^2)^{1/2}(1 - \rho_{j1}^2)^{1/2}} \end{aligned} \quad (78)$$

For example, to go from dimension 1 to dimension 2, this takes the form

$$\begin{aligned} \int_{-\infty}^x \mathcal{N}(az + B)n(z) dz &= \mathcal{N}_2\left(x, \frac{B}{\sqrt{1+a^2}}; \frac{-a}{\sqrt{1+a^2}}\right) \end{aligned} \quad (79)$$

or more generally,

$$\begin{aligned} \int_{-\infty}^x e^{Az} \mathcal{N}(az + B)n(z) dz &= e^{\frac{A^2}{2}} \mathcal{N}_2\left(x - A, \frac{aA + B}{\sqrt{1+a^2}}; \frac{-a}{\sqrt{1+a^2}}\right) \end{aligned} \quad (80)$$

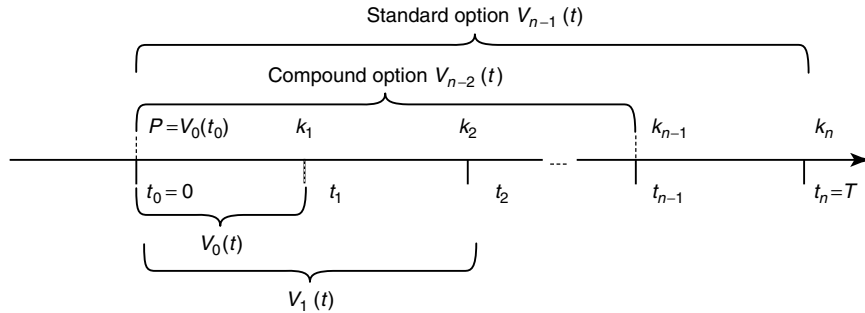

Figure 2 Lifetime of the options V_i

A Closed-form Solution for the Value of an Instalment Option

Heuristically, the formula which is given in the Theorem 1 has the structure of the **Black-Scholes formula** in higher dimensions, namely, $S_0 \mathcal{N}_n(\cdot) - k_n \mathcal{N}_n(\cdot)$ minus the later premium payments $k_i \mathcal{N}_i(\cdot)$

Theorem 1 Let $\mathbf{k} = (k_1, \dots, k_n)$ be the strike price vector, $\mathbf{t} = (t_1, \dots, t_n)$ the vector of the exercise dates of an n -variate instalment option and $\boldsymbol{\phi} = (\phi_1, \dots, \phi_n)$ the vector of the put/call-indicators of these n options.

The value function of an n -variate instalment option is given by

$$\begin{aligned}
 V_n(S_0, \mathbf{k}, \mathbf{t}, \boldsymbol{\phi}) &= e^{-r_f t_n} S_0 \phi_1 \cdots \phi_n \times \mathcal{N}_n \left[\phi_1 \frac{\ln \frac{S_0}{S_1^*} + \sigma \theta_+ t_1}{\sigma \sqrt{t_1}}, \phi_2 \frac{\ln \frac{S_0}{S_2^*} + \sigma \theta_+ t_2}{\sigma \sqrt{t_2}}, \dots, \phi_n \frac{\ln \frac{S_0}{S_n^*} + \sigma \theta_+ t_n}{\sigma \sqrt{t_n}}; R_n \right] \\
 &- e^{-r_d t_n} k_n \phi_1 \cdots \phi_n \times \mathcal{N}_n \left[\phi_1 \frac{\ln \frac{S_0}{S_1^*} + \sigma \theta_- t_1}{\sigma \sqrt{t_1}}, \phi_2 \frac{\ln \frac{S_0}{S_2^*} + \sigma \theta_- t_2}{\sigma \sqrt{t_2}}, \dots, \phi_n \frac{\ln \frac{S_0}{S_n^*} + \sigma \theta_- t_n}{\sigma \sqrt{t_n}}; R_n \right] \\
 &- e^{-r_d t_{n-1}} k_{n-1} \phi_1 \cdots \phi_{n-1} \times \mathcal{N}_{n-1} \left[\phi_1 \frac{\ln \frac{S_0}{S_1^*} + \sigma \theta_- t_1}{\sigma \sqrt{t_1}}, \phi_2 \frac{\ln \frac{S_0}{S_2^*} + \sigma \theta_- t_2}{\sigma \sqrt{t_2}}, \dots, \phi_{n-1} \frac{\ln \frac{S_0}{S_{n-1}^*} + \sigma \theta_- t_{n-1}}{\sigma \sqrt{t_{n-1}}}; R_{n-1} \right] \\
 &\vdots \\
 &- e^{-r_d t_2} k_2 \phi_1 \phi_2 \mathcal{N}_2 \left[\phi_1 \frac{\ln \frac{S_0}{S_1^*} + \sigma \theta_- t_1}{\sigma \sqrt{t_1}}, \phi_2 \frac{\ln \frac{S_0}{S_2^*} + \sigma \theta_- t_2}{\sigma \sqrt{t_2}}; \rho_{12} \right] \\
 &- e^{-r_d t_1} k_1 \phi_1 \mathcal{N} \left[\phi_1 \frac{\ln \frac{S_0}{S_1^*} + \sigma \theta_- t_1}{\sigma \sqrt{t_1}} \right]
 \end{aligned} \tag{81}$$

($i = 1, \dots, n-1$). This structure is a result of the integration of the vanilla option payoff, which is again integrated minus the next instalment, which in turn is integrated with the following instalment and so forth. By this iteration, the vanilla payoff is integrated with respect to the normal density function n times and the i th payment is integrated i times for $i = 1, \dots, n-1$.

The correlation coefficients ρ_{ij} of these normal distribution functions contained in the formula arise from the overlapping increments of the Brownian motion, which models the price process of the underlying S_t at the particular exercise dates t_i and t_j .

where S_i^* ($i = 1, \dots, n$) is to be determined as the spot price S_t for which the payoff of the corresponding i -variate instalment option ($i = 1, \dots, n$) is equal to 0, that is, $V_i(S_i^*, \mathbf{k}, \mathbf{t}, \boldsymbol{\phi}) = 0$. This has to be done numerically by a zero search.

The correlation coefficients in R_i of the i -variate normal distribution function can be expressed through the exercise dates t_i ,

$$\rho_{ij} = \sqrt{t_i/t_j} \text{ for } i, j = 1, \dots, n \text{ and } i < j \tag{82}$$

The proof is established with equation (78). Formula (81) has been independently derived by Thomassen and Wouve in [16] and Griebisch *et al.* in [6].

Foreign Exchange Symmetries

Motivation

The symmetries of the foreign exchange (FX) market are the key features that distinguish this market from all others. With an EUR-USD exchange rate of 1.2500 USD per EUR, there is an equivalent USD-EUR exchange rate of 0.8000 EUR per USD, which is just the reciprocal. Any model S_t for an exchange rate at time t should guarantee that $1/S_t$ is within the same model class. This is satisfied by the Black–Scholes model or local volatility models, but not for many stochastic volatility models.

The further symmetry is that both currencies pay interest, which we can assume to be continuously paid. The FX market is the only market where this really works.

In the EUR-USD market, any EUR call is equivalent to an USD put. Any premium in USD can be also paid in EUR, any delta hedge can be specified in the amount of USD to sell or, alternatively, the amount of EUR to buy.

Furthermore, if S_1 is a model for EUR-USD and S_2 is a model for USD–JPY, then $S_3 = S_1 \cdot S_2$ should be a model for EUR-JPY. Therefore, besides the reciprocals, the products of two modeling quantities should also remain within the same model class.

Finally, the smile of an FX options market is summarized by Risk Reversals and Butterflies, the skew-symmetric part and the symmetric part of a smile curve.

In no other market are symmetries so prominent and so heavily used as in FX. It is this special feature that makes it hard for many newcomers to capture the way FX options market participants think.

Geometric Brownian Motion Model for the Spot

We consider the model *geometric Brownian motion*

$$dS_t = (r_d - r_f)S_t dt + \sigma S_t dW_t \quad (1)$$

for the underlying exchange rate quoted in foreign–domestic (FOR–DOM), which means that 1 unit of the foreign currency costs FOR–DOM units of the

domestic currency. In the case of EUR-USD with a spot of 1.2000, this means that the price of 1 EUR is 1.2000 USD. The notions of *foreign* and *domestic* do not refer to the location of the trading entity, but only to this quotation convention. We denote the (continuous) foreign interest rate by r_f and the (continuous) domestic interest rate by r_d . In an equity scenario, r_f would represent a continuous dividend rate. The volatility is denoted by σ , and W_t is a standard Brownian motion.

We consider this standard model, not because it reflects the statistical properties of the exchange rate (in fact, it does not), but because it is widely used in practice and front office systems and mainly serves as a tool to communicate prices in FX options. These prices are generally quoted in terms of volatility in the sense of this model.

Vanilla Options

The payoff for a vanilla option (European put or call) is given by

$$F = [\phi(S_T - K)]^+ \quad (2)$$

where the contractual parameters are the strike K , the expiration time T and the type ϕ , a binary variable, which takes the value $+1$ in the case of a call and -1 in the case of a put. The symbol x^+ denotes the positive part of x , that is, $x^+ = \max(0, x) = 0 \vee x$.

Value

In the Black–Scholes model, the value of the payoff F at time t if the spot is at S is denoted by $v(t, S)$. The result is the *Black–Scholes formula*

$$\begin{aligned} v(S, K, T, t, \sigma, r_d, r_f, \phi) \\ = \phi e^{-r_d \tau} [f \mathcal{N}(\phi d_+) - K \mathcal{N}(\phi d_-)] \end{aligned} \quad (3)$$

We abbreviate

- S : current price of the underlying
- $\tau = T - t$: time to maturity
- $f = \mathbb{E}[S_T | S_t = S] = S e^{(r_d - r_f)\tau}$: forward price of the underlying
- $\theta_{\pm} = \frac{r_d - r_f}{\sigma} \pm \frac{\sigma}{2}$

- $d_{\pm} = \frac{\ln \frac{S}{K} + \sigma \theta_{\pm} \tau}{\sigma \sqrt{\tau}} = \frac{\ln \frac{f}{K} \pm \frac{\sigma^2}{2} \tau}{\sigma \sqrt{\tau}}$
- $n(t) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}t^2} = n(-t)$
- $\mathcal{N}(x) = \int_{-\infty}^x n(t) dt = 1 - \mathcal{N}(-x)$

A Note on the Forward

The forward price f is the strike that makes the time zero value of the forward contract

$$F = S_T - f \quad (4)$$

equal to zero. It follows that $f = E[S_T] = S e^{(r_d - r_f) \cdot T}$, that is, the forward price is the expected price of the underlying at time T in a risk-neutral setup (drift of the geometric Brownian motion is equal to the cost of carry $r_d - r_f$).

Greeks

Greeks are derivatives of the value function with respect to model and contract parameters. They are an important information for traders and have become standard information provided by front-office systems. More details on Greeks and the relations among Greeks are presented in [5] or [6]. We now list some of them for vanilla options:

- Spot delta. The spot delta shows how many units of FOR in the spot must be traded to hedge an option with 1 unit of FOR notional.

$$\frac{\partial v}{\partial S} = \phi e^{-r_f \tau} \mathcal{N}(\phi d_+) \quad (5)$$

- Forward delta. The forward delta shows how many units of FOR of a forward contract must be traded to hedge an option with 1 unit of FOR notional.

$$\phi \mathcal{N}(\phi d_+) = IP \left[\phi S_T \leq \phi \frac{f^2}{K} \right] \quad (6)$$

It is also equal to the risk-neutral exercise probability or in-the-money probability of the symmetric put (see Section 1.4.3).

- Gamma.

$$\frac{\partial^2 v}{\partial S^2} = e^{-r_f \tau} \frac{n(d_+)}{S \sigma \sqrt{\tau}} \quad (7)$$

- Vega.

$$\frac{\partial v}{\partial \sigma} = S e^{-r_f \tau} \sqrt{\tau} n(d_+) \quad (8)$$

- Dual delta.

$$\frac{\partial v}{\partial K} = -\phi e^{-r_d \tau} \mathcal{N}(\phi d_-) \quad (9)$$

The forward dual delta

$$\mathcal{N}(\phi d_-) = IP[\phi S_T \geq \phi K] \quad (10)$$

can also be viewed as the risk-neutral exercise probability.

- Dual gamma.

$$\frac{\partial^2 v}{\partial K^2} = e^{-r_d \tau} \frac{n(d_-)}{K \sigma \sqrt{\tau}} \quad (11)$$

Identities

Any computations with vanilla options often rely on the symmetry identities

$$\frac{\partial d_{\pm}}{\partial \sigma} = -\frac{d_{\mp}}{\sigma} \quad (12)$$

$$\frac{\partial d_{\pm}}{\partial r_d} = \frac{\sqrt{\tau}}{\sigma} \quad (13)$$

$$\frac{\partial d_{\pm}}{\partial r_f} = -\frac{\sqrt{\tau}}{\sigma} \quad (14)$$

$$S e^{-r_f \tau} n(d_+) = K e^{-r_d \tau} n(d_-) \quad (15)$$

Put–Call Parity

The put–call parity is the relationship,

$$\begin{aligned} & v(S, K, T, t, \sigma, r_d, r_f, +1) \\ & - v(S, K, T, t, \sigma, r_d, r_f, -1) \\ & = S e^{-r_f \tau} - K e^{-r_d \tau} \end{aligned} \quad (16)$$

which is just a more complicated way to write the trivial equation $x = x^+ - x^-$. Taking the strike K to be equal to the forward price f , we see that the call and put have the same value. The forward is the center of symmetry for vanilla call and put values. However, this does not imply that the *deltas* are also symmetric about the forward price.

The put–call delta parity is

$$\begin{aligned} & \frac{\partial v(S, K, T, t, \sigma, r_d, r_f, +1)}{\partial S} \\ & - \frac{\partial v(S, K, T, t, \sigma, r_d, r_f, -1)}{\partial S} = e^{-r_f \tau} \end{aligned} \quad (17)$$

In particular, we learn that the absolute value of a put delta and a call delta do not exactly add up to 1, but only to a positive number $e^{-r_f \tau}$. They add up to 1 approximately if either the time to expiration τ is short or if the foreign interest rate r_f is close to 0. For this reason, traders often prefer to work with forward deltas, because these are symmetric in the sense that a 25-delta call is a 75-delta put.

Although the choice $K = f$ produces identical values for call and put, we seek the *delta-symmetric strike* $\check{K}$, which produces absolutely identical deltas (spot, forward, or driftless). This condition implies $d_+ = 0$ and thus

$$\check{K} = f e^{\frac{\sigma^2}{2} \tau} \quad (18)$$

in which case the absolute delta is $e^{-r_f \tau}/2$. In particular, we learn that always $\check{K} > f$, that is, there cannot be a put and a call with identical values *and* deltas. This is natural as the payoffs of calls and puts are not symmetric to start with: the call has unlimited upside potential, whereas the put payoff is always bounded by the strike. Note that the strike $\check{K}$ is usually chosen as the middle strike when trading a straddle or a butterfly. Similarly the dual-delta-symmetric strike $\hat{K} = f e^{-\frac{\sigma^2}{2} \tau}$ can be derived from the condition $d_- = 0$.

Note that the delta-symmetric strike $\check{K}$ also maximizes gamma and vega of a vanilla option and is thus often considered as a center of symmetry.

Homogeneity-based Relationships

Space Homogeneity

We may wish to measure the value of the underlying in a different unit. This will obviously effect the option pricing formula as follows:

$$\begin{aligned} av(S, K, T, t, \sigma, r_d, r_f, \phi) \\ = v(aS, aK, T, t, \sigma, r_d, r_f, \phi) \text{ for all } a > 0 \end{aligned} \quad (19)$$

Differentiating both sides with respect to a and then setting $a = 1$ yields

$$v = S v_S + K v_K \quad (20)$$

Comparing the coefficients of S and K in equations (3) and (20) leads to suggestive results for the delta v_S and dual delta v_K . This *space-homogeneity* is the reason behind the simplicity of the delta formulas, whose tedious computation can be saved this way.

Time Homogeneity

We can perform a similar computation for the time-affected parameters and obtain the obvious equation

$$\begin{aligned} v(S, K, T, t, \sigma, r_d, r_f, \phi) \\ = v\left(S, K, \frac{T}{a}, \frac{t}{a}, \sqrt{a}\sigma, ar_d, ar_f, \phi\right) \\ \text{for all } a > 0 \end{aligned} \quad (21)$$

Differentiating both sides with respect to a and then setting $a = 1$ yields

$$0 = \tau v_t + \frac{1}{2} \sigma v_\sigma + r_d v_{r_d} + r_f v_{r_f} \quad (22)$$

Of course, this can also be verified by direct computation. The overall use of such equations is to generate double checking benchmarks when computing Greeks. These homogeneity methods can easily be extended to other more complex options.

Put–Call Symmetry

By *put–call symmetry*, we understand the relationship (see [1–4])

$$\begin{aligned} v(S, K, T, t, \sigma, r_d, r_f, +1) \\ = \frac{K}{f} v\left(S, \frac{f^2}{K}, T, t, \sigma, r_d, r_f, -1\right) \end{aligned} \quad (23)$$

The geometric mean of the strike of the put $\frac{f^2}{K}$ and the strike of the call K is equal to $\sqrt{\frac{f^2}{K} \cdot K} = f$, the outright forward rate. Therefore, the outright forward rate can be interpreted as a *geometric mirror* reflecting a call into a certain number of puts. Note that for at-the-money (forward) options ($K = f$) the put–call symmetry coincides with the special case of

the put–call parity where the call and the put have the same value.

Rates Symmetry

Direct computation shows that the *rates symmetry*

$$\frac{\partial v}{\partial r_d} + \frac{\partial v}{\partial r_f} = -\tau v \quad (24)$$

holds for vanilla options. This relationship, in fact, holds for all European options and a wide class of path-dependent options as shown in [6].

Foreign–Domestic Symmetry

One can directly verify the *FOR–DOM symmetry*

$$\begin{aligned} & \frac{1}{S} v(S, K, T, t, \sigma, r_d, r_f, \phi) \\ &= K v\left(\frac{1}{S}, \frac{1}{K}, T, t, \sigma, r_f, r_d, -\phi\right) \end{aligned} \quad (25)$$

This equality can be viewed as one of the faces of put–call symmetry. The reason is that the value of an option can be computed both in a domestic as well as in a foreign scenario. We consider the example of S_t modeling the exchange rate of EUR/USD. In New York, the call option $(S_T - K)^+$ costs $v(S, K, T, t, \sigma, r_{\text{usd}}, r_{\text{eur}}, 1)$ USD and hence $v(S, K, T, t, \sigma, r_{\text{usd}}, r_{\text{eur}}, 1)/S$ EUR. This EUR call option can also be viewed as an USD put option with payoff $K \left(\frac{1}{K} - \frac{1}{S_T}\right)^+$. This option costs $K v\left(\frac{1}{S}, \frac{1}{K}, T, t, \sigma, r_{\text{eur}}, r_{\text{usd}}, -1\right)$ EUR in Frankfurt, because S_t and $\frac{1}{S_t}$ have the same volatility. Of course, the New York value and the Frankfurt value must agree, which leads to equation (25). This can also be seen as a change of measure to the foreign discount bond as numeraire (see, e.g., in [7]).

Exotic Options

In FX markets, one can use many symmetry relationships for exotic options.

Digital Options

For example, let us define the payoff of digital options by

$$\text{DOM paying: } \mathbb{1}_{\{\phi S_T \geq \phi K\}} \quad (26)$$

$$\text{FOR paying: } S_T \mathbb{1}_{\{\phi S_T \geq \phi K\}} \quad (27)$$

where the contractual parameters are the strike K , the expiration time T , and the type ϕ , a binary variable, which takes the value $+1$ in the case of a call and -1 in the case of a put. Then we observe that a DOM-paying digital call in the currency pair FOR–DOM with a value of v_d units of domestic currency must be worth the same as a FOR-paying digital put in the currency pair DOM–FOR with a value of v_f units of foreign currency. And since we are looking at the same product, we conclude that $v_d = v_f \cdot S$, where S is the initial spot of FOR–DOM.

Touch Options

This key idea generalizes from the path-independent digitals to touch products. Consider the value function for one-touch in EUR-USD paying 1 USD. If we want to find the value function of a one-touch in EUR-USD paying 1 EUR, we can price the one-touch in USD-EUR paying 1 EUR using the known value function with rates r_d and r_f exchanged, volatility unchanged, using the formula for a one-touch in EUR-USD paying 1 USD. We also note that an upper one-touch in EUR-USD becomes a lower one-touch in USD-EUR. The result we get is in domestic currency, which is EUR in USD-EUR notation. To convert it into an USD price, we just multiply by the EUR-USD spot S .

Barrier Options

For a standard knockout barrier option, we let the value function be

$$v(S, r_d, r_f, \sigma, K, B, T, t, \phi, \eta) \quad (28)$$

where B denotes the barrier and the variable η takes the value $+1$ for a lower barrier and -1 for an upper barrier. With this notation at hand, we can state our FOR–DOM symmetry as

$$\begin{aligned} & v(S, r_d, r_f, \sigma, K, B, T, t, \phi, \eta) \\ &= v\left(\frac{1}{S}, r_f, r_d, \sigma, \frac{1}{K}, \frac{1}{B}, T, t, -\phi, -\eta\right) SK \end{aligned} \quad (29)$$

Note that the rates r_d and r_f have been interchanged on purpose. This implies that if we know how to price

barrier contracts with upper barriers, we can derive the formulas for lower barriers.

Quotation

Quotation of the Underlying Exchange Rate

Equation (1) is a model for the exchange rate. The quotation is a permanently confusing issue, so let us clarify this here. The exchange rate means how much of the *domestic* currency are needed to buy 1 unit of *foreign* currency. For example, if we take EUR/USD as an exchange rate, then the default quotation is EUR-USD, where USD is the domestic currency and EUR is the foreign currency. The term *domestic* is in no way related to the location of the trader or any country. It merely means the *numeraire* currency. The terms *domestic*, *numeraire*, or *base currency* are synonyms as are *foreign* and *underlying*. Commonly, we denote with the slash (/) the currency pair and with a dash (-) the quotation. The slash (/) does *not* mean a division. For instance, EUR/USD can also be quoted in either EUR-USD, which then means how many USD are needed to buy one EUR, or in USD-EUR, which then means how many EUR are needed to buy 1 USD. There are certain market standard quotations listed in Table 1.

Quotation of Option Prices

Values and prices of vanilla options may be quoted in the six ways explained in Table 2.

The Black–Scholes formula quotes an option value in units of domestic currency per unit of foreign notional. Since this is usually a small number, it is often multiplied with 10 000 and quoted as domestic

Table 1 Standard market quotation of major currency pairs with sample spot prices

Currency pair	Default quotation	Sample quote
GBP/USD	GPB-USD	1.8000
GBP/CHF	GBP-CHF	2.2500
EUR/USD	EUR-USD	1.2000
EUR/GBP	EUR-GBP	0.6900
EUR/JPY	EUR-JPY	135.00
EUR/CHF	EUR-CHF	1.5500
USD/JPY	USD-JPY	108.00
USD/CHF	USD-CHF	1.2800

piPs per foreign, in short, **d piPs**. The others can be computed using the following instruction:

$$\mathbf{d\ piPs} \xrightarrow{\times \frac{1}{S}} \% \mathbf{f} \xrightarrow{\times \frac{S}{K}} \% \mathbf{d} \xrightarrow{\times \frac{1}{S}} \mathbf{f\ piPs} \xrightarrow{\times SK} \mathbf{d\ piPs} \quad (30)$$

Delta and Premium Convention

The spot delta of a European option without premium-adjustment is well known. It will be called *raw spot delta* δ_{raw} now and denotes the amount of FOR to buy when selling an option with 1 unit of FOR notional. However, the same option can also be viewed as an option with K units of DOM notional. The delta that goes with the same option, but 1 unit of DOM notional and tells how many units of DOM currency must be sold for the delta hedge is denoted by $\delta_{\text{raw}}^{\text{reverse}}$. In the market, both deltas can be quoted in either of the two currencies involved. The relationship is

$$\delta_{\text{raw}}^{\text{reverse}} = -\delta_{\text{raw}} \frac{S}{K} \quad (31)$$

The delta is used to buy or sell spot in the corresponding amount in order to hedge the option up

Table 2 Standard market quotation types for option values. In the example, we take FOR = EUR, DOM = USD, $S = 1.2000$, $r_d = 3.0\%$, $r_f = 2.5\%$, $\sigma = 10\%$, $K = 1.2500$, $T = 1$ year, $\phi = +1$ (call), notional = 1 000 000 EUR = 1 250 000 USD. For the piPs, the quotation 291.48 USD piPs per EUR is also sometimes stated as 2.9148% USD per 1 EUR. Similarly, the 194.32 EUR piPs per USD can also be quoted as 1.9432% EUR per 1 USD

Name	Symbol	Value in units of	Example
Domestic cash	d	DOM	29 148 USD
Foreign cash	f	FOR	24 290 EUR
% domestic	% d	DOM per unit of DOM	2.3318% USD
% foreign	% f	FOR per unit of FOR	2.4290% EUR
Domestic piPs	d piPs	DOM per unit of FOR	291.48 USD piPs per EUR
Foreign piPs	f piPs	FOR per unit of DOM	194.32 EUR piPs per USD

to first order. To interpret this relationship, note that the minus sign refers to selling DOM instead of buying FOR, and the multiplication by S adjusts the amounts. Furthermore, we divide by the strike, because a call on 1 EUR corresponds to K USD puts. More details on delta conventions are contained in **Foreign Exchange Options: Delta- and At-the-money Conventions**

For consistency, the premium needs to be incorporated into the delta hedge, since a premium in foreign currency will already hedge part of the option's delta risk. To make this clear, let us consider EUR-USD. In the standard arbitrage theory, $v(S)$ denotes the value or premium in USD of an option with 1 EUR notional, if the spot is at S , and the raw delta v_S denotes the number of EUR to buy for the delta hedge. Therefore, Sv_S is the number of USD to sell. If now the premium is paid in EUR rather than in USD, then we already have $\frac{v}{S}$ EUR, and the number of EUR to buy has to be reduced by this amount, that is, if EUR is the premium currency, we need to buy $v_S - v/S$ EUR for the delta hedge or equivalently sell $Sv_S - v$ USD.

To quote an FX option, we need to first sort out which currency is domestic, which is foreign, what is the notional currency of the option, and what is the premium currency. Unfortunately, this is not symmetric, since the counterparty might have another notion of domestic currency for a given currency pair. Hence, in the professional interbank market, there is one notion of delta per currency pair. Normally, it is the left-hand side delta of the *Fenics*^a screen if the option is traded in left-hand side premium, which is normally the standard and right-hand side delta if it is traded with right-hand-side premium, for example, EUR/USD lhs, USD/JPY lhs, EUR/JPY lhs, AUD/USD rhs, and so on. Since OTM options are traded most of the time, the difference is not huge and hence does not create a huge spot risk.

Additionally, the standard delta per currency pair (left-hand-side delta in *Fenics* for most cases) is used to quote options in volatility. This has to be specified by currency pair.

This standard interbank notion must be adapted to the real delta risk of the bank for an automated trading system. For currency pairs where the risk-free currency of the bank is the domestic or base currency, it is clear that the delta is the raw delta of

the option, and for risky premium this premium must be included. In the opposite case, the risky premium and the market value must be taken into account for the base currency premium, such that these offset each other. And for premium in underlying currency of the contract, the market value needs to be taken into account. In this way, the delta hedge is invariant with respect to the risky currency notion of the bank, for example, the delta is the same for a USD-based bank and an EUR-based bank.

Example

We consider two examples in Tables 3 and 4 to compare the various versions of deltas that are used in practice.

Greeks in Terms of Deltas

In FX markets, the moneyness of vanilla options is always expressed in terms of deltas and prices

Table 3 1 y EUR call USD put strike $K = 0.9090$ for a EUR-based bank. Market data: spot $S = 0.9090$, volatility $\sigma = 12\%$, EUR rate $r_f = 3.96\%$, USD rate $r_d = 3.57\%$. The raw delta is 49.15%EUR and the value is 4.427%EUR

Delta currency	Prem currency	Fenics	Formula	Delta
% EUR	EUR	lhs	$\delta_{\text{raw}} - P$	44.72
% EUR	USD	rhs	δ_{raw}	49.15
% USD	EUR	rhs	$-(\delta_{\text{raw}} - P)S/K$	-44.72
% USD	USD	lhs	$-(\delta_{\text{raw}})S/K$	-49.15
		[flip F4]		

Table 4 1 y call EUR call USD put strike $K = 0.7000$ for a EUR-based bank. Market data: spot $S = 0.9090$, volatility $\sigma = 12\%$, EUR rate $r_f = 3.96\%$, USD rate $r_d = 3.57\%$. The raw delta is 94.82%EUR and the value is 21.88%EUR

Delta currency	Prem currency	Fenics	Formula	Delta
% EUR	EUR	lhs	$\delta_{\text{raw}} - P$	72.94
% EUR	USD	rhs	δ_{raw}	94.82
% USD	EUR	rhs	$-(\delta_{\text{raw}} - P)S/K$	-94.72
% USD	USD	lhs	$-(\delta_{\text{raw}})S/K$	-123.13
		[flip F4]		

are quoted in terms of volatility. This makes a 10-delta call a financial object as such independent of spot and strike. This method and the quotation in volatility makes objects and prices transparent in a very intelligent and user-friendly way. At this point, we list the Greeks in terms of deltas instead of spot and strike. Let us introduce the quantities

$$\Delta_+ \triangleq \phi e^{-r_f \tau} \mathcal{N}(\phi d_+) \text{ spot delta} \quad (32)$$

$$\Delta_- \triangleq -\phi e^{-r_d \tau} \mathcal{N}(\phi d_-) \text{ dual delta} \quad (33)$$

which we assume to be given. From these we can retrieve

$$d_+ = \phi \mathcal{N}^{-1}(\phi e^{r_f \tau} \Delta_+) \quad (34)$$

$$d_- = \phi \mathcal{N}^{-1}(-\phi e^{r_d \tau} \Delta_-) \quad (35)$$

Interpretation of Dual Delta

The dual delta introduced in equation (9) as the sensitivity with respect to strike has another—more practical—interpretation in an FX setup. Recall from equation (25) that for vanilla options the domestic value

$$v(S, K, \tau, \sigma, r_d, r_f, \phi) \quad (36)$$

corresponds to a foreign value

$$v\left(\frac{1}{S}, \frac{1}{K}, \tau, \sigma, r_f, r_d, -\phi\right) \quad (37)$$

up to an adjustment of the nominal amount by the factor SK . From a foreign point of view, the delta is

thus given by

$$\begin{aligned} & -\phi e^{-r_d \tau} \mathcal{N}\left(-\phi \frac{\ln\left(\frac{1/S}{1/K}\right) + \left(r_f - r_d + \frac{1}{2}\sigma^2\tau\right)}{\sigma\sqrt{\tau}}\right) \\ & = -\phi e^{-r_d \tau} \mathcal{N}\left(\phi \frac{\ln\left(\frac{S}{K}\right) + \left(r_d - r_f - \frac{1}{2}\sigma^2\tau\right)}{\sigma\sqrt{\tau}}\right) \\ & = \Delta_- \end{aligned} \quad (38)$$

which means that the dual delta is the delta from the foreign point of view.

Now, we list value, delta, and vega in terms of $S, \Delta_+, \Delta_-, r_d, r_f, \tau$, and ϕ .

- Value.

$$\begin{aligned} & v(S, \Delta_+, \Delta_-, r_d, r_f, \tau, \phi) \\ & = S\Delta_+ + S\Delta_- \frac{e^{-r_f \tau} n(d_+)}{e^{-r_d \tau} n(d_-)} \end{aligned} \quad (39)$$

- Spot delta.

$$\frac{\partial v}{\partial S} = \Delta_+ \quad (40)$$

- Vega.

$$\frac{\partial v}{\partial \sigma} = S e^{-r_f \tau} \sqrt{\tau} n(d_+) \quad (41)$$

Notice that vega does not require knowing the dual delta.

Table 5 Vega in terms of Delta for the standard maturity labels and various deltas. It shows that one can neutralize a vega position of a long 9M 35 delta call with 4 short 1M 20 delta puts. This offsetting, however, is not a static, but only a momentary hedge

Matrix/ Δ	50%	45%	40%	35%	30%	25%	20%	15%	10%	5%
1D	2	2	2	2	2	2	1	1	1	1
1W	6	5	5	5	5	4	4	3	2	1
1W	8	8	8	7	7	6	5	5	3	2
1M	11	11	11	11	10	9	8	7	5	3
2M	16	16	16	15	14	13	11	9	7	4
3M	20	20	19	18	17	16	14	12	9	5
6M	28	28	27	26	24	22	20	16	12	7
9M	34	34	33	32	30	27	24	20	15	9
1Y	39	39	38	36	34	31	28	23	17	10
2Y	53	53	52	50	48	44	39	32	24	14
3Y	63	63	62	60	57	53	47	39	30	18

Vega in Terms of Delta

The mapping

$$\Delta \mapsto v_\sigma = S e^{-r_f \tau} \sqrt{\tau} n(\mathcal{N}^{-1}(e^{r_f \tau} \Delta)) \quad (42)$$

is important for trading vanilla options. Observe that this function does not depend on r_d or σ , just on r_f . Quoting vega in % foreign will additionally remove the spot dependence. This means that for a moderately stable foreign term structure curve, traders will be able to use a moderately stable vega matrix. For $r_f = 3\%$, the vega matrix is presented in Table 5.

The most important result of this paragraph is the fact that vega can be written in terms of delta, which is the main reason why the FX market uses implied volatility quotation based on deltas in the first place.

End Notes

^a. Fenics is one of the standard tools for FX option pricing (see <http://www.fenics.com/>)

Quanto Options

A quanto option can be any cash-settled option whose payoff is converted into a third currency at maturity at a prespecified rate, called the *quanto factor*. There can be quanto plain vanilla, quanto barriers, quanto forward starts, quanto corridors, and so on. The **arbitrage pricing theory** and the **fundamental theorem of asset pricing**, also covered for example in [3] and [2], allow the computation of option values. Other references include **Options: Basic Definitions; Option Pricing: General Principles; Foreign Exchange Markets**.

Foreign Exchange Quanto Drift Adjustment

We take the example of a gold contract with underlying XAU/USD in XAU–USD quotation that is quantoed into EUR. Since the payoff is in EUR, we let EUR be the numeraire or domestic or base currency and consider a **Black–Scholes model**

$$\begin{aligned} \text{XAU–EUR: } dS_t^{(3)} &= (r_{\text{EUR}} - r_{\text{XAU}})S_t^{(3)} dt \\ &+ \sigma_3 S_t^{(3)} dW_t^{(3)} \end{aligned} \quad (1)$$

$$\begin{aligned} \text{USD–EUR: } dS_t^{(2)} &= (r_{\text{EUR}} - r_{\text{USD}})S_t^{(2)} dt \\ &+ \sigma_2 S_t^{(2)} dW_t^{(2)} \end{aligned} \quad (2)$$

$$dW_t^{(3)} dW_t^{(2)} = -\rho_{23} dt \quad (3)$$

where we use a minus sign in front of the correlation, because both $S_t^{(3)}$ and $S_t^{(2)}$ have the same base currency (DOM), which is EUR in this case. The scenario is displayed in Figure 1. The actual underlying is then

$$\text{XAU–USD: } S_t^{(1)} = \frac{S_t^{(3)}}{S_t^{(2)}} \quad (4)$$

Using Itô's formula, we first obtain

$$\begin{aligned} d\frac{1}{S_t^{(2)}} &= -\frac{1}{(S_t^{(2)})^2} dS_t^{(2)} + \frac{1}{2} \cdot 2 \cdot \frac{1}{(S_t^{(2)})^3} (dS_t^{(2)})^2 \\ &= (r_{\text{USD}} - r_{\text{EUR}} + \sigma_2^2) \frac{1}{S_t^{(2)}} dt - \sigma_2 \frac{1}{S_t^{(2)}} dW_t^{(2)} \end{aligned} \quad (5)$$

and hence

$$\begin{aligned} dS_t^{(1)} &= \frac{1}{S_t^{(2)}} dS_t^{(3)} + S_t^{(3)} d\frac{1}{S_t^{(2)}} + dS_t^{(3)} d\frac{1}{S_t^{(2)}} \\ &= \frac{S_t^{(3)}}{S_t^{(2)}} (r_{\text{EUR}} - r_{\text{XAU}}) dt + \frac{S_t^{(3)}}{S_t^{(2)}} \sigma_3 dW_t^{(3)} \\ &\quad + \frac{S_t^{(3)}}{S_t^{(2)}} (r_{\text{USD}} - r_{\text{EUR}} + \sigma_2^2) dt \\ &\quad - \frac{S_t^{(3)}}{S_t^{(2)}} \sigma_2 dW_t^{(2)} + \frac{S_t^{(3)}}{S_t^{(2)}} \rho_{23} \sigma_2 \sigma_3 dt \\ &= (r_{\text{USD}} - r_{\text{XAU}} + \sigma_2^2 + \rho_{23} \sigma_2 \sigma_3) S_t^{(1)} dt \\ &\quad + S_t^{(1)} (\sigma_3 dW_t^{(3)} - \sigma_2 dW_t^{(2)}) \end{aligned} \quad (6)$$

Since $S_t^{(1)}$ is a geometric Brownian motion with volatility σ_1 , we introduce a new Brownian motion $W_t^{(1)}$ and find

$$\begin{aligned} dS_t^{(1)} &= (r_{\text{USD}} - r_{\text{XAU}} + \sigma_2^2 + \rho_{23} \sigma_2 \sigma_3) S_t^{(1)} dt \\ &\quad + \sigma_1 S_t^{(1)} dW_t^{(1)} \end{aligned} \quad (7)$$

Now Figure 1 and the *law of cosine* imply

$$\sigma_3^2 = \sigma_1^2 + \sigma_2^2 - 2\rho_{12}\sigma_1\sigma_2 \quad (8)$$

$$\sigma_1^2 = \sigma_2^2 + \sigma_3^2 + 2\rho_{23}\sigma_2\sigma_3 \quad (9)$$

which yields

$$\sigma_2^2 + \rho_{23}\sigma_2\sigma_3 = \rho_{12}\sigma_1\sigma_2 \quad (10)$$

As explained in the *currency triangle* in Figure 1, ρ_{12} is the correlation between XAU–USD and USD–EUR, whence $\rho \triangleq -\rho_{12}$ is the correlation between XAU–USD and EUR–USD. Inserting this into equation (7), we obtain the usual formula for the drift adjustment

$$\begin{aligned} dS_t^{(1)} &= (r_{\text{USD}} - r_{\text{XAU}} - \rho\sigma_1\sigma_2) S_t^{(1)} dt \\ &\quad + \sigma_1 S_t^{(1)} dW_t^{(1)} \end{aligned} \quad (11)$$

This is the **risk neutral pricing** process that can be used for the valuation of any derivative depending on $S_t^{(1)}$, which is quantoed into EUR.

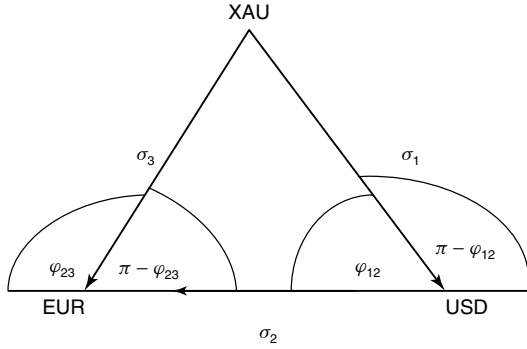

Figure 1 XAU-USD-EUR FX quanto triangle. The arrows point in the direction of the respective base currencies. The length of the edges represents the volatility. The cosine of the angles $\cos \phi_{ij} = \rho_{ij}$ represents the correlation of the currency pairs $S^{(i)}$ and $S^{(j)}$, if the base currency (DOM) of $S^{(i)}$ is the underlying currency (FOR) of $S^{(j)}$. If both $S^{(i)}$ and $S^{(j)}$ have the same base currency (DOM), then the correlation is denoted by $-\rho_{ij} = \cos(\pi - \phi_{ij})$

Extensions to Other Models

The previous derivation can be extended to the case of term-structure of volatility and correlation. However, introduction of volatility smile would distort the relationships. Nevertheless, accounting for smile effects is important in real-market scenarios. See **Foreign Exchange Smiles** and **Foreign Exchange Smile Interpolation** for details. To do this, one could, for example, capture the smile for a multicurrency model with a *weighted Monte Carlo technique* as described in [1]. This would still allow to use the previous result.

Quanto Vanilla

Common among **foreign exchange options** is a quanto plain vanilla paying

$$Q[\phi(S_T - K)]^+ \quad (12)$$

where K denotes the strike, T the expiration time, ϕ the usual put-call indicator taking the value +1 for a call and -1 for a put, S the underlying in FOR-DOM quotation, and Q the quanto factor from the domestic currency into the quanto currency. We let

$$\tilde{\mu} \triangleq r_d - r_f - \rho\sigma\tilde{\sigma} \quad (13)$$

be the *adjusted drift*, where r_d and r_f denote the risk-free rates of the domestic and foreign underlying currency pair, respectively, $\sigma = \sigma_1$ the volatility of this currency pair, $\tilde{\sigma} = \sigma_2$ the volatility of the currency pair DOM-QUANTO, and

$$\rho = \frac{\sigma_3^2 - \sigma^2 - \tilde{\sigma}^2}{2\sigma\tilde{\sigma}} \quad (14)$$

the correlation between the currency pairs FOR-DOM and DOM-QUANTO in this quotation. Furthermore, we let r_Q be the risk-free rate of the quanto currency. With the same principles as in **pricing formulae for foreign exchange options**, we can derive the formula for the value as

$$v = Qe^{-r_Q T} \phi[S_0 e^{\tilde{\mu} T} \mathcal{N}(\phi d_+) - K \mathcal{N}(\phi d_-)] \quad (15)$$

$$d_{\pm} = \frac{\ln \frac{S_0}{K} + (\tilde{\mu} \pm \frac{1}{2}\sigma^2) T}{\sigma \sqrt{T}} \quad (16)$$

where $\mathcal{N}$ denotes the cumulative standard normal distribution function and n its density.

Quanto Forward

Similarly, we can easily determine the value of a quanto forward paying

$$Q[\phi(S_T - K)] \quad (17)$$

where K denotes the strike, T the expiration time, ϕ the usual long-short indicator, S the underlying in FOR-DOM quotation, and Q the quanto factor from the domestic currency into the quanto currency. Then the formula for the value can be written as

$$v = Qe^{-r_Q T} \phi[S_0 e^{\tilde{\mu} T} - K] \quad (18)$$

This follows from the vanilla quanto value formula by taking both the normal probabilities to be 1. These normal probabilities are exercise probabilities under some measure. Since a forward contract is always exercised, both these probabilities must be equal to 1.

Quanto Digital

A European-style quanto digital pays

$$Q \mathbb{I}_{\{\phi S_T \geq \phi K\}} \quad (19)$$

Table 1 Example of a quanto digital put. The buyer receives 100 000 EUR if at maturity, the European Central Bank fixing for USD–JPY (computed *via* EUR–JPY and EUR–USD) is below 108.65. Terms were created on January 12, 2004 with the following market data: USD–JPY spot reference 106.60, USD–JPY at-the-money volatility 8.55%, EUR–JPY at-the-money volatility 6.69%, EUR–USD at-the-money volatility 10.99% (corresponding to a correlation of -27.89% for USD–JPY against JPY–EUR), USD rate 2.5%, JPY rate 0.1%, and EUR rate 4%

Notional	100 000 EUR
Maturity	3 months (92 days)
European-style barrier	108.65 USD–JPY
Theoretical value	71 555 EUR
Fixing source	European Central Bank

where K denotes the strike, S_T is the spot of the currency pair FOR–DOM at maturity T , ϕ takes the values $+1$ for a digital call and -1 for a digital put, and Q is the prespecified conversion rate from the domestic to the quanto currency. The valuation of the European-style quanto digitals follows the same principle as in the quanto vanilla option case. The value is

$$v = Qe^{-r_Q T} \mathcal{N}(\phi d_-) \quad (20)$$

We provide an example of a European-style digital put in USD/JPY quantoed into EUR in Table 1.

Hedging of Quanto Options

Hedging of quanto options can be done by running a multicurrency options book. All the usual Greeks can be hedged. **Delta hedging** is done by trading in the underlying spot market. An exception is the **correlation risk**, which can only be hedged with other derivatives depending on the same correlation. This is often difficult to do in practice. In FX, the correlation risk can be translated into vega positions as shown in [4, 5] or in **Foreign Exchange Basket Options**. We now illustrate this approach for quanto plain vanilla options.

Vega Positions of Quanto Plain Vanilla Options

Starting from equation (15), we obtain the sensitivities

$$\frac{\partial v}{\partial \sigma} = QS_0 e^{(\tilde{\mu} - r_Q)T} \left[n(d_+) \sqrt{T} - \phi \mathcal{N}(\phi d_+) \rho \tilde{\sigma} T \right],$$

$$\begin{aligned} \frac{\partial v}{\partial \tilde{\sigma}} &= -QS_0 e^{(\tilde{\mu} - r_Q)T} \phi \mathcal{N}(\phi d_+) \rho \sigma T, \\ \frac{\partial v}{\partial \rho} &= -QS_0 e^{(\tilde{\mu} - r_Q)T} \phi \mathcal{N}(\phi d_+) \sigma \tilde{\sigma} T, \\ \frac{\partial v}{\partial \sigma_3} &= \frac{\partial v}{\partial \rho} \frac{\partial \rho}{\partial \sigma_3} \\ &= \frac{\partial v}{\partial \rho} \frac{\sigma_3}{\sigma \tilde{\sigma}} \\ &= -QS_0 e^{(\tilde{\mu} - r_Q)T} \phi \mathcal{N}(\phi d_+) \sigma \tilde{\sigma} T \frac{\sigma_3}{\sigma \tilde{\sigma}} \\ &= -QS_0 e^{(\tilde{\mu} - r_Q)T} \phi \mathcal{N}(\phi d_+) \sigma_3 T \\ &= -QS_0 e^{(\tilde{\mu} - r_Q)T} \phi \mathcal{N}(\phi d_+) \sqrt{\sigma^2 + \tilde{\sigma}^2 + 2\rho\sigma\tilde{\sigma}} T \end{aligned} \quad (21)$$

Note that the computation is standard calculus and repeatedly uses the identity

$$S_0 e^{\tilde{\mu} T} n(\phi d_+) = Kn(\phi d_-) \quad (22)$$

The understanding of these greeks is that σ and $\tilde{\sigma}$ are both risky parameters, independent of each other. The third independent risk is either σ_3 or ρ , depending on what is more likely to be known.

This shows exactly how the three vega positions can be hedged with plain vanilla options in all the three legs, provided there is a liquid vanilla options market in all the three legs. In the example with XAU–USD–EUR, the currency pairs XAU–USD and EUR–USD are traded; however, there is no liquid vanilla market in XAU–EUR. Therefore, the correlation risk remains unhedgeable. Similar statements would apply for quantoed stocks or stock indices. However, in FX, there are situations with all the legs being hedgeable, for instance, EUR–USD–JPY.

The signs of the vega positions are not uniquely determined in all the legs. The FOR–DOM vega is smaller than the corresponding vanilla vega in the case of a call and positive correlation or put and negative correlation, and larger in case of a put and positive correlation or call and negative correlation. The DOM–QUANTO vega takes the sign of the correlation in case of a call and its opposite sign in case of a put. The FOR–QUANTO vega takes the opposite sign of the put–call indicator ϕ .

We provide an example of pricing and vega hedging scenario in Table 2, where we notice that the dominating vega risk comes from the FOR–DOM pair, whence most of the risk can be hedged.

Table 2 Example of a quanto plain vanilla

		Data set 1	Data set 2	Data set 3
FX pair	FOR–DOM	XAU–USD	XAU–USD	XAU–USD
Spot	FOR–DOM	800.00	800.00	800.00
Strike	FOR–DOM	810.00	810.00	810.00
Quanto	DOM–QUANTO	1.0000	1.0000	1.0000
Volatility	FOR–DOM	10.00%	10.00%	10.00%

Applications

The standard applications are performance-linked deposits or performance notes as in [6]. Any time the performance of an underlying asset needs to be converted into the notional currency invested, and the exchange rate risk is with the seller, we need a quanto product. Naturally, an underlying like gold, which is quoted in USD, would be a default candidate for a quanto product, when the investment is in a currency other than USD.

Performance-linked Deposits

A performance-linked deposit is a deposit with a participation in an underlying market. The standard is that a GBP investor waives her coupon that the money market would pay and instead buys a EUR–GBP call with the same maturity date as the coupon, strike K and notional N in EUR. These parameters have to be chosen in such a way that the offer price of the EUR call equals the money market interest rate plus the sales margin. The strike

is often chosen to be the current spot. The notional is often a percentage p of the deposit amount A , such as 50 or 25%. The annual coupon paid to the investor is then a predefined minimum coupon plus the participation

$$p \cdot \frac{\max[S_T - S_0, 0]}{S_0} \quad (23)$$

which is the return of the exchange rate viewed as an asset, where the investor is protected against negative returns. So, obviously, the investor buys a EUR call GBP put with strike $K = S_0$ and notional $N = pA$ GBP or $N = pA/S_0$ EUR. Thus, if the EUR goes up by 10% against the GBP, the investor gets a coupon of $p \cdot 10\%$ per annum in addition to the minimum coupon.

Example 1 We consider the example shown in Table 3. In this case, if the EUR–GBP spot fixing is 0.7200, the additional coupon would be 0.8571% per annum. The breakeven point is at 0.7467, so this product is advisable for a very strong EUR bullish view. For a weakly bullish view, an alternative would

Table 3 Example of a performance-linked deposit, where the investor is paid 30% of the EUR–GBP return. Note that in GBP the day count convention in the money market is act^(a)/365 rather than act/360

Notional	5 000 000 GBP
Start date	3 June 2005
Maturity	2 September 2005 (91 days)
Number of days (act)	91
Money market reference rate	4.00% act/365
EUR–GBP spot reference	0.7000
Minimum rate	2.00% act/365
Additional coupon	$30\% \cdot \frac{100 \max[S_T - 0.7000, 0]}{0.7000}$ act/365
S_T	EUR–GBP fixing on 31 August 2005 (88 days)
Fixing source	ECB

^(a)(act = actual number of days)

be to buy an up-and-out call with barrier at 0.7400 and 75% participation, where we would find the best case to be 0.7399 with an additional coupon of 4.275% per annum, which would lead to a total coupon of 6.275% per annum.

Composition

- From the money market we get 49 863.01 GBP at the maturity date.
- The investor buys a EUR call GBP put with strike 0.7000 and with notional 1.5 million GBP.
- The offer price of the call is 26 220.73 GBP, assuming a volatility of 8.0% and a EUR rate of 2.50%.
- The deferred premium is 24 677.11 GBP.
- The investor receives a minimum payment of 24 931.51 GBP.
- Subtracting the deferred premium and the minimum payment from the money market leaves a sales margin of 254.40 GBP (which is extremely poor).
- Note that the option the investor is buying must be cash-settled.

Variations. There are many variations of the performance-linked notes. Of course, one can think of the European style knock-out calls or window-barrier calls. For a participation in a downward trend, the investor can buy puts. One of the frequent issues in

foreign exchange, however, is the deposit currency being different from the domestic currency of the exchange rate, which is quoted in FOR–DOM (foreign–domestic), meaning how many units of domestic currency are required to buy one unit of foreign currency. So, if we have a EUR investor who wishes to participate in a EUR–USD movement, we need to *quanto* the domestic payoff currency (USD) into the foreign currency (EUR). The payoff of the EUR call USD put

$$[S_T - K]^+ \quad (24)$$

is in domestic currency (USD). Of course, this payoff can be converted into the foreign currency (EUR) at maturity, but the question is, at what rate? If we convert at rate S_T , which is what we could do in the spot market at no cost, then the investor buys a vanilla EUR call. But here, the investor receives a coupon given by

$$p \cdot \frac{\max[S_T - S_0, 0]}{S_T} \quad (25)$$

If the investor wishes to have performance of equation (23) rather than equation (25), then the payoff at maturity is converted at a rate of 1.0000 into EUR, and this rate is set at the beginning of the trade. This is the *quanto factor*, and the vanilla is actually a *self-quanto* vanilla, that is, a EUR call USD put, cash settled in EUR, where the payoff in USD is converted into EUR at a rate of 1.0000. This self-quanto vanilla can be valued by inverting the exchange rate, that is, looking at USD–EUR. This way the valuation can incorporate the smile of EUR–USD.

Similar considerations need to be taken into account if the currency pair to participate in does not contain the deposit currency at all. A typical situation is a EUR investor, who wishes to participate in the gold price, which is measured in USD, so the investor needs to buy a XAU call USD put quantoed into EUR. So the investor is promised a coupon as in equation (23) for a XAU–USD underlying, where the coupon is paid in EUR; this implicitly means that we must use a quanto plain vanilla with a quanto factor of 1.0000.

Vanna–Volga Pricing

The vanna–volga method, also called the *traders’ rule of thumb*, is an empirical procedure that can be used to infer an implied-volatility smile from three available quotes for a given maturity. It is based on the construction of locally replicating portfolios whose associated hedging costs are added to corresponding Black–Scholes prices to produce smile-consistent values. Besides being intuitive and easy to implement, this procedure has a clear financial interpretation, which further supports its use in practice. In fact, SuperDerivatives has implemented a type of this method in their pricing platform, as one can read in the patent that SuperDerivatives has filed.

The vanna–volga method is commonly used in foreign exchange options markets, where three main volatility quotes are typically available for a given market maturity: the delta-neutral straddle, referred to as *at-the-money (ATM)*; the risk reversal (RR) for 25 delta call and put; and the (vega-weighted) butterfly (BF) with 25 delta wings. The application of vanna–volga pricing allows us to derive implied volatilities for any option’s delta, in particular for those outside the basic range set by the 25 delta put and call quotes. The notion of risk reversals and butterflies is explained in the article on foreign exchange (FX) market terminology (see **Foreign Exchange Markets**).

In the financial literature, the vanna–volga approach was introduced by Lipton and McGhee in [2], who compare different approaches to the pricing of double-no-touch (DNT) options, and by Wystup in [5], who describes its application to the valuation of one-touch (OT) options. The vanna–volga procedure is reviewed in more detail and some important results concerning the tractability of the method and its robustness are derived by Castagna and Mercurio in [1].

The following is based on the section *Traders’ Rule of Thumb* by Wystup in [6].

The traders’ rule of thumb is a method of traders to determine the cost of risk managing the volatility risk of exotic options with vanilla options. This cost is then added to the theoretical value (*TV*) in the Black–Scholes model and is called the *overhedge*. We explain the rule and then consider an example of a one-touch option.

Delta and vega are the most relevant sensitivity parameters for FX options maturing within one year. A delta-neutral position can be achieved by trading the spot. Changes in the spot are explicitly allowed in the Black–Scholes model. Therefore, model and practical trading have very good control over spot change risk. The more sensitive part is the vega position. This is not taken care of in the Black–Scholes model. Market participants need to trade other options to obtain a vega-neutral position. However, even a vega-neutral position is subject to changes of spot and volatility. For this reason, the sensitivity parameters *vanna* (change of vega due to change of spot) and *volga* (change of vega due to change of volatility) are of special interest. Vanna is also called $d \text{ vega} / d \text{ spot}$, volga is also called $d \text{ vega} / d \text{ vol}$. The plots for vanna and volga for a vanilla option are displayed in Figures 1 and 2. In this section, we outline how the cost of such a vanna and volga exposure can be used to obtain prices for options that are closer to the market than their theoretical Black–Scholes value.

Cost of Vanna and Volga

We fix the rates r_d and r_f , the time to maturity T , and the spot x and define

$$\begin{aligned} \text{cost of vanna} &\triangleq \text{exotic vanna ratio} \\ &\quad \times \text{value of RR} \end{aligned} \quad (1)$$

$$\begin{aligned} \text{cost of volga} &\triangleq \text{exotic volga ratio} \\ &\quad \times \text{value of BF} \end{aligned} \quad (2)$$

$$\text{exotic vanna ratio} \triangleq B_{\sigma x} / \text{RR}_{\sigma x} \quad (3)$$

$$\text{exotic volga ratio} \triangleq B_{\sigma\sigma} / \text{BF}_{\sigma\sigma} \quad (4)$$

$$\text{value of RR} \triangleq [\text{RR}(\sigma_\Delta) - \text{RR}(\sigma_0)] \quad (5)$$

$$\text{value of BF} \triangleq [\text{BF}(\sigma_\Delta) - \text{BF}(\sigma_0)] \quad (6)$$

where σ_0 denotes the ATM (forward) volatility and σ_Δ denotes the wing volatility at the delta pillar Δ , and B denotes the value function of a given exotic option. The values of risk reversals and butterflies are defined by

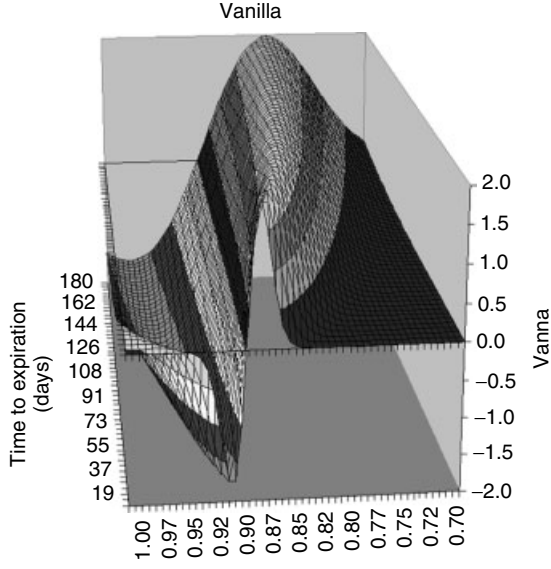

Figure 1 Vanna of a vanilla option as a function of spot and time to expiration, showing the skew symmetry about the at-the-money line

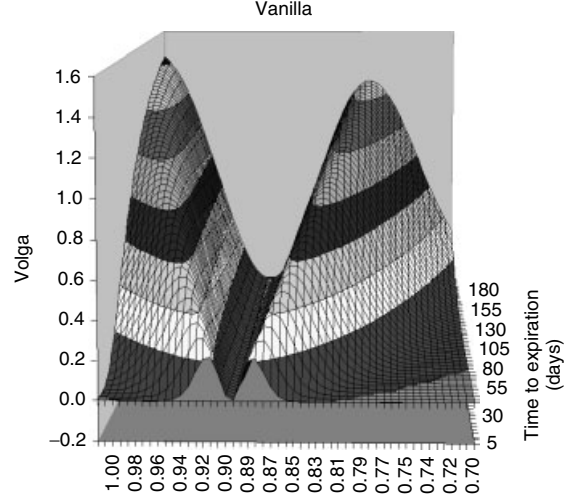

Figure 2 Volga of a vanilla option as a function of spot and time to expiration, showing the symmetry about the at-the-money line

$$RR(\sigma) \triangleq \text{call}(x, \Delta, \sigma, r_d, r_f, T) - \text{put}(x, \Delta, \sigma, r_d, r_f, T) \quad (7)$$

$$BF(\sigma) \triangleq \frac{\text{call}(x, \Delta, \sigma, r_d, r_f, T) + \text{put}(x, \Delta, \sigma, r_d, r_f, T)}{2} - \frac{\text{call}(x, \Delta_0, \sigma_0, r_d, r_f, T) + \text{put}(x, \Delta_0, \sigma_0, r_d, r_f, T)}{2} \quad (8)$$

where $\text{vanilla}(x, \Delta, \sigma, r_d, r_f, T)$ means $\text{vanilla}(x, K, \sigma, r_d, r_f, T)$ for a strike K chosen to imply $|\text{vanilla}_x(x, K, \sigma, r_d, r_f, T)| = \Delta$ and Δ_0 is the delta that produces the ATM strike. To summarize, we abbreviate

$$c(\sigma_\Delta^+) \triangleq \text{call}(x, \Delta^+, \sigma_\Delta^+, r_d, r_f, T) \quad (9)$$

$$p(\sigma_\Delta^-) \triangleq \text{put}(x, \Delta^-, \sigma_\Delta^-, r_d, r_f, T) \quad (10)$$

and obtain

cost of vanna

$$= \frac{B_{\sigma x}}{c_{\sigma x}(\sigma_\Delta^+) - p_{\sigma x}(\sigma_\Delta^-)} \times [c(\sigma_\Delta^+) - c(\sigma_0) - p(\sigma_\Delta^-) + p(\sigma_0)] \quad (11)$$

cost of volga

$$= \frac{2B_{\sigma\sigma}}{c_{\sigma\sigma}(\sigma_\Delta^+) + p_{\sigma\sigma}(\sigma_\Delta^-)} \times \left[\frac{c(\sigma_\Delta^+) - c(\sigma_0) + p(\sigma_\Delta^-) - p(\sigma_0)}{2} \right] \quad (12)$$

where we note that volga of the butterfly should actually be

$$\frac{1}{2} [c_{\sigma\sigma}(\sigma_\Delta^+) + p_{\sigma\sigma}(\sigma_\Delta^-) - c_{\sigma\sigma}(\sigma_0) - p_{\sigma\sigma}(\sigma_0)] \quad (13)$$

but the last two summands are close to zero. The *vanna–volga adjusted value* of the exotic is then

$$B(\sigma_0) + p \times [\text{cost of vanna} + \text{cost of volga}] \quad (14)$$

A division by the spot x converts everything into the usual quotation of the price in per cent of the underlying currency. The cost of vanna and volga is commonly adjusted by a number $p \in [0, 1]$, which is often taken to be the risk-neutral no-touch (NT) probability. The reason is that in the case of options that can knock out, the hedge is not needed anymore once the option has knocked out. The exact choice of p depends on the product to be priced; see Table 1. Taking $p = 1$ as the default value would lead to overestimated overhedges for DNT options as pointed out in [2].

The values of risk reversals and butterflies in equations (11) and (12) can be approximated by a first-order expansion as follows. For a risk reversal, we take the difference of the call with correct implied volatility and the call with ATM volatility minus the difference of the put with correct implied volatility and the put with ATM volatility. It is easy to see that this can be well-approximated by the vega of the ATM vanilla times the risk reversal in terms of volatility. Similarly, the cost of the butterfly can be approximated by the vega of the ATM volatility times the butterfly in terms of volatility. In formulae, this is

$$\begin{aligned} & c(\sigma_\Delta^+) - c(\sigma_0) - p(\sigma_\Delta^-) + p(\sigma_0) \\ & \approx c_\sigma(\sigma_0)(\sigma_\Delta^+ - \sigma_0) - p_\sigma(\sigma_0)(\sigma_\Delta^- - \sigma_0) \\ & = \sigma_0[p_\sigma(\sigma_0) - c_\sigma(\sigma_0)] + c_\sigma(\sigma_0)[\sigma_\Delta^+ - \sigma_\Delta^-] \\ & = c_\sigma(\sigma_0)RR \end{aligned} \quad (15)$$

and, similarly,

$$\begin{aligned} & \frac{c(\sigma_\Delta^+) - c(\sigma_0) + p(\sigma_\Delta^-) - p(\sigma_0)}{2} \\ & \approx c_\sigma(\sigma_0)BF \end{aligned} \quad (16)$$

Table 1 Adjustment factors for the overhedge for first-generation exotics

Option	p
KO	No-touch probability
RKO	No-touch probability
DKO	No-touch probability
OT	$0.9 \times \text{no-touch probability} - 0.5 \times \text{bid-offer-spread} \times (TV - 33\%)/66\%$
DNT	0.5

KO, knock out; RKO, reverse knockout; DKO, double knock-out; OT, one touch; DNT, double no touch

With these approximations, we obtain the formulae

$$\text{cost of vanna} \approx \frac{B_{\sigma x}}{c_{\sigma x}(\sigma_\Delta^+) - p_{\sigma x}(\sigma_\Delta^-)} c_\sigma(\sigma_0)RR \quad (17)$$

$$\text{cost of volga} \approx \frac{2B_{\sigma\sigma}}{c_{\sigma\sigma}(\sigma_\Delta^+) + p_{\sigma\sigma}(\sigma_\Delta^-)} c_\sigma(\sigma_0)BF \quad (18)$$

Observations

1. The price supplements are linear in butterflies and risk reversals. In particular, there is no cost of vanna supplement if the risk reversal is zero and no cost of volga supplement if the butterfly is zero.
2. The price supplements are linear in the ATM vanilla vega. This means supplements grow with growing volatility change risk of the hedge instruments.
3. The price supplements are linear in vanna and volga of the given exotic option.
4. We have not observed any relevant difference between the exact method and its first-order approximation. Since the computation time for the approximation is shorter, we recommend using the approximation.
5. It is not clear up front which target delta to use for the butterflies and risk reversals. We take a delta of 25% merely on the basis of its liquidity.
6. The prices for vanilla options are consistent with the input volatilities as shown in Figures 3, 4, and 5.
7. The method assumes a zero volga of risk reversals and a zero vanna of butterflies. This way the two sources of risk can be decomposed and hedged with risk reversals and butterflies. However, the assumption is actually not exact. For this reason, the method should be used with a lot of care. It causes traders and financial engineers to keep adding exceptions to the standard method.

Consistency Check

A minimum requirement for the vanna–volga pricing to be correct is the consistency of the method with vanilla options. We show in Figures 3, 4, and 5 that

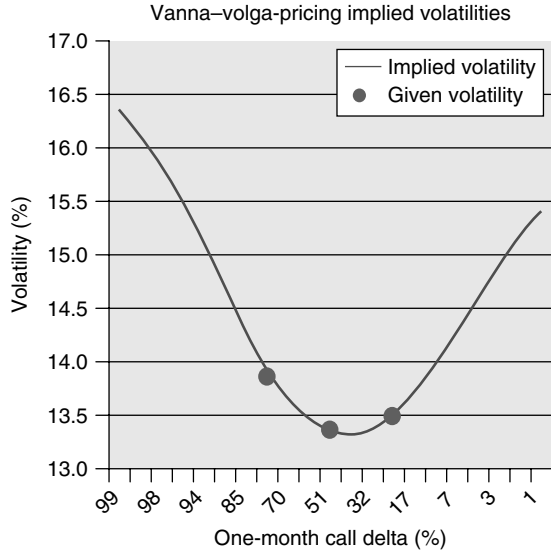

Figure 3 Consistency check of vanna-volga pricing. Vanilla option smile for a one-month maturity EUR/USD call, spot = 0.9060, $r_d = 5.07\%$, $r_f = 4.70\%$, $\sigma_0 = 13.35\%$, $\sigma_{\Delta}^+ = 13.475\%$, $\sigma_{\Delta}^- = 13.825\%$

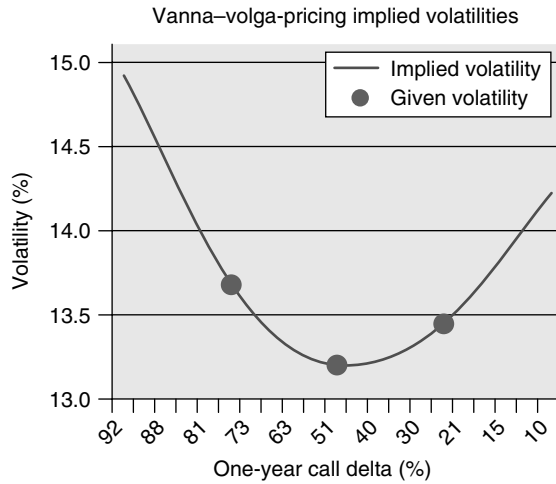

Figure 4 Consistency check of vanna-volga pricing. Vanilla option smile for a one-year maturity EUR/USD call, spot = 0.9060, $r_d = 5.07\%$, $r_f = 4.70\%$, $\sigma_0 = 13.20\%$, $\sigma_{\Delta}^+ = 13.425\%$, $\sigma_{\Delta}^- = 13.575\%$

the method does, in fact, yield a typical foreign exchange smile shape and produces the correct input volatilities ATM and at the delta pillars. We will now prove the consistency in the following way. Since the

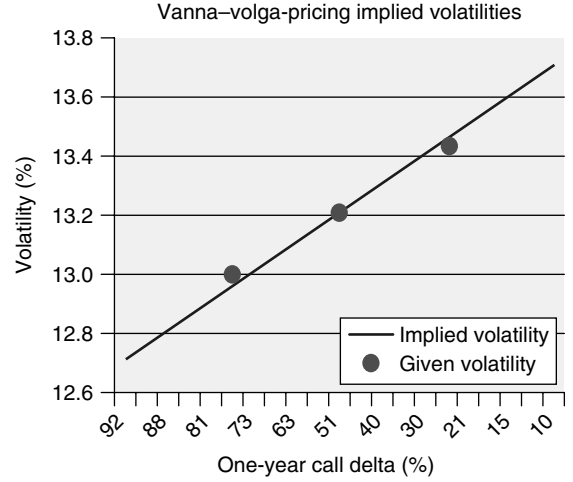

Figure 5 Consistency check of vanna-volga pricing. Vanilla option smile for a one-year maturity EUR/USD call, spot = 0.9060, $r_d = 5.07\%$, $r_f = 4.70\%$, $\sigma_0 = 13.20\%$, $\sigma_{\Delta}^+ = 13.425\%$, $\sigma_{\Delta}^- = 13.00\%$

input consists only of three volatilities (ATM and two delta pillars), it would be too much to expect that the method produces correct representation of the entire volatility matrix. We can only check if the values for ATM and target- Δ puts and calls are reproduced correctly. To verify this, we check if the values for an ATM call, a risk reversal, and a butterfly are priced correctly. Of course, we only expect approximately correct results. Note that the number p is taken to be 1, which agrees with the risk-neutral NT probability for vanilla options.

For an ATM call, vanna and volga are approximately zero, and hence there are no supplements due to vanna or volga cost.

For a target- Δ risk reversal,

$$c(\sigma_{\Delta}^+) - p(\sigma_{\Delta}^-) \quad (19)$$

we obtain

cost of vanna

$$\begin{aligned} &= \frac{c_{\sigma_x}(\sigma_{\Delta}^+) - p_{\sigma_x}(\sigma_{\Delta}^-)}{c_{\sigma_x}(\sigma_{\Delta}^+) - p_{\sigma_x}(\sigma_{\Delta}^-)} \\ &\quad \times [c(\sigma_{\Delta}^+) - c(\sigma_0) - p(\sigma_{\Delta}^-) + p(\sigma_0)] \\ &= c(\sigma_{\Delta}^+) - c(\sigma_0) - p(\sigma_{\Delta}^-) + p(\sigma_0) \end{aligned} \quad (20)$$

cost of volga

$$= \frac{2[c_{\sigma\sigma}(\sigma_{\Delta}^+) - p_{\sigma\sigma}(\sigma_{\Delta}^-)]}{c_{\sigma\sigma}(\sigma_{\Delta}^+) + p_{\sigma\sigma}(\sigma_{\Delta}^-)} \times \left[\frac{c(\sigma_{\Delta}^+) - c(\sigma_0) + p(\sigma_{\Delta}^-) - p(\sigma_0)}{2} \right] \quad (21)$$

and observe that the cost of vanna yields a perfect fit and the cost of volga is small, because in the first fraction we divide the difference of two quantities by the sum of the quantities, which are all of the same order.

For a target- Δ butterfly

$$\frac{c(\sigma_{\Delta}^+) + p(\sigma_{\Delta}^-)}{2} - \frac{c(\sigma_0) + p(\sigma_0)}{2} \quad (22)$$

we analogously obtain a perfect fit for the cost of volga and

cost of vanna

$$= \frac{c_{\sigma x}(\sigma_{\Delta}^+) - p_{\sigma x}(\sigma_0) - [c_{\sigma x}(\sigma_0) - p_{\sigma x}(\sigma_{\Delta}^-)]}{c_{\sigma x}(\sigma_{\Delta}^+) - p_{\sigma x}(\sigma_0) + [c_{\sigma x}(\sigma_0) - p_{\sigma x}(\sigma_{\Delta}^-)]} \times [c(\sigma_{\Delta}^+) - c(\sigma_0) - p(\sigma_{\Delta}^-) + p(\sigma_0)] \quad (23)$$

which is again small.

The consistency can actually fail for certain parameter scenarios. This is one of the reasons that the traders' rule of thumb has been criticized repeatedly by a number of traders and researchers.

We introduce the abbreviations for first generation exotics listed as below.

KO, knock-out; KI, knock-in; RKO, reverse knock-out; RKI, reverse knock-in; DKO, double knock-out; OT, one-touch; NT, no-touch; DOT, double one-touch; DNT, double no-touch.

Adjustment Factor

The factor p has to be chosen in a suitable fashion. Since there is no mathematical justification or indication, there is a lot of dispute in the market about this choice. Moreover, the choices may also vary over time. An example for *one of many possible choices* of p is presented in Table 1.

For options with strike K , barrier B and type $\phi = 1$ for a call and $\phi = -1$ for a put, we use the following pricing rules, which are based on no-arbitrage conditions:

- Knock in (KI) is priced *via* $KI = \text{vanilla} - KO$.
- Reverse knock in (RKI) is priced *via* $RKI = \text{vanilla} - RKO$.
- Reverse knockout (RKO) is priced *via* $RKO(\phi, K, B) = KO(-\phi, K, B) - KO(-\phi, B, B) + \phi(B - K)NT(B)$.
- Double one touch (DOT) is priced *via* DNT.
- NT is priced *via* OT.

Volatility for Risk Reversals, Butterflies and Theoretical Value

To determine the volatility and the vanna and volga for the risk reversal and butterfly, the convention is the same as for the building of the smile curve. Hence the 25% delta risk reversal retrieves the strike for 25% delta call and put with the spot delta and calculates the vanna and volga of these options using the corresponding volatilities from the smile.

The TV of the exotics is calculated using the ATM volatility, retrieving it with the same convention that was used to build the smile, to build the smile.

Pricing Barrier Options

Ideally, one would be in a situation to hedge all barrier contracts with a portfolio of vanilla options or simple barrier building blocks. In the Black–Scholes model, there are exact rules on how to statically hedge many barrier contracts. A state-of-the art reference is given in [3]. However, in practice, most of these hedges fail, because volatility is not constant.

For regular KO options, one can refine the method to incorporate more information about the global shape of the vega surface through time.

We chose M future points in time as $0 < a_1\% < a_2\% < \dots < a_M\%$ of the time to expiration. Using the same cost of vanna and volga, we calculate the overhedge for the regular KO with a reduced time to expiration. The factor for the cost is the probability not to touch the barrier within the remaining times to expiration $1 > 1 - a_1\% > 1 - a_2\% > \dots > 1 - a_M\%$ of the total time to expiration. Some desks believe that for ATM strikes, the long time to maturity should be weighted higher and for low-delta strikes the short time to maturity should be weighted higher. The weighting can be chosen (rather arbitrarily) as

$$w = \tanh[\gamma(|\delta - 50\%| - 25\%)] \quad (24)$$

with a suitable positive γ . For $M = 3$, the total overhedge is given by

$$OH = \frac{OH(1 - a_1\%) \times w + OH(1 - a_2\%) + OH(1 - a_3\%) \times (1 - w)}{3} \quad (25)$$

Which values to use for M , γ , and the a_i , whether to apply a weighting and what kind, varies for different trading desks.

An additional term can be used for single-barrier options to account for glitches in the stop loss of the barrier. The theoretical value of the barrier option is determined with a barrier that is moved by four basis points and 50% of that adjustment is added to the price if it is positive. If it is negative, it is omitted altogether. The theoretical foundation for such a method is explained in [4].

Pricing Double-barrier Options

Double-barrier options behave similar to vanilla options for a spot far away from the barrier and more like OT options for a spot close to the barrier. Therefore, it appears reasonable to use the traders' rule of thumb for the corresponding regular KO to determine the overhedge for a spot closer to the strike and for the corresponding OT option for a spot closer to the barrier. This adjustment is the intrinsic value of the RKO times the overhedge of the corresponding OT option. The border is the arithmetic mean between strike and the in-the-money barrier.

Pricing Double-no-touch Options

For DNT options with lower barrier L and higher barrier H at spot S , one can use the overhedge

$$OH = \max\{\text{vanna-volga-}OH; \delta(S - L) - TV - 0.5\%; \delta(H - S) - TV - 0.5\%\} \quad (26)$$

where δ denotes the delta of the DNT option.

Pricing European-style Options

Digital Options

Digital options are priced using the overhedge of the call/put spread with the corresponding volatilities.

European Barrier Options

European barrier options (EKO) are priced using the prices of European and digital options and the relationship

$$EKO(\phi, K, B) = \text{vanilla}(\phi, K) - \text{vanilla}(\phi, B) - \text{digital}(B)\phi(B - K) \quad (27)$$

No-touch Probability

The NT probability is obviously equal to the nondiscounted value of the corresponding NT option paying at maturity (under the risk-neutral measure). Note that the price of the OT option is calculated using an iteration for the touch probability. This means that the price of the OT option used to compute the NT probability is itself based on the traders' rule of thumb. This is an iterative process that requires an abortion criterion. One can use a standard approach that ends either after 100 iterations or as soon as the difference of two successive iteration results is less than 10^{-6} . However, the method is so crude that it actually does not make much sense to use such precision at just this point. Therefore, to speed up the computation, we suggest that this procedure is omitted and no iterations are taken, which means to use the non-discounted TV of the no-touch option as a proxy for the NT probability.

The Cost of Trading and Its Implication on the Market Price of One-touch Options

Now let us take a look at an example of the traders' rule of thumb in its simple version. We consider OT options, which hardly ever trade at TV . The tradable price is the sum of the TV and the overhedge. Typical examples are shown in Figure 6, one for an upper touch level in EUR/USD, and one for a lower touch level.

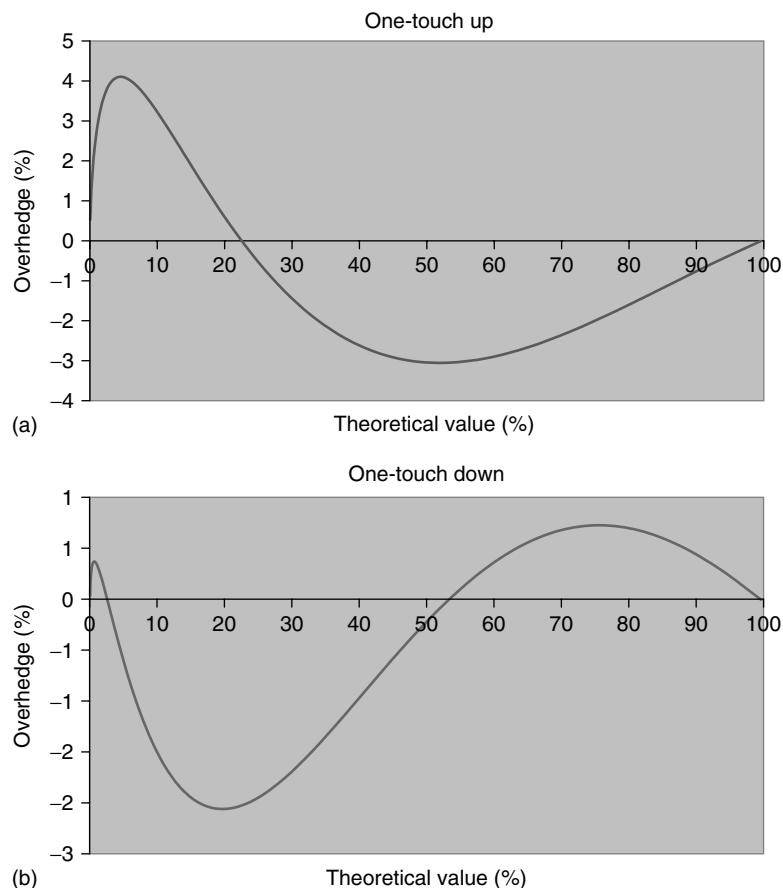

Figure 6 Overhedge of a one-touch option in EUR/USD for (a) an upper touch level and (b) a lower touch level, based on the traders' rule of thumb

Clearly, there is no overhedge for OT options with a TV of 0% or 100%, but it is worth noting that low-TV OT options can be twice as expensive as their TV, sometimes even more. The overhedge arises from the cost of risk managing the OT option. In the Black–Scholes model, the only source of risk is the underlying exchange rate, whereas the volatility and interest rates are assumed constant. However, volatility and rates are themselves changing, whence the trader of options is exposed to instable vega and rho (change of the value with respect to volatility and rates). For short-dated options, the interest rate risk is negligible compared to the volatility risk as shown in Figure 7. Hence the overhedge of an OT option is a reflection of a trader's cost occurring because of the risk management of his vega exposure.

Example

We consider a one-year OT option in USD/JPY with payoff in USD. As market parameters, we assume a spot of 117.00 JPY per USD, JPY interest rate 0.10%, USD interest rate 2.10%, volatility 8.80%, 25-delta risk reversal -0.45% ,^a and 25-delta butterfly 0.37% .^b

The touch level is 127.00, and the TV is at 28.8%. If we now only hedge the vega exposure, then we need to consider two main risk factors, namely,

1. the change of vega as the spot changes, often called vanna;
2. the change of vega as the volatility changes, often called volga or volgamma or vomma.

To hedge this exposure, we treat the two effects separately. The vanna of the OT option is 0.16%,

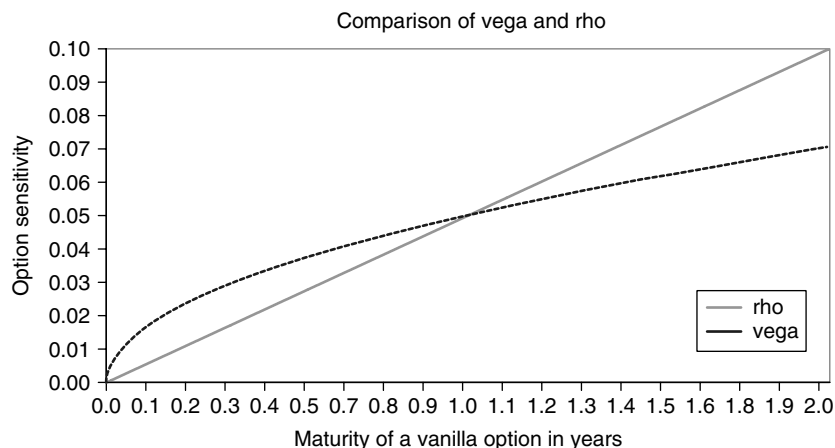

Figure 7 Comparison of interest rate and volatility risk for a vanilla option. The volatility risk behaves like a square-root function, whereas the interest rate risk is close to linear. Therefore, short-dated FX options have higher volatility risk than interest rate risk

and the vanna of the risk reversal is 0.04%. So we need to buy 4 ($= 0.16/0.04$) risk reversals, and, for each of them, we need to pay 0.14% of the USD amount, which causes an overhedge of -0.6% . The volga of the OT is -0.53% , and the volga of the butterfly is 0.03% . So we need to sell 18 ($= -0.53/0.03$) butterflies, each of which pays us 0.23% of the USD amount, which causes an overhedge of -4.1% . Therefore, the overhedge is -4.7% . However, we will get to the touch level with a risk-neutral probability of 28.8%, in which case we would have to pay to unwind the hedge. Therefore, the total overhedge is $-71.2\% \times 4.7\% = -3.4\%$. This leads to a midmarket price of 25.4%. Bid and offer could be 24.25%–36.75%. There are different beliefs among market participants about the unwinding cost. Other observed prices for OT options can be due to different existing vega profiles of the trader's portfolio, a marketing campaign, a hidden additional sales margin, or even the overall view of the trader in charge.

Further Applications

The method illustrated above shows how important the current smile of the vanilla options market is for the pricing of simple exotics. Similar types of approaches are commonly used to price other exotic options. For long-dated options, the interest rate risk will take over the lead in comparison to short-dated options where the volatility risk is dominant.

End Notes

^aThis means that a 25-delta USD call is 0.45% cheaper than a 25-delta USD put in terms of implied volatility.

^bThis means that a 25-delta USD call and 25-delta USD put is, on average, 0.37% more expensive than an ATM option in terms of volatility.

Foreign Exchange Smiles

Smile Regularities for Foreign Exchange Options

One trend in the empirical investigation of implied volatilities has been to concentrate on understanding the behavior of implied volatilities across strike prices and time to expiration [see 10]. This line of research assumes implicitly that these divergences provide information about the dynamics of the options markets. Another approach [3, 5, 6, 14] suggests that the divergences of implied volatilities across strike prices may provide information about the expected dispersion process for underlying asset prices. These papers assume that asset return volatility is a (locally) deterministic function of the asset price and time and that this information can be used to enhance the traditional Black–Scholes–Merton (BSM) option-pricing approach (*see also Dupire Equation; Local Volatility Model*). All these papers examine implied volatility patterns at a single point in time and assume that option prices provide an indication of the deterministic volatility function. However, Dumas *et al.* [4] (1998) tested for the existence of a deterministic implied volatility function and rejected the hypothesis that the inclusion of such a model in option pricing was an improvement in terms of predictive or hedging performance compared with BSM. Their research examined whether at a single point in time, implied volatility surfaces provide predictions of implied volatilities at some future date (one week hence).

Tompkins [15] looked at this problem in a slightly different way. The approach of Dumas *et al.* [4] assumes that the deterministic volatility function provides both a prediction of the future levels of implied volatility and the relative shapes of implied volatilities across strike prices and time. If the future levels of implied volatilities cannot be predicted, this does not mean that the *relative* shapes of implied volatilities cannot be predicted. Tompkins [15] examined the relative implied volatility bias rather than the absolute implied volatility bias. When the volatilities of each strike price were standardized by dividing the level of the at-the-money (ATM) volatility, regularities in the volatility function were found. He further found that these standardized smile

patterns were dependent upon the term to expiration of the option. For a large sample of option expiration cycles, the smile patterns were almost identical for all options with the same time to expiration.

For currency options, Tompkins [15] examined options on futures for US dollar/Deutsche mark, US dollar/British pound, US dollar/Japanese yen, and US dollar/Swiss franc for a time period from 1985 to 2000. To determine relative shapes, the implied volatilities for each currency pair were standardized by

$$VSI = \left(\frac{\sigma_x}{\sigma_{ATM}} \right) \cdot 100 \quad (1)$$

where VSI is the volatility smile index, σ_x is the volatility of an option with strike price x , and σ_{ATM} is the volatility of the ATM option. The ATM volatility was determined using a simple linear interpolation for the two implied volatilities of the strike prices that bracketed the underlying asset price. This relative volatility measure will facilitate comparisons of biases (in percentage terms) within and between markets.

The strike prices were standardized to allow intra- and intermarket comparisons to be drawn. The standardized strike prices can be expressed as

$$\frac{\ln(X_\tau/F_\tau)}{\sigma\sqrt{\tau/365}} \quad (2)$$

where X is the strike price of the option, F is the underlying futures price and the square root of time factor reflects the percentage in a year of the remaining time until the expiration of the option. The sigma (σ) is the level of the ATM volatility.

As the analysis was restricted to the actively traded quarterly expiration schedule of March, June, September, and December maturities, implied volatility surfaces with a maximum term to expiration of approximately 90 days were obtained. Data were further pruned by restricting the analysis to 18 time points from (the date nearest to) 90 calendar days to expiration to (the date nearest) 5 calendar days to expiration in 5-day increments. Finally, the analysis of the implied volatilities was limited to those strike prices in the range ± 3.5 standard deviations away from the underlying futures price. Figure 1 displays the aggregated patterns for the 15-year period.

A logical starting point for an appropriate functional form to fit an implied volatility surface is the approach suggested by Dumas *et al.* [4] (1996), who

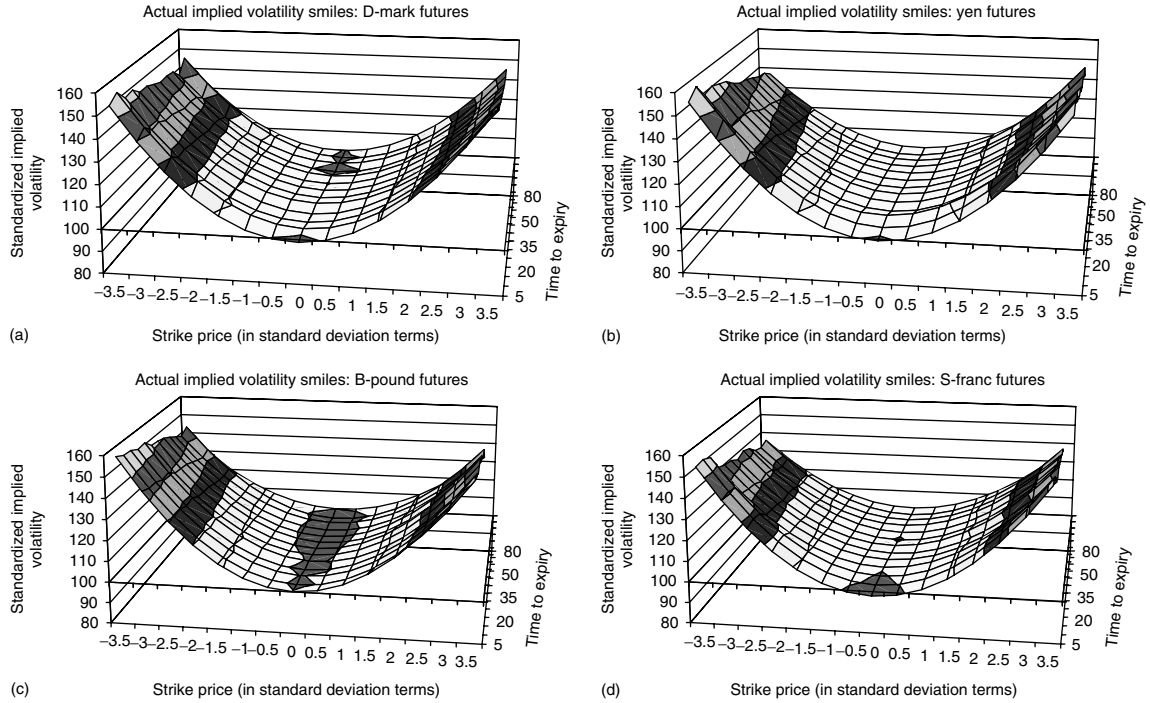

Figure 1 Actual implied volatility surfaces of option prices for four foreign exchange futures standardized to the level of the ATM volatility (1985–2000)

tested a number of arbitrary models based upon a polynomial expansion across strike price (x) and time (t). Tompkins [15] extended the polynomial expansion to degree three and included additional factors, which might also influence the behaviors of volatility surfaces.

For all four foreign exchange options markets, a parsimonious model explains the vast majority of the variance in the standardized implied volatility surfaces. The analysis allowed strike price effects to be separated into a first-order effect (the skew), a second-order effect (the smile), and higher order effects. For the skew effect, the results suggested that an asymmetrical smile pattern is a function of the level of the foreign exchange rate. The evidence suggests that when futures prices are low (high), the implied volatility pattern becomes more negatively (positively) skewed.

For the second-order “curved” pattern, all four markets display a convex pattern that becomes more extreme as the options expiration date is approached. Furthermore, a significant negative relationship is found between the degree of curvature and the level

of the ATM implied volatility. Curved patterns are independent of the level of the exchange rate. Finally, Tompkins [15] reports a significant third-order strike price effect for all four foreign exchange option markets. Tompkins [15] shows that the high degree of explanatory power is invariant to the time period of analysis and that the model provides accurate smile predictions outside of the estimation sample period. Under these assumptions, we conclude that regularities in implied volatility surfaces exist and are similar for the four currency markets. Furthermore, the regularities are time period invariant. These general results provide means to test alternative models, which could potentially explain why implied volatility surfaces exist. This is discussed in the following section.

Empirical Regularities for Currency Option Smiles

From [15], the following general conclusions can be drawn for the behaviors of implied volatility surfaces

for options on foreign exchange:

1. Implied volatility patterns are symmetrical on average for options on currencies.
2. For three of the four markets, the skew effect is related to the level of the underlying futures price. The only exception is for the British pound/US dollar. The level of the futures price impacts the skewness in an inverse manner to the pure skewness effect. This suggests that for low futures prices a negative skew occurs and at higher futures prices the skew flattens and can become positive.
3. The skew effect for currency options is relatively invariant to the time to expiration of the options. It is solely due to extreme levels of the underlying exchange rate or to some market shock.
4. For two of the four markets, the level of the skew effect is inversely related to the level of the ATM implied volatility. For the Deutsche mark and Swiss franc, the higher (lower) the level of the ATM implied volatility, the more negative (positive) the level of the skew.
5. Shocks change the degree and sign of the skew effect. For the Deutsche mark and Swiss franc, the concerted intervention in the currency markets by the Group of Seven (G7) caused a negative skew to occur. The 1987 stock crash had minimal impact on the currency markets, with only a slightly negative skew impact for the Deutsche mark. For the second shock, the only currency option skew affected was the Japanese yen. This occurred in January 1988 and appears to have been associated with international capital flows out of the US dollar into yen.
6. All implied volatility patterns display some degree of curvature and the degree of curvature is inversely related to the option's term to expiration. The longer the term to expiration, the less extreme the degree of curvature in the smile.
7. Shocks change the degree of curvature of the implied volatility pattern. However, the effect is not systematic and often shocks reduce the degree of curvature. For the G7 intervention in 1985, there was a reduction in the degree of smile curvature for both the Deutsche mark and Swiss franc, while for the Japanese yen, this event caused greater curvature for the smiles. For the second shock, both the British pound and Japanese yen displayed greater smile curvature thereafter.
8. For all four markets, the degree of curvature of the implied volatility pattern is inversely related to the level of the ATM implied volatility. Thus, the higher the level of ATM implied volatility, the less pronounced the degree of curvature in the smile.
9. For three of the four currency markets, the degree of curvature is independent of the level of the underlying futures price. The only exception is for the Japanese yen, where the higher the level of the exchange rate, the lesser the curvature (however, this impact is small).
10. For all four markets, the degree of curvature of the implied volatility pattern is asymmetrical. For the Deutsche mark, Japanese yen, and Swiss franc, the degree of asymmetry is negative. This suggests that the curvature is more extreme for options with strike prices below the current level of the underlying futures. For the British pound, the relationship is positive, indicating that the curvature is more extreme for options with strike prices above the current level of the underlying futures.

Using these 10 stylized facts as clues, we now examine alternative explanations for the existence of implied volatility smiles. It is crucial that any coherent explanation must conform to all of these facts simultaneously. If selected models are internally inconsistent with these facts, it is grounds for rejection.

A nontrivial problem is that the statistical testing of any option-pricing model has to be a joint hypothesis that the option-pricing model is correct and that the markets are efficient. Given that smiles do exist, we can reject the hypothesis that actual option values conform to the Black [2] model. However, we are uncertain as to why this occurs. Consider two possible reasons for the existence of smiles: the underlying asset may follow an alternative price process or the Black [2] model is correct but market imperfections exist. The next sections discuss both possibilities to better understand the regularities in implied volatility surfaces presented in [15].

Models with Alternative Price and Volatility Processes

Consider first that some alternative price (and volatility) process is at work instead of geometric Brownian motion with constant variance. Following the general approach of Jarrow and Rudd [11], we consider alternative true terminal distributions for the underlying asset. Consider the following models that include stochastic volatility ($\hat{\sigma}$) and alternative price processes. For the sake of convenience, the volatility processes will be evaluated in terms of a stochastic variance process ($\sqrt{V}$). Given that our previous results examined options on futures, the notation indicates that the underlying asset is a futures price (F). The first model, which will be considered, is a stochastic volatility model: the square root process model proposed by Heston [7] (*see also Stochastic Volatility Models: Foreign Exchange; Heston Model*). This choice is due to the ability of this model to allow correlated underlying and volatility processes. This will be defined as

Model 1

$$dF(t) = \mu F(t) dt + \hat{\sigma} F(t) dZ_1(t) \quad (3)$$

with the variance process defined by

$$dV(t) = \kappa(\theta - V(t)) dt + \xi \sqrt{V(t)} dZ_2(t) \quad (4)$$

where Z_1 and Z_2 are standard Wiener processes with correlation ρ . The term κ indicates the rate of mean reversion of the variance, θ is the long-term variance, and ξ indicates the volatility of the variance. The terms V and $\sqrt{V}$ represent the variance and the volatility of the process, respectively.

The second model that we consider is the jump-diffusion model proposed by Merton [13] (*see also Jump-diffusion Models*). Using his notation, this can be expressed as

Model 2

$$dF(t) = F(\alpha - \lambda\kappa) dt + F\sigma(t) dZ(t) + dq(t) \quad (5)$$

Using his notation, α is the instantaneous expected return on the futures contract, $\sigma(t)$ is the instantaneous volatility of the futures contract, conditional on no arrivals of important new information (no

jumps), dZ is a standard Wiener process, $q(t)$ is the independent Poisson process, which captures the jumps. The term λ is the mean number of arrivals per unit time and κ represents the jumps size (which can also be a random variable).

Bates [1], Ho *et al.* [8], and Jiang [12] assumed that the volatility process is subordinated in a non-normal price process; this provides the inspiration for the third model (see [1] for tests of these models). In this spirit, the third proposed model is a variant of the Heston [7] model, proposed by Tompkins [16, 17], which includes jumps (as captured by a normal inverse Gaussian (NIG) process) in the underlying price process.

Model 3

$$dF(t) = \mu F(t-) dt + \hat{\sigma}(t) F(t-) dN(t) \quad (6)$$

with the variance process defined by

$$dV(t) = k(\theta - V(t)) dt + \xi \sqrt{V(t)} dZ(t) \quad (7)$$

where $N(t)$ is a purely discontinuous martingale corresponding to log returns driven by an NIG Lévy process (*see Normal Inverse Gaussian Model*). This model will be referred to as *normal inverse Gaussian stochastic volatility (NIGSV)* for the sake of convenience.

Smile Patterns Associated with the Proposed Models

Tompkins [17] discussed how parameters for each of these models could be estimated (under the physical measure) and the change of measure to allow risk neutral pricing. Of more interest to this article is the resulting smile behavior of each model. This can be seen in Figure 2 (restricted solely to the Deutsche mark/US dollar). Figure 2(a) shows the empirical smile patterns for Deutsche mark/US dollar from 1985 to 2000. Figure 2(b) shows the smile surface associated with the Heston [7] model. Figure 2(c) shows the smile surface associated with the jump-diffusion model of Merton [13]. Figure 2(d) represents the combination of stochastic volatility and jump processes (NIGSV model).

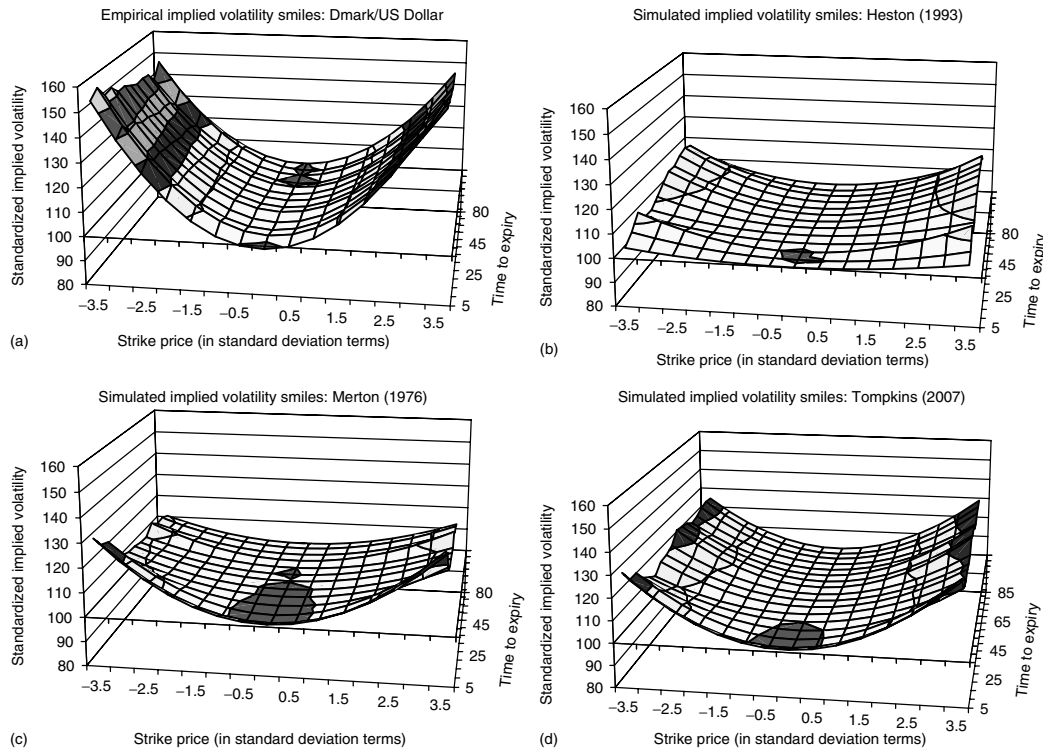

Figure 2 Simulated implied volatility smiles for options on Deutsche mark/US dollar

Smile Patterns Associated with Stochastic Volatility

As one can see in Figure 2(b), the Heston [7] model does generate a symmetrically curved smile function consistent with point #1, but the smiles are flat as the option expiration approaches and become more curved, the longer the term to expiration (which is inconsistent with point #6). This is exactly the opposite of what is observed for currency smiles empirically. The Heston [7] model can generate a skewed implied volatility pattern from a nonzero correlation between the volatility and underlying processes (see equations 3 and 4). However, the longer the term to expiration, the more extreme the skew pattern would be. This is inconsistent with point #3, that skewed patterns for currency options are time invariant and are only associated with the levels of the ATM implied volatility or the underlying currency exchange rate. However, this model is consistent with fact #5 that shocks could change the degree of skewness. The model could still be valid under a regime

of stochastic correlations. However, it seems inconsistent from an economic standpoint; if shocks change the degree of asymmetry in the expected terminal distribution of the underlying asset, it is not clear why in half of the instances the degree of curvature (fact #8) is reduced. This model is also inconsistent with fact #8, that the higher the level of expected variance (ATM volatility), the flatter the degree of curvature. Given that this model would produce effects that are contradictory to both first and second strike price effects observed empirically, we must reject it. An alternative explanation is that the jump-diffusion model of Merton [13] may be more appropriate.

Smile Patterns Associated with Stochastic Volatility

According to Hull [9], this model could produce a curved implied volatility surface and this curve would be consistent with fact #6, that curves exist and become more extreme the shorter the time to expiration of the option. This can be seen in Figure 2,

where the degree of curvature is most extreme closest to expiration. However, as the Poisson process in equation (5) is independent and identically distributed (i.i.d.), this will converge over time to a normal distribution and thus, the implied volatility surface would flatten, which is what occurs in Figure 2. It could also hold under a regime associated with fact #7, that shocks do change the degree of curvature. It could be that the inflow of new information changes the expectations of market agents regarding the degree and magnitude of future jumps. However, the model, as it stands, would not be able to explain the first-order strike price effects. One alternative would be to allow the shocks to be asymmetric. This would allow a skewed implied volatility pattern to exist. However, if the jumps follow some i.i.d. process, the central limit theorem would imply that the degree of skewness would be highest when the options are closest to expiration and would flatten as the term to expiration is lengthened. This is at variance with fact #3 that for currency options the skew effects are time invariant. Therefore, we can also reject a jump-diffusion model as being inconsistent with the empirical record.

Smile Patterns Associated with the NIGSV Model

This model assumes a symmetrical jump-diffusion process with a subordinated stochastic volatility process with nonzero correlations between the two processes. The simulated implied volatility smiles appear in Figure 2(d) and seem to resemble most the actual smiles for Deutsche mark/US dollars options in Figure 2(a). As can be seen, there is curvature in the smile patterns for both short term and longer term options. The shorter term curvature is associated with the jump process, while the longer term curvature is associated with stochastic volatility. This is consistent with both fact #1 and fact #6, that the average smile pattern is symmetrical and the degree of curvature is inversely related to time. Dynamics of the skew relationship can be explained with variations of the correlation between the two processes. Finally, the asymmetry of the smile shapes can be explained by the jump process. While this model appears to display many of the dynamics of empirical smiles, the degree of curvature is not as extreme as

is observed for the actual smiles. The reason for this is that the parameters for the model were estimated using the underlying Deutsche mark/US dollar currency futures (see [17] for details). While a feasible measure change was used to price options (that omitted arbitrage), it is unlikely that this measure change is unique as nontraded sources of risk have been introduced into the state space. These include jumps and stochastic volatility. Given this, we should expect that option prices will also contain some risk premium above and beyond the values associated with the underlying asset.

Conclusions and Implications

In this article, we have examined currency option smiles. Previous research by Tompkins [15] suggests that when implied volatility patterns are standardized, regularities are observed both across markets and across time. He concludes that this may suggest that market participants have developed some consistent algorithm to vary option prices in a consistent manner away from Black [2] values.

To better understand the nature of this algorithm, 10 stylized results are identified from his results for the four currency option markets. With these 10 results we test whether alternative models, which have been proposed to explain the existence of implied volatility surfaces, can generate the same dynamics as these empirical results. Initially, models were examined that suggest an alternative price process may better define the underlying price and volatility processes. We reject both the Heston [7] and the Merton [13] models as appropriate models, as they cannot produce all the empirical dynamics for actual smiles. The only model that could explain all the dynamics is a model that combines stochastic volatility and nonnormal innovations for currency returns. When appropriate parameters are input into this model and a feasible change of measure is made, option prices can be determined. The smiles associated with this model match the dynamics observed for actual currency option smiles. However, the model smiles do not display the same extreme degree of curvature as the empirical smiles. Following Tompkins [17], this suggests that a substantial risk premium exists for currency options and that the hypothesis that the existence of implied volatility surfaces are due solely to an alternative price process is rejected.

Alternatively, market imperfections may be the reason for the existence of implied volatility surfaces. Given that existing research has previously rejected this, we tend to concur that market imperfections alone are also probably not sufficient to explain the existence of implied volatility smiles. However, it is possible that both alternative price processes and market imperfections jointly contribute to the existence of implied volatility smiles.

ROBERT G. TOMPKINS

Foreign Exchange Smile Interpolation

This article provides a short introduction into the handling of FX-implied volatility market data—especially their inter- and extrapolation across delta space and time. We discuss a low-dimensional Gaussian kernel approach as the method of choice showing several advantages over usual smile interpolation methods such as cubical splines.

FX-implied Volatility

Implied volatilities for FX vanilla options are normally quoted against Black–Scholes deltas

$$\Delta_{BS} = e^{-r_f T} N \left(\frac{\ln(S/K) + (r_d - r_f + (\sigma^2(\Delta)/2)) T}{\sigma(\Delta)\sqrt{T}} \right) \quad (1)$$

Note that these deltas are dependent on $\sigma(\Delta)$, that is, the market-given volatility should be quoted. Thus, when retrieving a volatility for a given strike, an iterative processes is needed. However, under normal circumstances, the mapping from a delta-volatility to a strike-volatility coordinate system works *via* a quickly converging fixed point iteration.

Proposition 1 (Delta–Strike fixed point iteration). *Let*

$\Delta_n : A \mapsto A, A \subset (0, 1)$ *be a mapping, defined by*

$$\begin{aligned} \sigma_0 &= \sigma_{ATM} \\ \Delta_0 &= \Delta(K_{Call}, \sigma_{ATM}) \end{aligned}$$

$$\begin{aligned} \Delta_{n+1} &= e^{-r_f(T-t)} N(d_1(\Delta_n)) \\ &= e^{-r_f(T-t)} N \left(\frac{\ln(S/K) + (r_d - r_f + \sigma^2(\Delta_n)/2)(T-t)}{\sigma(\Delta_n)\sqrt{T-t}} \right) \end{aligned} \quad (2)$$

(3)

For sufficiently large $\sigma(\Delta_n)$ and a smooth, differentiable volatility smile, the sequence converges for $n \rightarrow \infty$ against the unique fixed point $\Delta^ \in A$ with $\sigma^* = \sigma(\Delta^*)$, corresponding to strike K .*

The usual FX smiles normally satisfy the above mentioned regularity conditions. More details concerning this proposition can be found in [5]. However, note that already smoothness is demanded here, which directly leads to the issue of an appropriate smile interpolation.

Interpolation

Before the discussion of specific interpolation methods, let us take a step backward and remember Rebonato’s well-known statement of implied volatility as the wrong number in the wrong formula to obtain the right price [3]. Therefore, the explanatory power of implied volatilities for the dynamics of a stochastic process remains limited. Implied volatilities give a lattice on which marginal distributions can be constructed. However, even using many data points to generate marginal distributions, forward distributions and extremal distributions, which determine the prices of some products such as compound and barrier products, cannot be uniquely defined by implied volatilities (see [4] for a discussion of this).

The attempt to capture FX smile features can lead to two different general approaches.

Parametrization

One possibility to express smile or skew patterns is just to capture it as the calibration parameter set of an arbitrary stochastic volatility or jump diffusion model that generates the observed market implied volatilities. However, as spreads are rather narrow in liquid FX options markets, it is preferred to exactly fit the given input volatilities. This automatically leads to an interpolation approach.

Pure Interpolation

As an introduction, we would like to pose four requirements for an acceptable volatility surface interpolation:

1. Smoothness in the sense of continuous differentiability. Especially with respect to the possible

application of Dupire-style local volatility models, it is crucial to construct an interpolation that is at least $\mathcal{C}^2$ in strike and at least $\mathcal{C}^1$ in time direction. This becomes obvious when considering the expression for the local volatility in this context:

$$\begin{aligned}\sigma_{loc}^2(S, K) &= \frac{\partial C(K, T)/\partial T + r_f C(K, T) + K(r_d - r_f)\partial C(K, T)/\partial K}{(1/2)K^2(\partial^2 C(K, T)/K^2)} \\ &= \frac{\frac{\sigma_i}{T} + 2(r_d - r_f)K(\partial\sigma_i/\partial K) + 2(\partial\sigma_i/\partial T)}{K^2 \left(\frac{1}{\sigma_i} \left(1/(K\sqrt{T} + d_+ \partial\sigma_i/\partial K) \right)^2 + \partial^2\sigma_i/\partial K^2 - d_+ \sqrt{T} (\partial\sigma_i/\partial K)^2 \right)}\end{aligned}\quad (4)$$

where $C(K, T)$ denotes the Black–Scholes prices of a call option with strike K , σ_i its corresponding implied volatility, and

$$d_+ = \frac{\ln(S/K) + (r_d - r_f + \sigma^2(\Delta)/2)T}{\sigma(\Delta)\sqrt{T}} \quad (5)$$

Note in addition that local volatilities can directly be extracted from delta-based FX volatility surfaces, that is, the Dupire formula can alternatively be expressed in terms of delta. See [2] for details.

2. Absence of oscillations, which is guaranteed if the sign of the curvature of the surface does not change over different strike or delta levels.
3. Absence of arbitrage possibilities on single smiles of the surface as well as absence of calendar arbitrage
4. A reasonable extrapolation available for the interpolation method.

A widely used classical interpolation method is cubical splines. They attempt to fit surfaces by fitting piecewise cubical polynomials to given data points. They are specified by matching their second derivatives at each intersection. Although this ensures the required smoothness by construction, it does not prevent oscillations, which directly leads to the danger of arbitrage possibilities or it does not define how to extrapolate the smile. We, therefore, introduce the concept of a slice kernel volatility surface as an alternative:

Definition 1 (Slice Kernel). Let $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$ be n given points and $g : \mathbb{R} \mapsto \mathbb{R}$ a smooth function which fulfills

$$g(x_n) = y_n, \quad n = 1, \dots, n \quad (6)$$

A smooth interpolation is then given by

$$g(x) := \frac{1}{\Phi_\lambda(x)} \sum_{i=1}^N \alpha_i K_\lambda(\|x - x_i\|) \quad (7)$$

where

$$\Phi_\lambda(x) := \sum_{i=1}^N K_\lambda(\|x - x_i\|) \quad (8)$$

and

$$K_\lambda(u) := \exp \left\{ -\frac{u^2}{2\lambda^2} \right\} \quad (9)$$

The described kernel is also called *Gaussian Kernel*. The interpolation reduces to determining the α_i , which is straightforward *via* solving a linear equation system. Note that λ remains as a free smoothing parameter, which also affects the condition of the equation system. At the same time, it can be used to fine-tune the extrapolation behavior of the kernel.

Generally, the slice kernel produces reasonable output smiles based on a maximum of seven delta-volatility points. Then it fulfills all the above-mentioned requirements. It is $\mathcal{C}^\infty$, does not create oscillations, passes typical no-arbitrage conditions as they are, for example, posed by Gatheral [1], and finally has an inherent extrapolation method.

In time direction, one might connect different slice kernels by linear interpolation of the variances for same deltas. This also normally ensures the absence of calendar arbitrage, for which a necessary condition

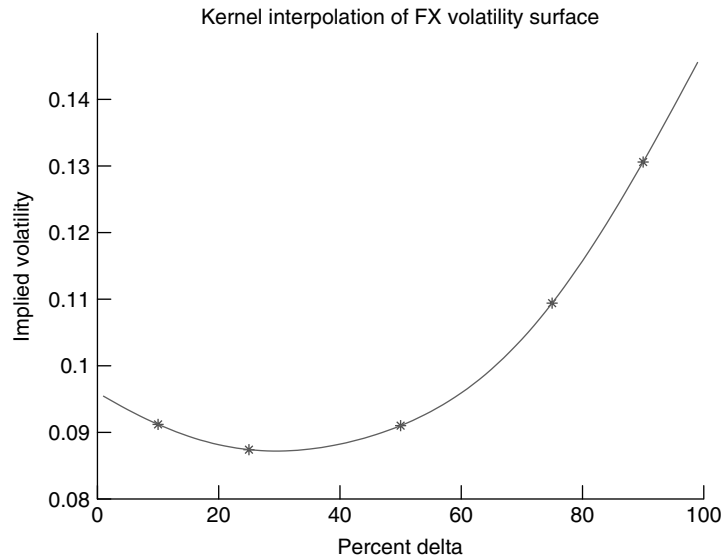

Figure 1 Kernel interpolation of an FX volatility surface

is a nondecreasing variance for constant moneyness F/K (see also [1] for a discussion of this).

Figure 1 displays the shape of a slice kernel applied to a typical FX volatility surface constructed from 10 and 25 delta volatilities, and the ATM volatility (in this example $\lambda = 0.25$ was chosen).

Margrabe Formula

An exchange option gives its owner the right, but not the obligation, to exchange b units of one asset for a units of another asset at a specific point in time, that is, it is a claim that pays off $(aS_1(T) - bS_2(T))^+$ at time T .

Outperformance option or Margrabe option are alternative names for the same payoff.

Let us assume that the interest rate is constant (r) and that the underlying assets follow correlated ($dW_1 dW_2 = \rho dt$) geometric Brownian motions under the risk-neutral measure,

$$dS_i = \mu_i S_i dt + \sigma_i S_i dW_i \quad \text{for } i = 1, 2 \quad (1)$$

Note that allowing μ_i 's that are different from r enables us to use resulting valuation formula for the exchange option directly in cases with nontrivial carrying costs on the underlying. This could be for futures (where the drift rate is 0), currencies (where the drift rate is the difference between domestic and foreign interest rates, *see Foreign Exchange Options*), stocks with dividends (where the drift rate is r less the dividend yield), or nontraded quantities with convenience yields.

The value of the exchange option at time t is

$$\pi^{\text{EO}}(t) = \text{EO}(T - t, aS_1(t), bS_2(t)) \quad (2)$$

where the function EO is given by

$$\text{EO}(\tau, S_1, S_2) = S_1 e^{(\mu_1 - r)\tau} \mathcal{N}(d_+) - S_2 e^{(\mu_2 - r)\tau} \mathcal{N}(d_-) \quad (3)$$

with

$$d_{\pm} = \frac{\ln(S_1/S_2) + (\mu_1 - \mu_2 \pm \sigma^2/2)\tau}{\sigma\sqrt{\tau}} \quad (4)$$

where $\sigma = \sqrt{\sigma_1^2 + \sigma_2^2 - 2\sigma_1\sigma_2\rho}$, $\mathcal{N}$ denotes the standard normal distribution function and $\tau = T - t$. The formula was derived independently by Margrabe [12] and Fisher [6], but despite the two papers being published side by side in the *Journal of Finance*, the formula commonly bears only the former author's name. The result is most easily proven by using a

change of numeraire (*see Change of Numeraire*), writing

$$\pi^{\text{EO}}(t) = S_2(t) \mathbf{E}_t^{Q_{S_2}}((aS_1(T)/S_2(T) - b)^+) \quad (5)$$

noting that S_1/S_2 follows a geometric Brownian motion, and reusing the Black–Scholes calculation for the mean of a truncated lognormal variable.

If the underlying asset prices are multiplied by a positive factor, then the exchange option's value changes by that same factor. This means that we can use Euler's homogeneous function theorem to read off the partial derivatives of the option value with respect to the underlying assets (the deltas) directly from the Margrabe formula (see [15] for more such tricks), specifically

$$\frac{d\text{EO}}{dS_1} = e^{(\mu_1 - r)\tau} \mathcal{N}(d_+) \quad (6)$$

and similarly for S_2 . If the S assets are traded, then a portfolio with these holdings (scaled by a and b) that is made self-financing with the risk-free asset replicates the exchange option, and the Margrabe formula gives *the only* no-arbitrage price.

If the underlying assets do not pay dividends during the life of the exchange option (so that the risk-neutral drift rates are $\mu_1 = \mu_2 = r$), then early exercise is never optimal, and the Margrabe formula holds for American options too. With nontrivial carrying costs, this is not true, but as noted by [2], a change of numeraire reduces the dimensionality of the problem so that standard one-dimensional methods for American option pricing can be used.

The Margrabe formula is still valid with stochastic interest rates, provided the factors that drive interest rates are independent of those driving the S assets.

Exchange options are most common in over-the-counter foreign exchange markets, but exchange features are embedded in many other financial contexts; mergers and acquisitions (see [12]) and indexed executive stock options (see [9]) to give just two examples.

Variations and Extensions

Some variations of exchange options can be valued in closed form. In [10], a formula for a so-called traffic light option that pays

$$(S_1(T) - K_1)^+(S_2(T) - K_2)^+ \quad (7)$$

is derived, and [4] gives a formula for the value of a compound exchange option, that is, a contract that pays

$$(\pi^{\text{EO}}(T_C) - S_2(T_C))^+ \text{ at time } T_C < T \quad (8)$$

Both formulas involve the bivariate normal distribution function, and in the case of the compound exchange option a nonlinear but well-behaved equation that must be solved numerically.

For knock-in and knockout exchange options whose barriers are expressed in terms of the ratio of the two underlying assets, [7] show that the reflection-principle-based closed-form solutions (see [14]) from the Black-Scholes model carry over; this means that barrier option values can be expressed solely through the EO-function evaluated at appropriate points.

However, there are not always easy answers; in the simple case of a spread option

$$(S_1(T) - S_2(T) - K)^+ \quad (9)$$

there is no commonly accepted closed-form solution. The reason for this is that a sum of lognormal variables is not lognormal. More generally, many financial valuation problems can be cast as follows: calculate the expected value of

$$\left(\sum_{i=1}^n \alpha_{i,n} X_{i,n} - K \right)^+ \quad (10)$$

where the $X_{i,n}$'s are lognormally distributed. One can use generic techniques such as direct integration, numerical solution of partial differential equations, or Monte Carlo simulation, but there is an extensive literature on other approximation methods. These include

- moment approximation, where the moments of $\sum_{i=1}^n \alpha_{i,n} X_{i,n}$ are calculated, the variable then treated as lognormal, and the option priced by a Black-Scholes-like formula; an application to Asian options is given in [11].
- integration by Fourier transform techniques, which extends beyond lognormal models and works well if n is not too large (say 2–4); an application to spread options is given in [1].
- limiting results for $n \rightarrow \infty$ as obtained in [5] and [13]; the relation to the reciprocal gamma

distribution has been used for Asian and basket options.

- changing to Gaussian processes as suggested in [3]; this may be suitable for commodity markets where spread contracts are popular, and it allows for the inclusion of mean reversion.
- if the $\alpha_{i,n} X_{i,n}$'s depend monotonically on a common random variable, then Jamshidian's approach from [8] can be used to decompose an option on a portfolio into a portfolio of simpler options. This is used to value options on coupon-bearing bonds in one-factor interest-rate models.

ROLF POULSEN

Foreign Exchange Options: Delta- and At-the-money Conventions

In financial markets, the value of a plain-vanilla European option is generally quoted in terms of its implied volatility, that is, the volatility that, when plugged into the Black–Scholes formula, gives the correct market price. By observation of market prices the implied volatility, however, turns out to be a function of the option’s strike, thus giving rise to the so-called *volatility smile*.

In foreign exchange (FX) markets, it is common practice to quote volatilities for FX call and put options in terms of their delta sensitivities rather than in terms of their strikes or their moneyness. Volatilities and deltas are quoted by means of a table, the *volatility smile table*, consisting of rows for each FX option expiry date and columns for a number of delta values, as well as a column for the at-the-money (ATM) volatilities.

The definition and usage of a volatility smile table is complicated by the fact that FX markets have established various delta and ATM conventions. In this article, we summarize these conventions and highlight their intuition. For each delta convention, we give formulas and methods for the conversion of deltas to strikes and *vice versa*. We describe how to retrieve volatilities from the table for an arbitrary FX option that is to be priced in accordance with the information contained therein. We point out some mathematical problems and pitfalls when trying to do so and give criteria under which these problems surface.

Definitions

FX Rate

Before discussing the various delta conventions, we summarize some basic terms and definitions that we use in this article.

- *FX spot rate* $S(t)$: The FX spot rate $S(t)$ is the *current* exchange rate at the present time t

(“today”) between the domestic and the foreign currency. It is specified as the number of units of domestic currency that an investor gets in exchange for one unit of foreign currency,

$$S(t) := \frac{\text{number of units of domestic currency}}{\text{one unit of foreign currency}} \quad (1)$$

- *FX forward rate* $F(t, T)$: The FX forward rate $F(t, T)$ is the exchange rate between the domestic and the foreign currency at some *future* point of time T as observed at the present time t ($t < T$). It is again specified as the number of units of domestic currency that an investor gets in exchange for one unit of foreign currency at time T .

Using arbitrage arguments, spot and forward FX rates are related by (see, for instance, [3]):

$$F(t, T) = S(t) \cdot \frac{D_{\text{for}}(t, T)}{D_{\text{dom}}(t, T)} \quad (2)$$

where $D_{\text{for}} := D_{\text{for}}(t, T)$ is the foreign discount factor for time T (observed at time t) and $D_{\text{dom}} := D_{\text{dom}}(t, T)$ is the domestic discount factor for time T (observed at time t).

Note that the terminology in FX transactions is always confusing. In this article, we refer to the “domestic” currency in the sense of a base currency in relation to which “foreign” amounts of money are measured (see also [4]). By definition (1), an amount x in foreign currency, for example, is equivalent to $x \cdot S(t)$ units of domestic currency at time t .

In the markets, FX rates are usually quoted in a standard manner. For example, the USD–JPY exchange rate is usually quoted as the number of Japanese yen an investor receives in exchange for 1 USD. For a Japanese investor, the exchange rate would fit the earlier definition, while a US investor would either need to look at the reverse exchange rate $1/S(t)$ or think of Japanese yen as the “domestic” currency.

Value of FX Forward Contracts

When two parties agree on an FX forward contract at time s , they agree on the exchange of an amount of money in foreign currency at an agreed exchange rate

K against an amount of money in domestic currency at time $T > s$. When choosing $K = F(s, T)$, the FX forward contract has no value to either of the parties at time s .

As, in general, the forward exchange rate changes over time, at some time t ($s < t < T$), the FX forward contract will have a nonzero value (in domestic currency) given by

$$\begin{aligned} v_f(t, T) &= D_{\text{dom}}(F(t, T) - K) \\ &= S(t)D_{\text{for}} - K D_{\text{dom}} \end{aligned} \quad (3)$$

Value of FX Options

Upon deal inception, the holder of an FX option obtains the right to exchange a specified amount of money in domestic currency against a specified amount of money in foreign currency at an agreed exchange rate K . Assuming nonstochastic interest rates and the standard lognormal dynamics for the spot exchange rate, at time t , the domestic currency values of plain-vanilla European call and put FX options with strike K and expiry date T are given by their respective Black–Scholes formulas:

$$\begin{aligned} \text{Call option: } v_c(t, T) &= D_{\text{dom}} F(t, T) \mathcal{N}(d_+) \\ &\quad - D_{\text{dom}} K \mathcal{N}(d_-) \end{aligned} \quad (4)$$

$$\begin{aligned} \text{Put option: } v_p(t, T) &= (-1) \cdot [D_{\text{dom}} F(t, T) \mathcal{N}(-d_+) \\ &\quad - D_{\text{dom}} K \mathcal{N}(-d_-)] \end{aligned} \quad (5)$$

$$\begin{aligned} &= D_{\text{dom}} F(t, T) (\mathcal{N}(d_+) - 1) \\ &\quad - D_{\text{dom}} K (\mathcal{N}(d_-) - 1) \end{aligned} \quad (6)$$

where

$$d_{\pm} = \frac{\ln(F(t, T)/K) \pm 1/2\sigma^2\tau}{\sigma\sqrt{\tau}},$$

K : strike of the FX option,

σ : Black–Scholes volatility,

$\tau = T - t$: time to expiry of FX option, and

$\mathcal{N}(x)$: cumulative normal distribution function (7)

Note that $v_c(t, T)$ and $v_p(t, T)$ as given earlier are measured in *domestic* currency. The option position, however, may also be held in foreign currency.

We call the currency in which an option's value is measured as its *premium currency*.

Also note that the present value of call and put options are related by the *put–call parity*:

$$v_c - v_p = v_f = D_{\text{dom}}(F(t, T) - K) \quad (8)$$

Definition of Delta Types

This section summarizes the delta conventions used in FX markets and gives some of their properties. We outline the correspondence of each delta sensitivity with a particular delta hedge strategy the holder of an FX option chooses. FX options are peculiar in that the underlying coincides with the exchange rate. While, in general, it makes no sense to measure the value of an option in units of its underlying (e.g., in the number of shares of a company), the FX option position can be held either in domestic or in foreign currency. This gives rise to the premium-adjusted deltas.

For the ease of notation, we drop the time dependency of $S(t)$ and $F(t, T)$ in the following and denote the spot exchange rate as of time t by S and the forward exchange rate for time T as observed in t by F .

Unadjusted Deltas

Spot Delta.

Definition 1 For FX options, the *spot delta* is defined as the derivative of the option price $v_{c/p}$ with respect to the FX spot rate S :

$$\Delta_S^{c/p} := \frac{\partial v_{c/p}}{\partial S} \quad (9)$$

Interpretation Spot delta is the “usual” delta sensitivity that follows from the Black–Scholes equation. It can be derived by considering an FX option position that is held and hedged in *domestic* currency (see, for instance, [2, 3]).

Note that Δ_S is an amount in units of foreign currency. This makes sense from the hedging perspective: an amount of money in foreign currency is needed to make up for changes in the domestic currency value of an FX option (held in domestic currency), due to changes of the exchange rate. If,

for example, an investor is long an FX call option, a decrease in the exchange rate will lead to a decrease in his option position. By having shorted Δ_S units of foreign currency, the investor will make a hedge profit in domestic currency balancing his losses in the option position to first order.

Properties

$$\text{Call option: } \Delta_S^c = D_{\text{for}} \mathcal{N}(d_+) \quad (10)$$

$$\begin{aligned} \text{Put option: } \Delta_S^p &= D_{\text{for}} \{ \mathcal{N}(d_+) - 1 \} \\ &= -D_{\text{for}} \mathcal{N}(-d_+) \end{aligned} \quad (11)$$

$$\text{Put-call delta parity: } \Delta_S^c - \Delta_S^p = D_{\text{for}} \quad (12)$$

Forward Delta

Definition 2 The forward delta Δ_F (also called driftless delta [4]) of an FX option is defined as the ratio of the option's spot delta and the delta of a long forward contract on the FX rate (where the forward price of the FX forward contract equals the strike of the FX option):

$$\Delta_F^{c/p} := \frac{\partial v_{c/p} / \partial S}{\partial v_f / \partial S} = \frac{\Delta_S^{c/p}}{\Delta_S^f} \quad (13)$$

Interpretation The forward delta is not simply the derivative of the option price formula with respect to the forward FX rate F . The rationale for the above-mentioned definition follows from the construction of a hedge portfolio using FX forward contracts as hedge instruments for the FX option position (both held in domestic currency). The forward delta gives the number of forward contracts that an investor needs to enter into to completely delta hedge his/her FX option position; Δ_F , therefore, is simply a number without units.

Properties

$$\text{Call option: } \Delta_F^c = \frac{D_{\text{for}} \cdot \mathcal{N}(d_+)}{D_{\text{for}}} = \mathcal{N}(d_+) \quad (14)$$

$$\begin{aligned} \text{Put option: } \Delta_F^p &= \frac{D_{\text{for}} \cdot (\mathcal{N}(d_+) - 1)}{D_{\text{for}}} \\ &= \mathcal{N}(d_+) - 1 = -\mathcal{N}(-d_+) \end{aligned} \quad (15)$$

Put-call delta parity:

$$\Delta_F^c - \Delta_F^p = 1 \quad (16)$$

Premium-adjusted Deltas

Spot Delta Premium Adjusted.

Definition 3 The premium-adjusted spot delta is defined as

$$\Delta_{S,pa}^{c/p} := S \cdot \frac{\partial}{\partial S} \left(\frac{v_{c/p}}{S} \right) = \Delta_S^{c/p} - \frac{v_{c/p}}{S} \quad (17)$$

Interpretation The definition of the premium-adjusted spot delta follows from an FX option position that is held in foreign currency, while being hedged in domestic currency.

While v is the option's value in domestic currency, $v/S(t)$ is the option's value converted to foreign currency (i.e., its premium currency) at time t . The term $\partial(v/S(t))/\partial S \cdot dS$, thus, gives the change of the option value (measured in foreign currency) with the underlying exchange rate. To complete a delta hedge in domestic currency, the derivative needs to be multiplied by $S(t)$ from where the defining equation (17) for the premium-adjusted spot delta follows.

Note that the delta sensitivity is equal to spot delta, adjusted for the premium effect $v/S(t)$. This is easily interpreted as a delta that is corrected by a premium amount already paid in foreign currency. Also note that $\Delta_{S,pa}$ itself is denominated in units of foreign currency.

Properties

Call option:

$$\Delta_{S,pa}^c = D_{\text{for}} \frac{K}{F} \mathcal{N}(d_-) \quad (18)$$

Put option:

$$\begin{aligned} \Delta_{S,pa}^p &= D_{\text{for}} \frac{K}{F} \{ \mathcal{N}(d_-) - 1 \} \\ &= -D_{\text{for}} \frac{K}{F} \{ \mathcal{N}(-d_-) \} \end{aligned} \quad (19)$$

Put-call delta parity:

$$\begin{aligned} \Delta_{S,pa}^c + \Delta_{S,pa}^p &= D_{\text{for}} \frac{K}{F} (\mathcal{N}(d_-) - \mathcal{N}(-d_-)) \\ &= 2\Delta_{S,pa}^c - D_{\text{for}} \frac{K}{F} \end{aligned} \quad (20)$$

$$\Delta_{S,pa}^c - \Delta_{S,pa}^p = D_{\text{for}} \frac{K}{F} \quad (21)$$

The defining equations for premium-adjusted deltas have interesting consequences: while put deltas are unbounded and strictly monotonous functions of K , call deltas are bounded (i.e., $\Delta_S^c \in [0; \Delta_{\max}^c]$ with $\Delta_{\max}^c < 1$) and are *not* monotonous functions of K . Thus, the relationship between call deltas and strikes K is not one to one.

Forward Delta Premium Adjusted.

Definition 4 *The premium-adjusted forward delta is defined in analogy to the unadjusted delta:*

$$\Delta_{F,pa}^{c/p} = \frac{S \cdot \partial / \partial S (v_{c/p} / S)}{\partial v_f / \partial S} = \frac{\Delta_{S,pa}^{c/p}}{\partial v_f / \partial S} \quad (22)$$

Interpretation The intuition behind the definition of the premium-adjusted forward delta follows from an FX option position that is held in *foreign* currency and hedged by forward FX contracts in *domestic* currency. The premium-adjusted forward delta gives the number of forward contracts that are needed for the delta hedge in *domestic* currency of an FX option held in *foreign* currency. The derivation of the defining equation (22) is similar to the one for spot delta premium adjusted (cf. the section Spot Delta Premium Adjusted). Note that $\Delta_{F,pa}$ is a pure number without units.

Properties

Call option:

$$\Delta_{F,pa}^c = \frac{K}{F} \mathcal{N}(d_-) \quad (23)$$

Put option:

$$\Delta_{F,pa}^p = \frac{K}{F} \cdot \{\mathcal{N}(d_-) - 1\} = -\frac{K}{F} \mathcal{N}(-d_-) \quad (24)$$

Put-call delta parity:

$$\begin{aligned} \Delta_{F,pa}^c + \Delta_{F,pa}^p &= \frac{K}{F} (\mathcal{N}(d_-) - \mathcal{N}(-d_-)) \\ &= 2\Delta_{F,pa}^c - \frac{K}{F} \end{aligned} \quad (25)$$

$$\Delta_{F,pa}^c - \Delta_{F,pa}^p = \frac{K}{F} \quad (26)$$

Also note the important remarks in the previous section on the domain, the range of values, and the relationship between call delta and option strike. They apply likewise to premium-adjusted forward deltas.

Definition of At-the-money Types

In this section, we summarize the various ATM definitions, comment on their financial interpretation, and give the relations between all relevant quantities in Table 1.

Table 1 Strike values and delta values at the ATM point for the different FX delta conventions^(a)

	Δ -neutral	$K_{\text{atm}} = F$	Vega/gamma = max	$\Delta = 50\%$
ATM strike values				
Spot delta	$F \, \text{e}^{1/2\sigma^2\tau}$	F	$F \, \text{e}^{1/2\sigma^2\tau}$	$F \, \text{e}^{1/2\sigma^2\tau}$
Fwd delta	$F \, \text{e}^{1/2\sigma^2\tau}$	F	$F \, \text{e}^{1/2\sigma^2\tau}$	
Spot delta p.a.	$F \, \text{e}^{-1/2\sigma^2\tau}$	F	$F \, \text{e}^{1/2\sigma^2\tau}$	
Fwd delta p.a.	$F \, \text{e}^{-1/2\sigma^2\tau}$	F	$F \, \text{e}^{1/2\sigma^2\tau}$	
ATM delta values				
Spot delta	$D_{\text{for}} \, \mathcal{N}(0)$	$D_{\text{for}} \, \mathcal{N}\left(\frac{1}{2}\sigma\sqrt{\tau}\right)$	$D_{\text{for}} \, \mathcal{N}(0)$	$\mathcal{N}(0)$
Fwd delta	$\mathcal{N}(0)$	$\mathcal{N}\left(\frac{1}{2}\sigma\sqrt{\tau}\right)$	$\mathcal{N}(0)$	
Spot delta p.a.	$D_{\text{for}} \, \text{e}^{-1/2\sigma^2\tau} \mathcal{N}(0)$	$D_{\text{for}} \, \mathcal{N}\left(-\frac{1}{2}\sigma\sqrt{\tau}\right)$	$D_{\text{for}} \, \text{e}^{+1/2\sigma^2\tau} \mathcal{N}\left(-\frac{1}{2}\sigma\sqrt{\tau}\right)$	
Fwd delta p.a.	$\text{e}^{-1/2\sigma^2\tau} \mathcal{N}(0)$	$\mathcal{N}\left(-\frac{1}{2}\sigma\sqrt{\tau}\right)$	$\text{e}^{+1/2\sigma^2\tau} \mathcal{N}\left(-\frac{1}{2}\sigma\sqrt{\tau}\right)$	

^(a)Note that $\mathcal{N}(0) = 1/2$. The delta values are given for call options, the corresponding values for put options can be obtained, by replacing $\mathcal{N}(x)$ with $(\mathcal{N}(x) - 1)$

ATM Definition “Delta Neutral”

Definition 5 The ATM point is defined as the strike K_{atm} , for which the delta of a call and a put option add up to zero:

$$\Delta_x^c(K_{\text{atm}}, \sigma_{\text{atm}}) + \Delta_x^p(K_{\text{atm}}, \sigma_{\text{atm}}) = 0 \quad (27)$$

Here, x represents any of the delta conventions defined in the section Definition of Delta Types.

Interpretation The definition follows directly from a “straddle” position where a long call and a long put option with the same strike are combined. If the strike is chosen appropriately, the change in value of the call and the put option compensate (to first order) when the underlying FX rate changes. The straddle position’s value, thus, is insensitive (“delta neutral”) to changes in the underlying FX rate. The reason for this choice is that traders can use straddles to hedge the vega of their position without upsetting the delta.

Properties The ATM definition mentioned earlier for delta neutral FX options is equivalent to $\mathcal{N}(d_+) = 1/2$ in case of the unadjusted delta conventions and $\mathcal{N}(d_-) = 1/2$ in case of the premium-adjusted delta conventions. From this, the relationships of Table 1 follow in a straightforward manner.

ATM Definition via Forward

Definition 6 The ATM point is defined as the strike equaling the forward exchange rate:

$$K_{\text{atm}} := F \quad (28)$$

Interpretation This definition reflects the view that (given the information at deal inception) an option is ATM when its strike is chosen equal to the expected exchange rate at option expiry. If the spot exchange rate, indeed, approached F as $t \rightarrow T$ (as would be the case in a fully deterministic world by arbitrage arguments, cf. equation (2)), then the ATM strike would mark the dividing point between options that expire in-the-money (ITM) and out-of-the-money (OTM). From the put–call parity (8), we see that this is also the strike at which put and call options have the same value. Thus, this ATM definition is also called *value parity* [4].

Properties The relationships of Table 1 can again be derived in a straightforward manner from the definitions.

ATM Definition “vega = max”

Definition 7 The ATM point is defined as the strike K_{atm} for which vega of the FX option is at its maximum. Vega is the sensitivity of the FX option, with respect to the implied volatility of the underlying exchange rate. It is given by (cf. [4])

$$\text{vega}_{c/p} = \frac{\partial v_{c/p}}{\partial \sigma} = S D_{\text{for}} \sqrt{\tau} n(d_+) \quad (29)$$

where $n(x)$ is the normal density distribution.

The ATM strike can be derived from $\partial \text{vega} / \partial K = 0$ as

$$K_{\text{atm}} = F e^{1/2\sigma^2\tau} \quad (30)$$

Properties Table 1 again summarizes the relevant quantities for this ATM definition. Note that in case of unadjusted deltas, this ATM definition is equivalent to the delta neutral ATM definition. This is, however, not the case for adjusted deltas.

ATM Definition “ $\gamma = \max$ ”

Definition 8 The ATM point is defined as the strike K_{atm} for which the gamma sensitivity of the FX option is at its maximum.

We restrict the discussion to the case of gamma spot,

$$\gamma_S^{c/p} := \frac{\partial \Delta_S^{c/p}}{\partial S} = D_{\text{for}} \frac{n(d_+)}{S \sigma \sqrt{\tau}} \quad (31)$$

From $\partial \gamma / \partial K = 0$, the ATM strike can be derived as

$$K_{\text{atm}} = F e^{1/2\sigma^2\tau} \quad (32)$$

thus revealing the equivalence to the ATM definition “vega = max”.^a

ATM Definition “50%”

Definition 9 According to this convention, the ATM point is defined by

$$\Delta^c = 0.5 \quad \text{and} \quad |\Delta^p| = 0.5 \quad (33)$$

This condition can only be true for the forward delta convention and, thus, does not apply to any of the other delta conventions.

Properties of ATM Definitions

Table 1 summarizes the properties of the ATM point for all possible combinations of ATM definitions and delta conventions.

In this context, it is interesting to note that, beside their financial interpretation, mathematically, the various definitions of the ATM point lead to three characteristic relationships between the strike K and the forward exchange rate F :

$$K = F \Rightarrow d_{\pm} = \pm \sigma \sqrt{\tau} \quad (34)$$

$$K = F e^{1/2\sigma^2\tau} \Rightarrow d_+ = 0, \quad d_- = -\sigma \sqrt{\tau} \quad (35)$$

$$K = F e^{-1/2\sigma^2\tau} \Rightarrow d_+ = \sigma \sqrt{\tau}, \quad d_- = 0 \quad (36)$$

Converting Deltas to Strikes and Vice Versa

Quoting volatilities as a function of the options' deltas rather than as a function of the options' strikes brings about a problem when it comes to pricing FX options. Consider the case that we want to price a vanilla European option for a given strike K . To price this option, we have to find the correct volatility. As the volatility is given in terms of delta and delta itself is a function of volatility *and* strike, we have to solve an implicit problem, which, in general, has to be done numerically.

The following sections outline the algorithms that can be used to that end for the various delta conventions and directions of conversion. As the spot and forward deltas differ only by constant discount factors, we restrict the presentation to the forward versions of the adjusted and unadjusted deltas.

Forward Delta

For unadjusted deltas, there are simple one-to-one relationships between put and call deltas, the put-call delta parities (12) and (16). PUT deltas can therefore easily be translated into the corresponding CALL deltas and it is sufficient to perform all the calculations for call deltas here.

Conversion of Forward Delta to Strike. If volatilities are given as a function of forward delta, the strike corresponding to a given forward delta Δ_F^c can be calculated analytically. Let $\sigma(\Delta_F^c)$ denote the volatility associated with Δ_F^c ; $\sigma(\Delta_F^c)$ may either be quoted or interpolated from the volatility smile table.

With Δ_F^c and $\sigma(\Delta_F^c)$ given, we can directly solve equation (14),

$$\Delta_F^c = \mathcal{N}(d_+) = \mathcal{N}\left(\frac{\ln(F/K) + 1/2\sigma(\Delta_F^c)^2 T}{\sigma(\Delta_F^c)\sqrt{T}}\right) \quad (37)$$

for the strike K . We get

$$K = F \exp\left\{-\sigma(\Delta_F^c)\sqrt{T}\mathcal{N}^{-1}(\Delta_F^c) + \frac{1}{2}\sigma(\Delta_F^c)^2 T\right\} \quad (38)$$

Conversion of Strike to Forward Delta. The reverse conversion from strikes to forward deltas is more difficult and can only be achieved numerically. The following algorithm can be shown to converge [1] and has empirically proven to be very efficient.

In the first step, calculate a zero-order guess Δ_0 by using the ATM volatility σ_{atm} in equation (14):

$$\Delta_0 = \Delta_F^c(K, \sigma_{\text{atm}}) = \mathcal{N}\left(\frac{\ln(F/K) + 1/2\sigma_{\text{atm}}^2 T}{\sigma_{\text{atm}}\sqrt{T}}\right) \quad (39)$$

In the second step, use this zero-order guess for delta to derive a first-order guess σ_1 for the volatility by **interpolating** the curve $\sigma(\Delta)$:

$$\sigma_1 = \sigma(\Delta_0) \quad (40)$$

Finally, calculate the corresponding first-order guess for Δ_F^c in the third step:

$$\Delta_1 = \Delta_F^c(K, \sigma_1) = \mathcal{N}\left(\frac{\ln(F/K) + 1/2\sigma_1^2 T}{\sigma_1\sqrt{T}}\right) \quad (41)$$

and repeat steps two and three until the changes in Δ from one iteration to the next are below the specified accuracy.

Forward Delta Premium Adjusted

For the sake of clarity, we again restrict the discussion below to the case of call deltas. The algorithms for put deltas work analogously.

Conversion of Forward Delta Premium Adjusted to Strike. The conversion from forward delta premium adjusted to an absolute strike is more complicated than in the case of an unadjusted delta and cannot be formulated in a closed-form expression. The reason is that in the equation for the premium-adjusted call delta (23),

$$\begin{aligned}\Delta_{F,pa}^c &= \frac{K}{F} \mathcal{N}(d_-) \\ &= \frac{K}{F} \mathcal{N}\left(\frac{\ln(F/K) - 1/2\sigma(\Delta_{F,pa}^c)^2 T}{\sigma(\Delta_{F,pa}^c) \sqrt{T}}\right) \quad (42)\end{aligned}$$

the strike K appears inside and outside the cumulative normal distribution function so that one cannot solve directly for K . Even though both $\Delta_{F,pa}^c$ and $\sigma(\Delta_{F,pa}^c)$ are given, the problem has to be solved numerically.

So when converting a given call delta $\Delta_{F,pa}^c$, a root finder has to be used to solve for the correspondent strike K . This could, for example, be a simple bisection method where, for call deltas, the ATM-strike K_{atm} is the lower bound and some high (i.e., quasi infinite) value such as $100 K_{\text{atm}}$ can be used as upper bound. Of course, a more elaborate root finder to solve this problem could (and should!) be used, but a discussion of the various methods lies beyond the scope of this article.

Note, however, that all these methods require that Δ is a strictly monotonous function of K . We will see in section Ambiguities in the Conversion from Δ to Strike for Premium-adjusted Deltas that this is not always the case.

Conversion of Strike to Forward Delta Premium Adjusted. The conversion of an absolute strike to forward delta premium adjusted can be done analogously to the conversion into an unadjusted forward delta as described in section Conversion of Strike to Forward Delta.

First, use the previous guess Δ_{i-1} to obtain an improved guess σ_i for the volatility by interpolating

in the $\sigma(\Delta)$ curve.

$$\sigma_i = \sigma(\Delta_{i-1}) \quad (43)$$

In the second step, calculate the corresponding guess Δ_i by

$$\Delta_i = \Delta_{F,pa}^c(K, \sigma_i) = \frac{K}{F} \mathcal{N}\left(\frac{\ln(F/K) - 1/2\sigma_i^2 T}{\sigma_i \sqrt{T}}\right) \quad (44)$$

Iterate these two steps until the change in Δ from one step to the next is below the specified accuracy. A good initial guess for the volatility is, of course, again the ATM-volatility σ_{atm} .

Using the Volatility Smile Table

In FX markets, linear combinations of plain-vanilla FX options, such as “strangles”, “risk reversals”, and “butterflies”, are liquidly traded. These instruments are composed of ATM and OTM plain-vanilla put and call options at specific values of delta (typically, 0.25 or 0.1). When aggregating this market information, one obtains a scheme called the **volatility smile table** consisting of rows for each FX option expiry date, a column for ATM volatilities, and two distinct sets of columns for volatilities of OTM put and call options. We call these sets the *put and call* sides of the table.

Thus, OTM options can be priced by retrieving volatilities from the respective side of the volatility smile table, for example, OTM calls are priced using volatilities from the call side. By virtue of the put–call parity, ITM options can be priced using volatilities from the opposite side of the table, that is, ITM calls are priced using volatilities from the put side.

To exemplify this, consider the case of an option with arbitrary time to maturity and strike. The typical procedure to retrieve this option’s volatility from the smile table would be the following.

1. Determine the volatilities of the ATM point and the call and put sides at the option’s expiry. For this, the volatilities of each delta column will, in general, have to be interpolated in time.
2. Decide which side of the table to use depending on the option’s strike K : options with $K >$

K_{atm} are either OTM calls or ITM puts and are therefore priced using volatilities from the call side. Accordingly, options with $K < K_{\text{atm}}$ are priced using volatilities from the put side (cf. equation (4)).

3. Convert the option's strike to delta. This depends on the side of the table chosen in the previous step: convert to a call delta if $K > K_{\text{atm}}$, and to a put delta if $K < K_{\text{atm}}$. See the section Converting Deltas to Strikes and *vice versa* for the details of these conversions.
4. Retrieve the volatility from the table by interpolating volatilities in delta.

Alternatively, one could also translate the full smile volatility table from deltas to strikes. The conversion of deltas to strikes would then be necessary for the grid points of the table only, thus, making steps 2 and 3 of the earlier listed procedure obsolete. The interpolation in step 4 would be done in strikes. However, keep in mind that the strike grid points would vary from row to row.

It is important to note that the earlier procedure is based on the assumption that delta is a strictly monotonous function of the option's strike K : only in this case the option's delta and strike are equivalent measures of the option's moneyness, that is, only in this case we are guaranteed the equivalence

$$K > K_{\text{atm}} \iff \Delta^c < \Delta_{\text{atm}}^c \quad (45)$$

In the following section, we will show that the assumption of monotonicity is not always true and derive the conditions under which it is violated.

Problems and Pitfalls

Interpolation in Time Dimension when Delta Conventions Change

In FX markets, it is common to switch delta conventions with an option's time to maturity. For example, volatilities for options with less than two years to maturity are often quoted in terms of spot deltas, whereas volatilities for longer expiries are usually quoted in terms of one of the forward delta conventions.

When conventions change from one expiry T_k to the next one, it is *a priori* unclear how an interpolation in time on a delta-volatility table should

be performed. Which of the two conventions shall be used for options with expiries t within the range $T_k < t < T_{k+1}$?

Some possibilities are as follows: convert the grid points at T_k into the convention used for T_{k+1} and do interpolation in the long-term convention or, conversely, convert the grid points at T_{k+1} into the convention used for T_k and interpolate in the short-term convention. Another possibility would be to translate the delta grid into a strike grid and do the interpolation on strikes.

None of these approaches is *a priori* superior to the others. In real life, however, a choice has to be made. Even though the differences may be small, one should be aware that the choice is arbitrary.

ATM Delta Falling in the OTM Range

For long times to maturity, the delta of an ATM FX option may become smaller than the delta of the closest OTM option. In a sense, the ATM delta "crosses" the nearest OTM delta. In this case, it is unclear how the interpolation of volatilities (in delta) should be done or whether the ATM point or the crossed delta point should possibly be ignored.

The conditions under which this problem occurs vary with the delta and ATM types. In the following, we outline the derivation of these conditions for an exemplarily chosen combination (premium-adjusted spot deltas and forward ATM definition), summarize the results for other combinations, and finally discuss a typical numerical example for long-dated FX options.

Exemplary Derivation. We start from equation (17) for the ATM delta using $K_{\text{atm}} = F$:

$$\Delta_{S, pa}^c(F, \sigma_{\text{atm}}) = D_{\text{for}} \mathcal{N}\left(-\frac{\sigma_{\text{atm}}}{2}\sqrt{T}\right) \quad (46)$$

Obviously, the ATM delta will decrease with decreasing values of D_{for} and *increasing* values of $\sigma_{\text{atm}}\sqrt{T}$. Small values of D_{for} and/or large values of $\sigma_{\text{atm}}\sqrt{T}$ will therefore lead to ATM deltas that are smaller than the nearest OTM point Δ_1^c (which is usually $\Delta_1^c = 0.25$).

From the expression mentioned earlier, it follows immediately that the ATM delta is larger than the first

Table 2 Restrictions on discount factors and ATM volatilities for various combinations of delta and ATM types^(a)

	ATM-type forward	ATM-type delta neutral
Spot delta	$D_{\text{for}} > -2\Delta_1^p$ $\sigma_{\text{atm}} \sqrt{T} < 2\mathcal{N}^{-1} \left(1 + \frac{\Delta_1^p}{D_{\text{for}}} \right)$	$D_{\text{for}} > 2\Delta_1^c$
Forward delta	$\sigma_{\text{atm}} \sqrt{T} < 2\mathcal{N}^{-1} (1 + \Delta_1^p)$	No constraint
Spot delta p.a.	$D_{\text{for}} > 2\Delta_1^c$ $\sigma_{\text{atm}} \sqrt{T} < 2\mathcal{N}^{-1} \left(1 - \frac{\Delta_1^c}{D_{\text{for}}} \right)$	$D_{\text{for}} > 2\Delta_1^c$ $\sigma_{\text{atm}} \sqrt{T} < \sqrt{2 \ln \left(\frac{D_{\text{for}}}{2\Delta_1^c} \right)}$
Forward delta p.a.	$\sigma_{\text{atm}} \sqrt{T} < 2\mathcal{N}^{-1} (1 - \Delta_1^c)$	$\sigma_{\text{atm}} \sqrt{T} < \sqrt{2 \ln \left(\frac{1}{2\Delta_1^c} \right)}$

^(a)If these conditions are violated, the ATM point will cross the nearest OTM point. Note that the put delta Δ_1^p is negative

OTM point Δ_1^c only if

$$\sigma_{\text{atm}} \sqrt{T} < -2\mathcal{N}^{-1} \left(\frac{\Delta_1^c}{D_{\text{for}}} \right) = 2\mathcal{N}^{-1} \left(1 - \frac{\Delta_1^c}{D_{\text{for}}} \right) \quad (47)$$

This inequality has meaningful solutions only if the right-hand side is positive, that is, only if $1 - \Delta_1^c/D_{\text{for}} > 1/2$. We therefore have the additional constraint:

$$D_{\text{for}} > 2\Delta_1^c \quad (48)$$

The derivations for all other possible combinations are analogous. Their results are summarized in Table 2.

Numerical Example. To gain some intuition for these constraints, let us consider a numerical example for a relevant case. A typical combination of delta and ATM conventions for long-dated FX options is the ATM-type delta neutral for premium-adjusted forward deltas. Usually, the first OTM point is quoted at $\Delta_1^c = 0.25$. Inserting this value into the respective formula (see Table 2) yields the condition

$$\sigma_{\text{atm}} \sqrt{T} < \sqrt{2 \ln \left(\frac{1}{2\Delta_1^c} \right)} = \sqrt{2 \ln(2)} \approx 1.1774 \quad (49)$$

For a 30-year option, this condition restricts the ATM volatility to a maximum of 21.5%, a value that—*a priori*—does not seem unattainable.

Ambiguities in the Conversion from Δ to Strike for Premium-adjusted Deltas

Premium-adjusted deltas can cause further complications. Recall from the section Forward Delta Premium Adjusted

$$\Delta_F^c = \frac{K}{F} \mathcal{N}(d_-)$$

$$\text{where } d_- = \frac{\ln(F/K) - 1/2\sigma^2\tau}{\sigma\sqrt{\tau}} \quad (50)$$

and note that Δ_F^c is **not** a monotonous function of the strike K and therefore not invertible for all strikes as illustrated by Figure 1(a). Thus, while Δ_F^c can be calculated for any strike K , the reverse is not true: for any $\Delta_F^c < \Delta_{\text{max}}^c$, there are two strikes $K_1 \neq K_2$ with $\Delta_F^c(K_1) = \Delta_F^c(K_2)$.

In case $K_{\text{max}} < K_{\text{atm}}$, there is no problem. $\Delta_{F,pa}^c(K)$ is a monotone function of K for all $K > K_{\text{atm}}$ and is therefore directly related to the option's moneyness: the smaller a call option's delta value, the higher its strike and the deeper it is OTM. If desired, the volatility smile table defined in terms of delta can be translated uniquely into a smile table in strikes. Besides, when retrieving volatilities from the call side of the volatility

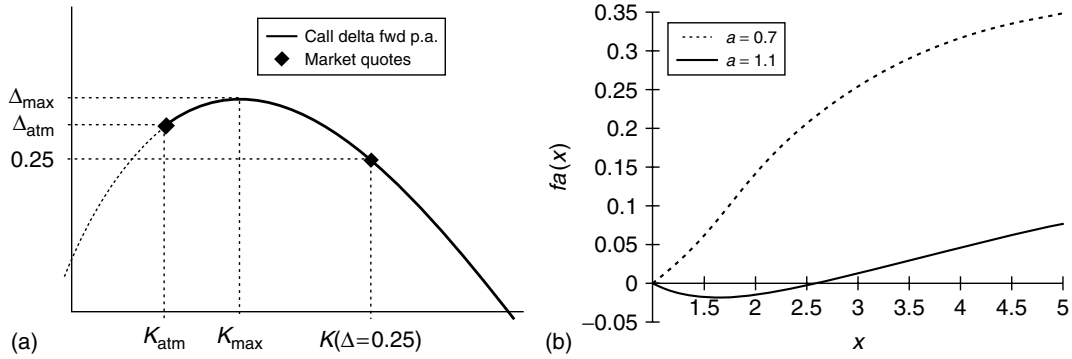

Figure 1 (a) Premium adjusted (forward) call delta as a function of strike. (b) The function $f_\alpha(x)$ as defined in equation (56) for $\alpha = 0.7$ (broken line) and $\alpha = 1.1$ (solid line)

smile table, this can be done by direct interpolation of the entries, possibly including the ATM point.

In case $K_{\max} > K_{\text{atm}}$, however, the situation is more complicated. $\Delta_{F,pa}^c(K)$ is no longer a monotonous function of K and the conversion of deltas to strikes is no longer unique for all OTM options. Thus, when translating a smile table in deltas into a smile table in strikes, particular care has to be taken. In addition, when retrieving the volatility for options with strikes $K \in (K_{\text{atm}}; K_{\max})$ from the volatility smile table, one has to *extrapolate* volatilities in delta beyond the ATM point which seems odd.

Note that the counterintuitive *extrapolation* in delta beyond the ATM point does not occur in case the volatility smile table in deltas is translated to a table in strikes on the grid points first (see the section Using the Smile Volatility Table) and the interpolation is done in strikes. This is possible as long as there is no crossing of the ATM point and the closest delta grid point as discussed in the section ATM Delta Falling in the OTM Range.

In the following discussion, we show that the case $K_{\max} > K_{\text{atm}}$ can, indeed, occur. We restrict ourselves to premium adjusted *forward* call deltas and ATM-type delta neutral. The conditions for the ATM-type forward can be derived analogously and we summarize the results at the end of this section. Similar arguments hold for premium-adjusted spot deltas, however, it is reasonable to assume that the problems outlined in the section ATM Delta Falling in the OTM Range surface beforehand.

Starting from the expressions for the ATM strike and the call delta, see Table 1,

$$K_{\text{atm}} = F e^{-1/2\sigma_{\text{atm}}^2 T} \quad (51)$$

$$\Delta_{\text{atm}}^c = \Delta_{F,pa}^c(K_{\text{atm}}, \sigma_{\text{atm}}^2) = \frac{1}{2} e^{-1/2\sigma_{\text{atm}}^2 T} \quad (52)$$

we need to find conditions under which there is a second solution with strike $K > K_{\text{atm}}$ that solves

$$\Delta_{\text{atm}}^c = \Delta_{F,pa}^c(K, \sigma(\Delta_{F,pa}^c)) \quad (53)$$

This may seem a difficult problem at first glance since the delta on the right-hand side depends on the volatility, which itself is given in terms of delta. It is, however, simplified considerably by the following argument: while we do not know the strike for the point that solves equation (53), we do know the delta there: it is the ATM delta. As the volatility is given in terms of delta, we also know the volatility on the right-hand side of equation (53): it must be the ATM-volatility σ_{atm} .

Therefore, the problem can be reformulated as follows: when does

$$\Delta_{\text{atm}}^c = \Delta_{F,pa}^c(K, \sigma_{\text{atm}}) \quad (54)$$

have a second solution with $K > K_{\text{atm}}$ (besides the trivial one at $K = K_{\text{atm}}$)?

Inserting the expressions for the ATM delta and the premium-adjusted forward call delta into equation

(54) we get

$$\frac{1}{2} e^{-1/2 \sigma_{\text{atm}}^2 T} = \frac{K}{F} \mathcal{N} \left(\frac{\ln(F/K) - 1/2 \sigma_{\text{atm}}^2 T}{\sigma_{\text{atm}} \sqrt{T}} \right) \quad (55)$$

With the definitions

$$\begin{aligned} \alpha &:= \sigma_{\text{atm}} \sqrt{T}, \\ x &:= \frac{K}{F} e^{1/2 \sigma_{\text{atm}}^2 T} = \frac{K}{F} e^{\alpha^2/2} \end{aligned}$$

the problem is equivalent to finding the roots of

$$f_{\alpha}(x) := e^{-\alpha^2/2} \left\{ \frac{1}{2} - x \mathcal{N} \left(-\frac{\ln(x)}{\alpha} \right) \right\} \quad (56)$$

The condition $K > K_{\text{atm}}$ in the previous equation corresponds to $x > 1$. Plotting $f_{\alpha}(x)$ for various values of α , see Figure 1(b), we make the following observation: for small values of α the function increases monotonically, taking on only positive values for $x > 1$. For larger values of α , the function decreases at first, thus, taking on negative values in a certain range, and then increases again, eventually reaching a second zero.

Therefore, the question reduces further to this: under which conditions does the function $f_{\alpha}(x)$ have a negative slope at $x = 1$? The first derivative of f_{α} can easily be calculated,

$$f'_{\alpha}(x) = -e^{-\alpha^2/2} \left\{ \mathcal{N} \left(-\frac{\ln(x)}{\alpha} \right) - \frac{1}{\alpha} \mathcal{N}' \left(-\frac{\ln(x)}{\alpha} \right) \right\} \quad (57)$$

and the slope of f_{α} at $x = 1$ is now readily obtained as

$$\begin{aligned} f'_{\alpha}(x=1) &= -e^{-\alpha^2/2} \left\{ \mathcal{N}(0) - \frac{1}{\alpha} \mathcal{N}'(0) \right\} \\ &= -e^{-\alpha^2/2} \left\{ \frac{1}{2} - \frac{1}{\alpha} \frac{1}{\sqrt{2\pi}} \right\} \end{aligned} \quad (58)$$

The constraint that it has to be positive yields the condition

$$\alpha = \sigma_{\text{atm}} \sqrt{T} < \sqrt{\frac{2}{\pi}} \quad (59)$$

which restricts the ATM volatility for a 30-year option to only 14.6%.

In other words, for a 30-year option, with ATM volatilities larger than 14.6%, the conversion between $\Delta_{F, pa}$ and strikes becomes ambiguous.

A similar condition can be derived for the forward ATM type. The major difference is that the function $f_{\alpha}(x)$ takes on a different form that ultimately yields the following expression for the turnover point α at which the conversion becomes ambiguous:

$$\mathcal{N} \left(-\frac{\alpha}{2} \right) = \frac{1}{\alpha} \mathcal{N}' \left(-\frac{\alpha}{2} \right) \quad (60)$$

This equation can be solved numerically and yields the constraint

$$\alpha = \sigma_{\text{atm}} \sqrt{T} < 1.224 \quad (61)$$

so that for a 30-year option, ATM volatilities above 22.3% will lead to ambiguities.

End Notes

^a. It should be noted that equation (32) was obtained under the assumption that the slope of the volatility σ as a function of the strike K in equation (31) is 0 ATM. This is necessary as otherwise this ATM definition would become impracticable. In general, however, the volatility smile implies a nonzero slope and the maximum value of γ will not be found at the strike given by equation (32).

Stochastic Volatility Models: Foreign Exchange

In finance, the term *volatility* has a dilative meaning. There exists a definition in the statistical sense, which states that volatility is the standard deviation per unit time (usually per year) of the (logarithmic) asset returns. However, empirical evidence about derivatives markets shows that refinements of this definition are necessary.

First, one can observe a dependency of Black–Scholes-implied volatility on at least the strike price and time to maturity implicit in option prices. This dependency defines the **implied volatility surface**. One possibility to incorporate this dependency into a model is by using a deterministic function for the instantaneous volatility, that is, the volatility governing the changes in spot returns in infinitesimal time steps. This function of spot price and time is called *local volatility* (see **Local Volatility Model**).

In addition, empirical evidence indicates that the local volatility surface is not constant over time, but is subject to changes. This is not surprising since the expectations of the market participants with respect to the future instantaneous volatility might change over time. Furthermore, for some derivative products, the dynamics of the volatility surface is crucial for a reliable valuation. A prominent example is the product class of cliquet options, which are basically a collection of forward start options with increasing forward start time. The payoff depends on the absolute or the relative performance of the underlying during the lifetime of the options. It is intuitive that an option with a forward start time of one year, for instance, depends substantially on the one-year forward volatility surface. Since this volatility is uncertain, it seems advisable to model this risk by an additional stochastic factor.

Stochastic Volatility FX Models

Now, we review some common procedures for incorporating a stochastic behavior of volatility into foreign exchange (FX) rate models. The first approach

is to model the FX rate X_t with a volatility process v_t by a system of stochastic differential equations, like

$$\begin{aligned} dX_t &= \mu_t X_t dt + \sigma_t X_t dW_t^X \\ dv_t &= \eta(v_t) dt + \zeta(v_t) dW_t^v \end{aligned} \quad (1)$$

where $v_t = f(\sigma_t)$ for a function f and the increments of the Brownian motions W^X and W^v are possibly correlated. Table 1 gives an overview of some common stochastic volatility models.

A general class of stochastic volatility models is formed by the affine jump diffusion models. They have been studied by Duffie *et al.* [5]. The Heston model is a special case of this kind of model.

The second approach is inspired by the observation that higher volatility comes along with an increased trading activity and *vice versa*. This is realized by a time change in the FX rate process. For instance, consider a standard Brownian motion $\{W_t\}_{t \geq 0}$ with variance t for W_t , that is, the value of the process after t units of physical time. Now, if the economic time elapses twice as fast as the physical time due to market activity, the process could be expressed by the deterministically time-changed process $\{W_{2t}\}_{t \geq 0}$. Hence, the variance for the values of the process after t units of physical time would then be $2t$. This idea can be generalized by representing the economic time as a stochastic process Y_t , which is named *stochastic clock*. For every realization of the process $\{Y_t\}_{t \geq 0}$, economic time must be a monotone function of physical time, that is, the process is a subordinator. Recently proposed models use a normal inverse gamma or variance gamma Lévy process for representing the exchange rate process and an integrated Cox–Ingersoll–Ross or Gamma–Ornstein–Uhlenbeck process for stochastic time. All these models have the common feature that the characteristic function of the logarithm of the time-changed exchange rate, $\ln X_{Y_t}$, can be expressed in closed form.

Besides the models mentioned here, there exist other modeling approaches. For a general overview of stochastic volatility models, see [6, 11] and for especially in the FX context see [12].

Heston’s Stochastic Volatility Model

In the following, we discuss the stochastic volatility model of Heston and its option valuation applied to

Table 1 Some common stochastic volatility models

$f(\sigma_t)$	$\eta(v_t)$	$\zeta(v_t)$	Reference
σ_t^2	$\kappa(\theta - v_t)$	ξv_t	GARCH similar diffusion model [11]
σ_t^2	$\kappa(\theta - v_t)$	$\xi \sqrt{v_t}$	Heston model [9]
σ_t^2	$\kappa(\theta v_t - v_t^2)$	$\xi v_t^{3/2}$	3/2 model [11]
$\ln \sigma_t^2$	$\kappa(\theta - v_t)$	ξ	Log-volatility Ornstein–Uhlenbeck [11]

an FX setting. The model is characterized by the stochastic differential equations:

$$\begin{aligned} dX_t &= (r_d - r_f)X_t dt + \sqrt{v_t}X_t dW_t^X \\ dv_t &= \kappa(\theta - v_t)dt + \sigma \sqrt{v_t}dW_t^v \end{aligned} \quad (2)$$

with $\text{Cov}[dW_t^X, dW_t^v] = \rho dt$. Here, the FX rate process $\{X_t\}_{t \geq 0}$ is modeled by a process, similar to the geometric Brownian motion, but with a non-constant instantaneous variance v_t . The variance process $\{v_t\}_{t \geq 0}$ is driven by a mean-reverting stochastic square-root process. The increments of the two Wiener processes $\{W_t^X\}_{t \geq 0}$ and $\{W_t^v\}_{t \geq 0}$ are assumed to be correlated with rate ρ . In an FX setting, the risk-neutral drift term of the underlying process is the difference between the domestic and the foreign interest rates $r_d - r_f$. The quantities $\kappa \geq 0$ and $\theta \geq 0$ denote the rate of mean reversion and the long-term variance. The parameter σ is often called *vol* of *vol*, but it should be called *volatility of instantaneous variance*.

The term $\sqrt{v_t}$ in equation (2) ensures a nonnegative volatility in the FX rate process. It is known that the distribution of values of $\{v_t\}_{t \geq 0}$ is given by a noncentral chi-squared distribution. Hence, the probability that the variance takes a negative value is equal to zero. Thus, if the process touches the zero bound, the stochastic part of the volatility process turns zero and the deterministic part will ensure a nonnegative volatility because of the positivity of κ and θ .

The Heston model is often not capable of fitting complicated structures of implied volatility surfaces. In particular, this is true if the term structure exhibits a nonmonotone form or the sign of the skew changes with increasing maturity. For a discussion of the implied volatility surface generated by this model, see [7]. One approach to tackle this limitation is to extend the original Heston model by time-dependent parameters [3, 14].

Valuation of Options in the Heston Model

For the valuation of options in the Heston model, we consider the value function of a general contingent claim $V(t, v, X)$. As shown in [8], applying Itô's lemma, the self-financing condition, and the possibility to trade in the underlying exchange rate, money market, and another option, which is dependent on time, volatility, and X , we arrive at Garman's partial differential equation:

$$\begin{aligned} \frac{\partial V}{\partial t} + \kappa(\theta - v) \frac{\partial V}{\partial v} + (r_d - r_f)X \frac{\partial V}{\partial X} + \frac{1}{2}\sigma^2 v \frac{\partial^2 V}{\partial v^2} \\ + \frac{1}{2}vX^2 \frac{\partial^2 V}{\partial X^2} + \rho\sigma vX \frac{\partial^2 V}{\partial v \partial X} - r_d V = 0 \end{aligned} \quad (3)$$

A solution to the above equation can be obtained by specifying appropriate boundary and exercise conditions, which depend on the contract specifications. In the case of European vanilla options, Heston [9] provided a closed-form solution, namely,

$$\text{Vanilla} = \phi \left[e^{-r_f \tau} X_t P_1 - K e^{-r_d \tau} P_2 \right] \quad (4)$$

where $\tau = T - t$ is the time to maturity, $\phi = \pm 1$ is the call–put indicator and K is the strike price. The quantities P_1 and P_2 define the probability that the exchange rate X at maturity is greater than K under the spot and the risk-neutral measure, respectively. The spot delta of the European vanilla option is equal to $\phi e^{-r_f \tau} P_1$.

Assuming that the distribution of $\ln X_T$ at time t under the two different measures is determined uniquely by its characteristic function φ_j , for $j = 1, 2$, it is shown, in [15], that P_1 and P_2 can be expressed in terms of the inverse Fourier transformation

$$P_j = \frac{1}{2} + \frac{1}{\pi} \phi \int_0^\infty \Re \left[\frac{\exp(-iu \ln K) \varphi_j(u)}{iu} \right] du \quad (5)$$

The integration in equation (5) can be done using numerical integration methods such as Gauss–Laguerre integration or fast Fourier transform approximation. In [10], it is shown that the computational time of the fast Fourier transform approach to compute vanilla option prices is higher

compared to a numerical integration method with certain caching techniques.

The characteristic function is exponentially affine and available in closed form as

$$\varphi_2(u) = \exp(B(u) + A(u)v_t + iu \ln X_t) \quad (6)$$

The functions A and B arise as the solution of the so-called Riccati differential equations as shown in [8]. They are defined as follows:

$$A(u) = -iu(1 - iu) \frac{(1 - e^{-d(u)\tau})}{\gamma(u)} \quad (7)$$

$$B(u) = iu(r_d - r_f)\tau + \frac{\kappa\theta}{\sigma^2}(\kappa - iu\rho\sigma - d(u))\tau + \frac{2\kappa\theta}{\sigma^2} \ln \frac{2d(u)}{\gamma(u)} \quad (8)$$

with $d(u) = \sqrt{(\rho\sigma iu - \kappa)^2 + iu\sigma^2(1 - iu)}$ and $\gamma(u) = d(u)(1 + e^{-d(u)\tau}) + (\kappa - iu\rho\sigma)(1 - e^{-d(u)\tau})$. The characteristic function φ_1 has the same form as the function φ_2 , but with u replaced by $u - i$ and multiplied by a factor $\exp(-(r_d - r_f)\tau - X_0)$. This is due to the change from the spot to the risk-neutral measure in the derivation of φ_1 .

There exist several different representations of the characteristic function φ . In some formulations of φ , the characteristic function can become discontinuous if the multivalued complex logarithm contained in the integrand is restricted to the calculation of its principal branch, as is the case in many implementations. Wrong results of the value P_j may occur unless a rotation count algorithm is employed. For other representations of φ , stability for all choices of model parameters can be proved. Details can be found in [1].

Besides vanilla options, closed-form solutions for exotic options have been found for the volatility option, the correlation option, the exchange option, the forward start option, the American option, the discrete barrier option, and others. Numerical pricing of exotic options in the Heston model can be carried out by using conventional numerical methods such as Monte Carlo simulation [2, 13], finite differences [8], or an exact simulation method [4].

Calibration of Heston's Model

We realize the estimation by fitting the Heston model parameters to the smile of the current vanilla option market. Thereby, the choice of the loss function to minimize the differences between the model and market Black–Scholes-implied volatilities is crucial. Here, we decide to do a least-squared error fit over absolute values of volatilities, rather than minimizing over relative volatilities or option values.

For a fixed time to maturity τ , given market-implied volatilities $\sigma_1^{\text{market}}, \dots, \sigma_n^{\text{market}}$ and corresponding spot delta (premium unadjusted) values $\Delta_1, \dots, \Delta_n$, the calibration is set up as follows:

1. Before starting the optimization, we determine the strikes K_i corresponding to σ_i^{market} with

$$K_i = X_0 \exp \left\{ -\phi N^{-1}(\phi e^{r_f \tau} \Delta_i) \sigma_i^{\text{market}} \sqrt{\tau} + \left(r_d - r_f + \frac{1}{2}(\sigma_i^{\text{market}})^2 \right) \tau \right\} \quad 1 \leq i \leq n \quad (9)$$

which requires the inversion of the cumulative normal distribution function N .

2. The aim is to minimize the objective function M defined below. We repeat the steps (a)–(c) until a certain accuracy in the optimization routine is achieved.
 - a. We use the analytic formula in equation (4) to calculate the vanilla option values in the Heston model for the strikes $K_1, \dots, K_n$:

$$H_i(\kappa, \sigma, \theta, \rho, v_0) = \text{Vanilla}(\kappa, \sigma, \theta, \rho, v_0, \text{market data}, K_i, \phi) \quad (10)$$

- b. For $i = 1, \dots, n$, we compute all option values H_i in terms of Black–Scholes-implied volatilities $\sigma_i^{\text{model}}(\kappa, \sigma, \theta, \rho, v_0)$ by applying a root search.

c. The objective function is given as

$$\begin{aligned} M(\kappa, \sigma, \theta, \rho, v_0) \\ = \sum_{i=1}^n w_i [\sigma_i^{\text{market}} - \sigma_i^{\text{model}}(\kappa, \sigma, \theta, \rho, v_0)]^2 \\ + \text{penalty} \end{aligned} \quad (11)$$

The implementation of a penalty function *penalty* and some weights w_i may give the calibration routine some additional stability. There exist various choices for the penalty function. For example, in [14], it is suggested to penalize the retraction from the initial set of model parameters, but we may also use the penalty to introduce further constraints such as the condition $2\kappa\theta - \sigma^2 > 0$ to ensure that in subsequent simulations the volatility process cannot sojourn in zero. In addition, we could use the weights w_i to favor at-the-money (ATM) or out-of-the-money fits.

For the minimization, a great variety of either local or global optimizers in multidimensions could be used. Algorithms of Levenberg–Marquardt type are frequently used, because they utilize the least-squares form of the objective function. Since the objective function is usually not convex, there may exist many local extrema and the use of a computationally more expensive global (stochastic) algorithm, such as simulated annealing or differential evolution, in the calibration routine may be considered. From a practical point of view, taking the value of a short-dated implied volatility as an initial value for v_0 is a good start for the calibration. In light of parameter stability, the result of the previous (the day before) calibration could be used as an initial guess for the remaining parameters. Furthermore, to enhance the speed of calibration, it is suggested in [8] to fix the model parameter κ and run the calibration in only four dimensions, since the influence of the mean reversion is often compensated by a stronger volatility of variance σ . To ensure that the correlation parameter ρ attains values in $[-1, 1]$, we reparametrize with the function $2 \arctan(\rho)/\pi$.

Hedging

If volatility is introduced as a stochastic factor but cannot be traded, the market is incomplete. By

the introduction of a tradable market instrument $U(t, v, X)$, which depends on the volatility, the market can be completed and volatility risk can be hedged dynamically. In the Heston model, to make a portfolio containing the contingent claim $V(t, v, X)$ instantaneously risk free, the hedge portfolio has to consist of Δ_X units of the foreign currency and Δ_U units of the contingent claim $U(t, v, X)$, with

$$\Delta_X = \frac{\partial V}{\partial X} - \Delta_U \frac{\partial U}{\partial X} \quad \text{and} \quad \Delta_U = \frac{\partial V / \partial v}{\partial U / \partial v} \quad (12)$$

Common FX market instruments applicable for market completion and hedging are, on the one hand, ATM forward plain vanilla options for different maturities. On the other hand, for most of the FX markets risk reversals (RR) and butterflies (BF) are traded for certain maturities and strikes. These instruments are defined as^a

$$\text{RR}(T, \Delta) = \text{Call}(T, K_\Delta) - \text{Put}(T, K_{-\Delta}) \quad (13)$$

$$\begin{aligned} \text{BF}(T, \Delta) = \frac{1}{2} (\text{Call}(T, K_\Delta) + \text{Put}(T, K_{-\Delta})) \\ - \text{Call}(T, K_{\text{ATM}}) \end{aligned} \quad (14)$$

where K_Δ is the strike as given in equation (9), such that the corresponding plain vanilla option has a Black–Scholes delta of Δ . K_{ATM} denotes the ATM strike, which is often taken to be the strike generating a zero delta for a straddle in FX markets. Risk reversals and butterflies are quoted in Black–Scholes-implied volatilities instead of prices, that is, if v_Δ denotes the implied volatility of a call with strike K_Δ (analogously, $v_{-\Delta}$ for puts and v_{ATM}), the FX smile quotes are

$$v_{\text{RR}} = v_\Delta - v_{-\Delta} \quad \text{and} \quad v_{\text{BF}} = \frac{1}{2}(v_\Delta + v_{-\Delta}) - v_{\text{ATM}} \quad (15)$$

Since individual ATM options are liquidly traded, and therefore v_{ATM} is known, the volatilities v_Δ and $v_{-\Delta}$ can be calculated from v_{RR} and v_{BF} .

The quantities v_{RR} and v_{BF} relate to the skew and smile, respectively, of the implied volatility surface. This is schematically illustrated for $\Delta = 0.25$ in Figure 1.

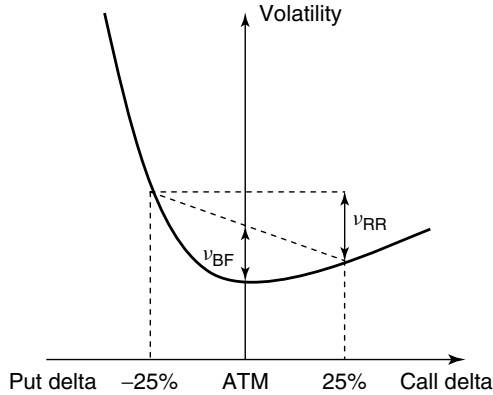

Figure 1 The meaning of v_{RR} and v_{BF} in the context of the implied volatility curve for a fixed maturity

Example

In this section, we give an example of the difference between Heston and Black–Scholes option prices. Thereby, we consider discrete down-and-out

put options written on the USD/JPY exchange rate. The option holder receives a vanilla put option payoff at maturity in 18 months as long as the FX rate does not fall below a given barrier B at the barrier fixing times in 6, 12, and 18 months. Otherwise, the option expires worthless. We compare ATM option prices for barriers of 10%, 50%, 60%, 70%, 80%, and 90% of the spot price.

For the valuation in the Heston model, we calibrate to European plain vanilla options with maturities of 1, 2, 3, 6, 9, 12, and 24 months and strikes with respect to 10% Δ put, 25% Δ put, ATM, 10% Δ call, and 25% Δ call for May 21, 2009 (Figure 2). The weights are set to 1 for ATM strikes, to 0.75 for 25% Δ strikes, and to 0.25 for 10% Δ strikes, since usually options with strikes far from the ATM forward are less liquidly traded. Figure 2(a) demonstrates that the market-implied volatilities (dots) are adequately matched by the calibrated model volatilities (circles connected by lines). Figure 2(b) shows the term structure of market-implied volatilities (dots) and calibrated implied volatilities (circles) for strikes with respect to 25% Δ call, ATM, and 25% Δ put (from

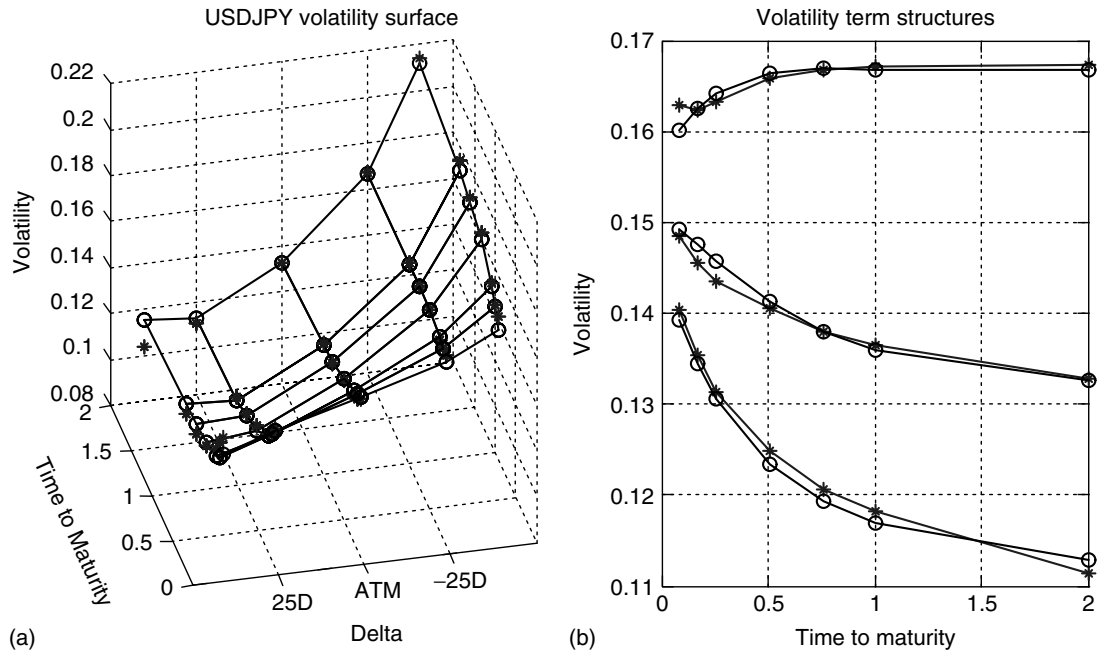

Figure 2 Implied volatilities of the Heston model fitted to market volatilities for USD/JPY with maturities of 1, 2, 3, 6, 9, 12, and 24 months and strikes for 10% Δ and 25% Δ put, ATM, 10% Δ , and 25% Δ call. The dots show the market volatilities and the circles the calibrated volatilities. (a) The whole volatility surface. (b) The implied volatility term structure for strikes 25% Δ call, ATM, and 25% Δ put (from bottom to top)

Table 2 Down-and-out put values with at-the-money strike and discrete monitoring at 6, 12, and 18 months

Barrier (% of spot)	90	80	70	60	50	10
Black–Scholes	0.8752	3.7068	5.7670	6.2663	6.3000	6.3012
Heston	0.6309	1.8723	3.1830	4.3376	5.2202	6.3023

The value of the corresponding plain vanilla put in the Heston model is given by 6.3060

bottom to top). The resulting model parameters are given by $\kappa = 0.2170$, $\theta = 0.0444$, $\sigma = 0.3410$, $\rho = -0.5927$, and $v_0 = 0.0228$.

As mentioned in the section Valuation of Options in the Heston Model, there exists a value function in (semi-) closed form for discrete barrier options in the Heston model. The distribution of the random variables $\ln X_{t_i}$ at the barrier fixing times t_i can be determined uniquely by the derivation of their joint characteristic function and with the application of Shephard's theorem given in [15] the required knock-out probabilities can be computed.

For the valuation in the Black–Scholes model, we use the interpolated ATM forward-implied volatility for plain vanilla options with a maturity of 18 months, which is $\sigma_{BS} = 0.1270$ in our example.

Finally, the FX spot trades at $X_0 = 94.43$, and the domestic and foreign interest rates for 18 months are given by $r_d = 0.0065$ and $r_f = 0.0139$. The resulting prices for the described options are shown in Table 2.

Comparing the prices, we can observe two effects. First, the Heston prices are lower than the corresponding Black–Scholes prices. This behavior might be in major part due to the fact that the Black–Scholes valuation uses a flat volatility, whereas the Heston model incorporates the whole volatility smile. Since the volatilities below the ATM strikes increase substantially (Figure 2), the knock-out probabilities also increase and the option prices drop. Second, the prices of Heston and Black–Scholes converge with decreasing barrier level. This appears reasonable, since the likelihood of a knock-out decreases more and more and the valuation finally results in put prices, which should be equal for both models in the case of a good calibration fit.

End Notes

^aThere exist different definitions for risk reversals and butterflyes in the literature with respect to sign and coefficients.

Foreign Exchange Basket Options

Quite often, corporate and institutional currency managers are faced with an exposure in more than one currency. Generally, these exposures would be hedged using individual strategies for each currency. These strategies are composed of spot transactions, forwards, and, in many cases, options on a single currency. Nevertheless, there are instruments that include several currencies, and these can be used to build a multicurrency strategy that is almost always cheaper than the portfolio of the individual strategies. As a leading example, we explain basket options in detail.^a

Basket Options

Basket options are derivatives based on a common base currency, say EUR and several other risky currencies. The option is actually written on the basket of risky currencies. Basket options are European options paying the difference between the basket value and the strike, if positive, for a basket call, or the difference between strike and basket value, if positive, for a basket put, respectively, at maturity. The risky currencies have different weights in the basket to reflect the details of the exposure.

For example, a basket call on two currencies USD and JPY pays off

$$\max \left(a_1 \frac{S_1(T)}{S_1(0)} + a_2 \frac{S_2(T)}{S_2(0)} - K; 0 \right) \quad (1)$$

at maturity T , where $S_1(t)$ denotes the exchange rate of EUR/USD and $S_2(t)$ denotes the exchange rate of EUR/JPY at time t , a_i the corresponding weights, and K the strike.

A basket option protects against a drop in both currencies at the same time. Individual options on each currency cover some cases, which are not protected by a basket option (shaded triangular areas in Figure 1) and that is why they cost more than a basket.

The ellipsoids connect the points that are reached with the same probability assuming that the forward prices are at the center.

Pricing Basket Options

Basket options should be priced in a consistent way with plain vanilla options. Hence the basic model assumption is a lognormal process for the individual correlated basket components. A decomposition into uncorrelated components of the exchange rate processes

$$dS_i = \mu_i S_i dt + S_i \sum_{j=1}^N \Omega_{ij} dW_j \quad (2)$$

is the basis for pricing. Here μ_i denotes the difference between the foreign and the domestic interest rate of the i th currency pair and dW_j the j th component of independent Brownian increments. The covariance matrix is given by $C_{ij} = (\Omega \Omega^T)_{ij} = \rho_{ij} \sigma_i \sigma_j$. Here σ_i denotes the volatility of the i th currency pair and ρ_{ij} the correlation coefficients.

Exact Method

Starting with the uncorrelated components, the pricing problem is reduced to the N -dimensional integration of the payoff. This method is accurate but rather slow for more than two or three basket components.

A Simple Approximation

A simple approximation method assumes that the basket spot itself is a lognormal process with drift μ and volatility σ driven by a Wiener Process $W(t)$:

$$dS(t) = S(t)[\mu dt + \sigma dW(t)] \quad (3)$$

with solution

$$S(T) = S(t)e^{\sigma W(T-t) + (\mu - 1/2\sigma^2)(T-t)} \quad (4)$$

given we know the spot $S(t)$ at time t . It is a fact that the sum of lognormal processes is not lognormal itself, but as a crude approximation, it is certainly a quick method that is easy to implement. To price the basket call, the drift and the volatility of the basket spot need to be determined. This is done by matching the first and second moment of the basket spot with the first and second moment of the lognormal model for the basket spot. The moments of lognormal spot are

$$\begin{aligned} E(S(T)) &= S(t)e^{\mu(T-t)} \\ E(S(T)^2) &= S(t)^2 e^{(2\mu + \sigma^2)(T-t)} \end{aligned} \quad (5)$$

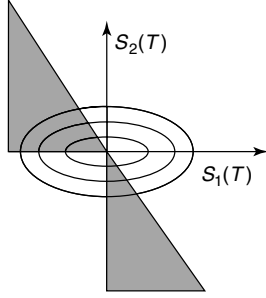

Figure 1 Basket-payoff and contour lines for probabilities

We solve these equations for the drift and volatility:

$$\begin{aligned}\mu &= \frac{1}{T-t} \ln \left(\frac{E(S(T))}{S(t)} \right) \\ \sigma &= \sqrt{\frac{1}{T-t} \ln \left(\frac{E(S(T)^2)}{E(S(T))^2} \right)}\end{aligned}\quad (6)$$

In these formulae we now use the moments for the basket spot:

$$\begin{aligned}E(S(T)) &= \sum_{i=1}^N \alpha_i S_i(t) e^{\mu_i(T-t)} \\ E(S(T)^2) &= \sum_{i,j=1}^N \alpha_i \alpha_j S_i(t) S_j(t) \\ &\quad \times e^{(\mu_i + \mu_j + \sum_{k=1}^N \Omega_{ki} \Omega_{jk})(T-t)}\end{aligned}\quad (7)$$

The pricing formula is the well-known Black–Scholes–Merton formula for plain vanilla call options:

$$\begin{aligned}v(0) &= e^{-r_d T} (F \mathbf{N}(d_+) - K \mathbf{N}(d_-)) \\ F &= S(0) e^{\mu T} \\ d_{\pm} &= \frac{1}{\sigma \sqrt{T}} \left(\ln \left(\frac{F}{K} \right) \pm \frac{1}{2} \sigma^2 T \right)\end{aligned}\quad (8)$$

Here $\mathbf{N}$ denotes the cumulative normal distribution function and r_d the domestic interest rate.

A More Accurate and Equally Fast Approximation

The previous approach can be taken one step further by introducing one more term in the Itô–Taylor

expansion of the basket spot, which results in

$$\begin{aligned}v(0) &= e^{-r_d T} (F \mathbf{N}(d_1) - K \mathbf{N}(d_2)) \\ F &= \frac{S(0)}{\sqrt{\eta}} e^{(\mu - \lambda/2 + (\lambda \sigma^2/2(\eta)))T} \\ d_2 &= \frac{\sigma - \sqrt{\sigma^2 + \lambda \left((1 + (\lambda/\eta)) \sigma^2 T - 2 \ln(F \sqrt{\eta}/K) \right)}}{\sqrt{T} \lambda} \\ d_1 &= \sqrt{\eta} d_2 + \frac{\sigma \sqrt{T}}{\sqrt{\eta}}\end{aligned}\quad (9)$$

where $\eta = 1 - \lambda T$

The new parameter λ is determined by matching the third moment of the basket spot and the model spot. For details, see [1].

Most remarkably, this major improvement in the accuracy only requires a marginal additional computation effort.

Correlation Risk

Correlation coefficients between market instruments are usually not obtained easily. Either historical data analysis or implied calibrations need to be done. However, in the foreign exchange (FX) market, the cross instrument is traded as well. For instance, in the example above, USD/JPY spot and options are traded, and the correlation can be determined from this contract. In fact, denoting the volatilities as in the tetrahedron (Figure 2), we obtain formulae for the correlation coefficients in terms of known market implied volatilities:

$$\begin{aligned}\rho_{12} &= \frac{\sigma_3^2 - \sigma_1^2 - \sigma_2^2}{2\sigma_1\sigma_2} \\ \rho_{34} &= \frac{\sigma_1^2 + \sigma_6^2 - \sigma_2^2 - \sigma_5^2}{2\sigma_3\sigma_4}\end{aligned}\quad (10)$$

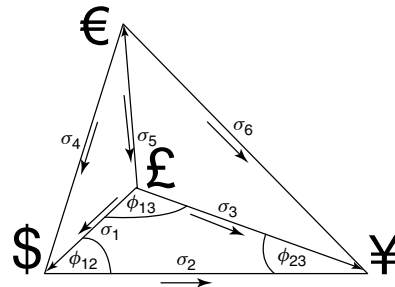

Figure 2 Currency tetrahedron including cross contracts

Table 1

EUR/USD	10.5%
EUR/GBP	7.5%
EUR/JPY	10.0%

FX implied volatilities for three-month at-the-money vanilla options as of November 23, 2001. *Source:* Reuters

This method also allows hedging correlation risk by trading FX implied volatility. For details see [1].

Practical Example

To find out how much one can save using a basket option, we take EUR as a base currency and consider a basket of three currencies USD, GBP, and JPY. For the volatilities, we take the values in Table 1.

The resulting correlation coefficients are given in Table 2.

The amount of option premium one can save using a basket call rather than three individual call options is illustrated in Table 3.

The amount of premium saved essentially depends on the correlation of the currency pairs (Figure 3). In Figure 3, we take the parameters of the previous scenario, but restrict ourselves to the currencies USD and JPY.

Upper Bound by Vanilla Options

It is actually clear that the price of the two vanilla options in the previous example is an upper bound of the basket option price. It seems intuitively clear that for a correlation of 100% the price is the same.

Table 3

Base currency	EUR	Interest rate	4.0%
Nominal in EUR	39 007	Strike K	1

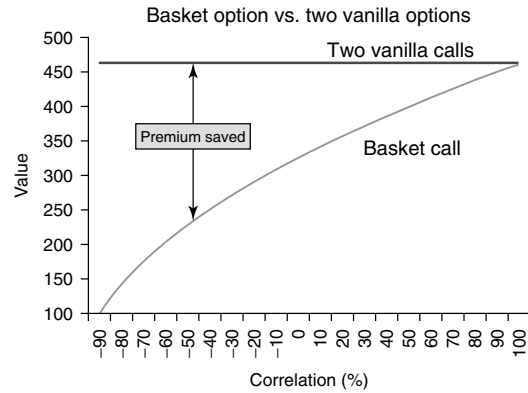

Figure 3 Premium of basket option versus premium of option strategy depending on the correlation

Surprisingly, this is just the case if a specific relation between the strike of the individual options and their volatilities is satisfied. The basket strike has to satisfy

$$K = a_1 \frac{K_1}{S_1(0)} + a_2 \frac{K_2}{S_2(0)} \quad (11)$$

Table 2

	GBP/USD (%)	USD/JPY (%)	GBP/JPY (%)	EUR/USD (%)	EUR/GBP (%)	EUR/JPY (%)
GBP/USD	100	-47	42	71	-19	27
USD/JPY	-47	100	60	-53	-18	45
GBP/JPY	42	60	100	10	-36	71
EUR/USD	71	-53	10	100	55	52
EUR/GBP	-19	-18	-36	55	100	40
EUR/JPY	27	45	71	52	40	100

FX implied three-month correlation coefficients as of Nov 23, 2001

which leads to the natural choice

$$K_i = K \frac{S_i(0)}{a_1 + a_2} \quad (12)$$

Each strike K_i satisfies the above constraint by choosing

$$K_i = S_i(0)e^{(\mu_i + 1/2\sigma_i^2)T + \chi\sigma_i\sqrt{T}} \quad (13)$$

for some arbitrary, but common χ for all basket components.

Smile Adjustment

For the pricing method, described there is no smile considered. Given the volatility smile for vanilla options, $\sigma_i(K, T)$, with the same maturity as the basket option, the implied density P for each currency pair in the basket can be derived from vanilla prices V .

$$P(K, T) = e^{rT} \partial_{KK} V(K, \sigma_i(K, T)) \quad (14)$$

A mapping $\varphi(w)$ can be derived that maps the Gaussian random numbers to smile-adjusted random numbers for each currency pair. The implicit construction solves the problem for the probability of the mapped Brownian to be the same as the smile-implied probability.

Using Monte Carlo simulation to price vanilla options using the mapping, it can be shown that in the limit, the derived prices are perfectly in line with the smile. The formula for the Monte Carlo simulation for a realization of a Brownian w is given by

$$S_i(0, w) = S_i(0)e^{(\mu_i + 1/2\sigma_i^2)T + \varphi(w)\sigma_i\sqrt{T}} \quad (15)$$

To price the basket option using the smile in Monte Carlo, a sequence of independent random numbers is used. These random numbers are correlated using the square-root matrix Ω as above and these are fed into the individual mappings, hence generating the simulated spot at the basket maturity. Evaluating the payoff and averaging will generate a smile-adjusted price (see Table 4). Black–Scholes prices and smile-adjusted prices are shown next to each other for a direct comparison.

Conclusion

Many corporate portfolios are exposed to multicurrency risk. One way to turn this fact into an advantage

Table 4

Base currency	EUR		
Nominal in EUR	39 007		
Currencies	USD	JPY	GBP
Nominals	29%	30%	41%
RR 25d	−0.25%	−4.30%	1.10%
Fly 25d	0.30%	0.17%	0.25%
BS-values (in EUR)	235	227	233
Smile values (in EUR)	233	168	278
Basket smile value	554		
Sum of individuals (smile)	680		
Basket value	563		
Sum of individuals	695		

is to use multicurrency hedge instruments. We have shown that basket options are convenient instruments protecting against exchange rates of most of the basket components changing in the *same* direction. A rather unlikely market move of half of the currencies' exchange rates in *opposite* directions is not protected by basket options, but when taking this residual risk into account, the hedging cost is reduced substantially. The smile impact on the basket value can be calculated rather easily without referring to a specific model, because the product is path-independent.

Call Options

Call options appeared as rights to buy an underlying traded asset for a prespecified price, named the *option strike* or the *exercise price*, at a prespecified future date named the *option expiry* or the *maturity*. Put options are analogous rights to sell an underlying asset. For strike K and maturity T with the underlying asset trading at maturity for S , the call expires unexercised if S is below K while the put expires unexercised if S is above K . On exercise, the value of the call option is $S - K$ while that of the put option is $K - S$. Hence, one may write the payoffs at maturity to the call and put options as $(S - K)^+$ and $(K - S)^+$, respectively. More generally, one may define a call or put payoff for any underlying random variable, which need not be a traded asset, for which the realized value at maturity is known to be A , as $(A - K)^+$ and $(K - A)^+$, respectively.

When call and put options trade before the maturity, on an underlying uncertainty resolved at maturity for various strikes K , with prices determined in markets at time $t < T$ as $c(t, K, T)$, $p(t, K, T)$, respectively, we have an options market for the underlying risk. Such markets provide a rich source of opportunities for holding the underlying asset or risk while simultaneously providing information on the prices of these risks. With regard to the opportunities, they make it possible to hold any function $f(A)$ of the underlying risk *via* a portfolio of put and call options. This fact is easily demonstrated as follows [2].

Let $f(A)$ be the function we wish to hold. We note that

$$\begin{aligned} f(A) &= f(a) + \mathbf{1}_{A>a} \int_a^A f'(u) du - \mathbf{1}_{a>A} \int_A^a f'(u) du \\ &= f(a) + \mathbf{1}_{A>a} \int_a^A \left[f'(a) + \int_a^u f''(v) dv \right] du \\ &\quad - \mathbf{1}_{a>A} \int_A^a \left[f'(a) - \int_u^a f''(v) dv \right] du \\ &= f(a) + f'(a)(A - a) + \mathbf{1}_{A>a} \\ &\quad \times \int_a^A dv f''(v)(A - v) \\ &\quad + \mathbf{1}_{a>A} \int_A^a dv f''(v)(v - A) \end{aligned}$$

$$\begin{aligned} &= f(a) + f'(a)(A - a) + \mathbf{1}_{A>a} \\ &\quad \times \int_a^\infty dv f''(v)(A - v)^+ \\ &\quad + \mathbf{1}_{a>A} \int_0^a dv f''(v)(v - A)^+ \end{aligned} \quad (1)$$

On the right hand side, we have a position in a bond with face value given by the constant term, a position in the underlying risk of $f'(a)$ and a position in puts struck below a and calls struck above a at strike v of $f''(v)$.

With regard to the information content of the market prices, we consider Breeden and Litzenberger [1], who showed how one may extract the pricing density at time $t < T$, $p(t, A)$ for the underlying risk from market option prices. By definition, we have

$$c(t, K, T) = e^{-r(T-t)} \int_K^\infty (A - K) p(t, A) dA \quad (2)$$

where r is the interest rate prevailing at time t for the maturity $(T - t)$. We may differentiate twice with respect to the strike to get

$$p(t, K) = e^{r(T-t)} \frac{\partial^2 c(t, K, T)}{\partial K^2} \quad (3)$$

In the case when the underlying risk is an asset price with a specific dynamics with exposure to a Brownian motion with a space–time deterministic volatility (*see Local Volatility Model*) as postulated by Dupire [6] plus a compensated jump martingale with a space–time deterministic arrival rate of jumps and a fixed dependence of the arrival rate on the jump size, one may extract information on the dynamics from market prices. Here, we follow Carr *et al.* [4]. Let $(S(t), t > 0)$ denote the path of the stock price, where r is the interest rate, η the dividend yield, $\sigma(S, t)$ the deterministic space–time volatility function, $(W(t), t > 0)$ a Brownian motion, $m(dx, ds)$ the integer-valued counting measure associated with the jumps in the logarithm of the stock price, $a(S, t)$ the deterministic space–time jump arrival rate, and $k(x)$ the Lévy density across jump sizes x . The dynamics for the stock price may be written as

$$\begin{aligned} S(t) &= S(0) + \int_0^t S(u_-)(r - \eta) du \\ &\quad + \int_0^t S(u_-)\sigma(S(u_-), u) dW(u) \end{aligned}$$

$$\begin{aligned}
& + \int_0^t \int_{-\infty}^{\infty} S(u_-) (e^x - 1) (m(dx, du) \\
& - a(S(u_-), u)k(x) dx du) \quad (4)
\end{aligned}$$

We now apply a generalization of Itô's lemma to convex functions known as the *Meyer–Tanaka formula* (see, e.g., [5, 7, 8] for the specific formulation below) to the call option payoff at maturity to obtain

$$\begin{aligned}
(S(T) - K)^+ &= (S(0) - K)^+ + \int_0^T \mathbf{1}_{S(u_-) > K} dS(u) \\
&+ \frac{1}{2} \int_0^T \delta_K(S(u_-)) \sigma^2 \\
&\times (S(u), u) S^2(u) du \\
&+ \sum_{u \leq T} \mathbf{1}_{S(u_-) > K} (K - S(u))^+ \\
&+ \mathbf{1}_{S(u_-) < K} (S(u) - K)^+ \quad (5)
\end{aligned}$$

The second integral denotes the value at K of the continuous local time L_T^a ; $a \in \mathbb{R}$, which is globally defined for every bounded Borel function f , as $\int_{-\infty}^{\infty} f(a) L_T^a da = \int_0^T f(S(u_-)) d\langle S^c \rangle_u$, where $d\langle S^c \rangle_u = \sigma^2(S(u), u) S^2(u) du$, and is applied here formally to the Dirac measure $f(a) = \delta_K(a)$. The last term, which is the discontinuous component of local time at level K , is made up of just the crossovers, whereby one receives $S(u) - K$ on crossing the strike into the money, whereas one receives $(K - S(u))$ on crossing the strike out of the money.

Computing expectations on both sides of equation (5) and introducing $q(\Sigma, u)$, the transition density that the stock price is Σ at time u given that at time 0 it is at $S(0)$, we may write the call price function at time zero as

$$\begin{aligned}
e^{rT} C(K, T) &= (S(0) - K)^+ \\
&+ \int_0^T \int_K^{\infty} dY q(Y, u) Y (r - \eta) du \\
&+ \frac{1}{2} \int_0^T q(K, u) \sigma^2(K, u) K^2 du \\
&+ \int_0^T \int_K^{\infty} dY q(Y, u) a(Y, u) \\
&\times \int_{\ln(\frac{K}{Y})}^{\ln(\frac{K}{Y})} (K - Y e^x) k(x) dx du
\end{aligned}$$

$$\begin{aligned}
&+ \int_0^T \int_0^K dY q(Y, u) a(Y, u) \\
&\times \int_{\ln(\frac{K}{Y})}^{\infty} (Y e^x - K) k(x) dx du \quad (6)
\end{aligned}$$

Now differentiating equation (6) with respect to T , we get

$$\begin{aligned}
r e^{rT} C + e^{rT} C_T &= (r - \eta) \int_K^{\infty} q(Y, T) Y dY \\
&+ \frac{\sigma^2(K, T) K^2}{2} q(K, T) \\
&+ \int_K^{\infty} dY Y q(Y, T) a(Y, T) \int_{-\infty}^{\ln(\frac{K}{Y})} \left(e^{\ln(\frac{K}{Y})} - e^x \right) \\
&\times k(x) dx + \int_0^K dY Y q(Y, T) a(Y, T) \\
&\times \int_{\ln(\frac{K}{Y})}^{\infty} \left(e^x - e^{\ln(\frac{K}{Y})} \right) k(x) dx \quad (7)
\end{aligned}$$

We now isolate C_T on the left, using some elementary properties of the relationship between call prices and the pricing density. In particular, we note

$$e^{-rT} \int_0^{\infty} Y q(Y, T) dY = C - K C_K \quad (8)$$

$$e^{-rT} q(K, T) = C_{KK} \quad (9)$$

and obtain

$$\begin{aligned}
C_T &= -\eta C - (r - \eta) K C_K \\
&+ \frac{\sigma^2(K, T) K^2}{2} C_{KK} \\
&+ \int_K^{\infty} dY Y C_{YY} a(Y, T) \\
&\times \int_{-\infty}^{\ln(\frac{K}{Y})} \left(e^{\ln(\frac{K}{Y})} - e^x \right) k(x) dx \\
&+ \int_0^K dY Y C_{YY} a(Y, T) \\
&\times \int_{\ln(\frac{K}{Y})}^{\infty} \left(e^x - e^{\ln(\frac{K}{Y})} \right) k(x) dx \quad (10)
\end{aligned}$$

We may define the function

$$\begin{aligned}\psi(x) &= \mathbf{1}_{x < 0} \int_{-\infty}^x (e^x - e^s)k(s) ds \\ &\quad + \int_x^{\infty} (e^s - e^x)k(s) ds\end{aligned}\quad (11)$$

and then write

$$\begin{aligned}C_T &= -\eta C - (r - \eta)KC_K \\ &\quad + \frac{\sigma^2(K, T)K^2}{2}C_{KK} \\ &\quad + \int_0^{\infty} C_{YY}Ya(Y, T)\psi\left(\ln\left(\frac{K}{Y}\right)\right)dY\end{aligned}\quad (12)$$

When there are no jumps in the process for X and $\psi \equiv 0$, equation (12) is identical to the formula in [6] for local volatility (see **Dupire Equation**). In the opposite case, when there is no continuous martingale component, we have the following result:

$$\begin{aligned}C_T + \eta C + (r - \eta)KC_K \\ = \int_0^{\infty} C_{YY}Ya(Y, T)\psi\left(\ln\left(\frac{K}{Y}\right)\right)dY\end{aligned}\quad (13)$$

It is now useful to rewrite equation (13) in terms of $k = \ln(K)$, $y = \ln(Y)$, and $c(k, T) = C(e^k, T)$. With this substitution, we may rewrite equation (12) as

$$\begin{aligned}c_T + \eta c + \left(r - \eta + \frac{\sigma^2(e^k, T)}{2}\right)c_k \\ - \frac{\sigma^2(e^k, T)}{2}c_{kk} = \int_{-\infty}^{\infty} b(y, T)\psi_e(k - y)dy\end{aligned}\quad (14)$$

where $b(y, T) = e^{2y}C_{YY}a(e^y, T)$. The forward speed function, $a(Y, T)$, may be identified as

$$a(Y, T) = \frac{b(\ln(Y), T)}{Y^2 C_{YY}}\quad (15)$$

For specific Lévy measures, the convolution equation (14) may be solved in closed form to yield explicit solutions for the Markov process from data on option prices (see **Fourier Methods in**

Options Pricing; Partial Integro-differential Equations (PIDEs)).

Apart from spanning all functions of the underlying risk and providing us with information on the possible dynamic movements of the stock price consistent with market option prices, we have the question of understanding the absence of arbitrage between option prices. This question was addressed in [3], where it was shown that if call spread, butterfly spread, and calendar spread arbitrages are excluded then the option quotes are free of static arbitrage. It is, therefore, important to document the three arbitrages that need to be checked. For a call spread, we have the inequality for two strikes $K_1 < K_2$ for a fixed maturity T :

$$\frac{c(K_1, T) - c(K_2, T)}{K_2 - K_1} < 1$$

For a butterfly spread, we have three strikes $K_1 < K_2 < K_3$ and a fixed maturity T for which we must have

$$\begin{aligned}c(K_1, T) - \left(\frac{K_3 - K_1}{K_3 - K_2}\right)c(K_2, T) \\ + \frac{K_2 - K_1}{K_3 - K_2}c(K_3, T) \geq 0\end{aligned}\quad (16)$$

Finally, the calendar spread inequality requires that for two maturities $T_1 < T_2$ and strike K

$$c(K, T_2) \geq c(K e^{-r(T_2 - T_1)}, T_1)\quad (17)$$

Similar results hold for put options *via* put-call parity that asserts in the case of a stock

$$p(K, T) = c(K, T) + K - S(0)e^{-\eta T}\quad (18)$$

The call spread inequality approximates the probability that the stock exceeds K_1 when we take K_2 close to and above K_1 . The butterfly spread inequality guarantees the existence of a positive pricing density and the calendar spread inequality arranges these densities to be increasing in the convex order with respect to the maturity. When the underlying risk is not a traded asset as occurs, for example, for options on the VIX index where the underlying is the price of the one month variance swap, we lose the calendar spread inequality and the requisite densities are not increasing in the convex order. One can check that on

most days VIX call option prices when deflated by the forward VIX are increasing in maturity for given strikes and we have an empirical increase in the convex order, but there are days when this monotonicity is lost. The conditions for VIX option surfaces to be free of arbitrage are, therefore, not as clear as they are for an underlying stock or a stock index.

Barrier Options

Barrier options are vanilla options with path-dependent payoffs, that is, the payoff is not only a function of stock level relative to option strike but also dependent upon whether or not the stock reaches certain prespecified barrier level before maturity. An example will illustrate the idea. Suppose an investor is long an up-and-in at-the-money call option on the S&P 500 index with barrier level at 110% of the initial S&P 500 index level. Before maturity, if the index never reaches 110% of the initial index level, the option never gets knocked in. The investor receives nothing at maturity. However, if the index level reaches 110% at some point before maturity, the investor receives a payoff identical to a vanilla at-the-money call option at maturity. In the latter scenario, the option is “knocked in” on the day when the index reaches 110% level.

There are many types of barrier options. We discuss two common ones, that is, knock-out and knock-in barrier options. For knock-out barrier options, the option will be knocked out and become worthless if the underlying asset crosses a prespecified barrier level. For knock-in barrier options, the barrier option will be knocked in and become a vanilla option only if the underlying asset crosses the prespecified level before maturity. The example used earlier is a knock-in barrier option.

Depending upon the barrier level relative to the initial underlying asset level, we can have an “up” barrier or a “down” barrier. If the barrier is above the initial underlying asset level, it is called an *up barrier*. If the barrier is below the initial underlying asset level, it is called a *down barrier*. Together, we can have four different variations of barrier options, that is, up-and-in, up-and-out, down-and-in, and down-and-out options. Table 1 shows these four variations schematically.

Basic Features

Up-and-in Call/Up-and-in Put

This is the first kind of knock-in barrier options. The up-and-in barrier option has a knock-in barrier level, which is higher than the initial underlying asset level. Before maturity, if the underlying asset goes above

the barrier level, the barrier option will be knocked in and become a vanilla option. Otherwise, the barrier option will expire worthless at maturity. Up-and-in calls are more common. This is because, when the underlying asset increases to knock-in barrier level, it would most likely stay above the initial underlying asset level. Therefore, call options will be more likely be in the money at maturity than put options. Bullish investors can buy up-and-in call options and pay a lower premium than that on the vanilla call options. This makes the on up-and-in calls more leveraged than vanilla calls.

Down-and-in Call/Down-and-in Put

The down-and-in barrier option has a knock-in barrier level, which is below the initial underlying asset level. Before the maturity, if the underlying asset goes below the barrier level the barrier option will be knocked in and become a vanilla option. Otherwise, the barrier option will expire worthless at maturity. Down-and-in puts are more common in this case. Bearish investors can buy down-and-in puts and pay a lower premium than that on the vanilla put options.

Up-and-out Call/Up-and-out Put

This is the first kind of knock-out barrier options. The up-and-out barrier option has a knock-out barrier level above the initial underlying asset level. Before maturity, if the underlying asset crosses the barrier level, the option will be knocked out and become worthless. Otherwise, the barrier option will just be a vanilla option. A bearish investor would buy up-and-out puts to achieve more leverage by paying a lower premium than that on vanilla puts.

Down-and-out Call/Down-and-out Put

The down-and-out barrier option has a knock-out barrier level below the initial underlying asset level. Before maturity, if the underlying asset goes below the barrier level, the option will be knocked out and become worthless. A bullish investor would buy down-and-out calls to achieve more leverage by paying a lower premium than that on vanilla calls.

Some Variations

With increased popularity of barrier options and growth of its market, some other features are being

2 Barrier Options

Table 1 Common barrier types

	Knock in	Knock out
Up barrier	Up-and-in call	Up-and-out call
	Up-and-in put	Up-and-out put
Down barrier	Down-and-in call	Down-and-out call
	Down-and-in put	Down-and-out put

introduced to better meet investors' needs. In the following, we discuss briefly some of the most popular variations to basic knock-in/knock-out barrier options.

Rebates

It is fairly common that a knock-out barrier option pays a rebate on a knock-out event to compensate the investor for the loss of the option. The rebate is typically a small amount and paid either immediately or deferred to the maturity. For knock-in barrier options, a rebate will be paid out at maturity if the barrier is never knocked in.

Double Barrier

A double barrier option is another variation that has two barriers, typically one up barrier and the other a down barrier. For example, investors seeking high leverage would consider double knock-out barrier options if they believe changes in the underlying asset level would be within a narrow range. The double knock-out barrier option would become worthless if the underlying asset drops below the down barrier or rises above the up barrier before maturity. Because of that, the double knock-out barrier option costs less than the single knock-out barrier option and thus provides more leverage.

Another popular variation of double barrier is the knock-in option with a knock-out barrier. The knock-in barrier option can be knocked out either before or after the option is knocked in. If the option can be knocked out even before the option is knocked in, this is called *knock-out dominant barrier option*. Again, this type of double barrier options provides more leverage than a single barrier option because it costs less than the single knock-in barrier option.

Discrete Barrier

The barrier specification varies from contract to contract. Many barrier options have the so-called continuous barrier or intraday barrier. This means that the barrier event can be triggered any time during intraday trading hours. However, some barrier options only allow the barrier event to be triggered by the end-of-day closing price. This is called *discrete barrier*. More generally, a discrete barrier is defined as any barrier type other than the continuous barrier.

American Style Exercise

Although it is not very common, there are a few types of barrier options that have American exercise feature. One example would be a six-month at-the-money call option with installment premium, that is, the premium would be paid monthly instead of a lump sum upfront. The knock-out barrier is at 90% of the initial underlying asset level. The option will be knocked out if the underlying asset drops below the knock-out barrier level before maturity. In addition, the option would be terminated automatically if the investor stops paying the installment premium on monthly reset dates. This installment feature provides more flexible financing for investors because they pay the premium over a period of time instead of paying the lump sum up front. It also allows investors to re-evaluate the market condition and decide if it is optimal to continue the knock-out option or terminate it.

Valuation of Barrier Options

Barrier options are less expensive than vanilla options because of the possibility that the barrier option would be knocked out or knocked in. There are many publications on how to price barrier options (see [2, 7] for a good summary). In general, the valuation of barrier options needs to take into account stock-level dependency of volatility dynamics, that is, local volatility surface. This requires using numerical methods like partial differential equations (see **Finite Difference Methods for Barrier Options**) or Monte Carlo simulation. In certain situations, the barrier options can be priced by using the static replication method (see [3, 4]).

In-Out Parity

Similar to put-call parity for the vanilla options, there is an interesting relationship between knock-in and knock-out barrier option. Using call options as example, an up-and-out call is complimentary to an up-and-in call if both have the same strike and barrier level. A portfolio of one up-and-in call and one up-and-out call will have the same payoff at maturity as a vanilla call option. The reason is simple. If the underlying asset stays below the barrier level before maturity, the up-and-in call will become worthless and the up-and-out call will become a vanilla call. On the other hand, if the underlying asset rises above the barrier level, the up-and-out call will become worthless and the up-and-in call will become a vanilla call. Therefore, for any given scenario of the underlying asset path before maturity, the portfolio will always have the same payoff as a vanilla call. The sum of an up-and-in call and an up-and-out call is the same as a vanilla call. This is so-called in-out parity for barrier options and applies to both the put and call options in the absence of rebates.

Constant Volatility

In the limit of constant volatility, Merton [5] provided the first analytical formula for a down-and-out call option. Later on, Reiner and Rubinstein [6] extended the formula for all eight combinations of barriers (*see Pricing Formulae for Foreign Exchange Options*).

Adjustment for Discrete Barrier

Often, the barrier option has a discrete barrier schedule but the exact valuation is only available for the case of continuous barrier. In the constant volatility

case, Broadie *et al.* [1] proposed that, by adjusting the barrier level in the continuous barrier option valuation, one would obtain a good approximation of the discrete barrier option value. The adjustment to the barrier level is prescribed by the following formula:

$$X_{\text{adj}} = Xe^{\alpha\sigma\sqrt{T/m}} \quad (1)$$

where α is 0.5826 for an “up” barrier and -0.5826 for a “down” barrier, m is the number of discrete samples of the underlying asset price over the term T of the barrier option, and σ is the constant volatility.

Corridor Options

Occupation time derivatives are debt securities that came into existence in 1993 and have attracted some attention from investors and researchers. A defining characteristic of these contracts is a payoff that depends on the time spent by the underlying asset in some predetermined region. Typical specifications consist in interest payments that are proportional to the time in which a reference index rate (most commonly the Libor rate) lies inside a given range. In return for the drawback that no interest will be paid for the time the corridor is left, they offer higher rates than comparable standard products, like floating rate notes. Various claims with features of this type have been studied and have been popularized with different names such as corridor bond or option, range note, range floater, range accrual note, LIBOR range note, fairway bond,^a and hamster option.^b The most common underlyings are stock indices, foreign currencies, and interest rates, such as LIBOR or swap rates. Also spread range notes are common. Range notes pay a coupon proportional to the number of days in which the difference between two interest rates (e.g., 10-year swap rate *versus* 30-year swap rate) is positive. Thus while the value of an interest range note depends on the volatility of the level of the term structure, the value of a range note depends on the volatility of the slope of the term structure. This makes it important to model the correlation of interest rates with different maturities accurately.

One of the most popular structures is the accrual note, typically of one- or two-year maturity, which offers a coupon calculated by the number of days in which three-month dollar Libor, for example, falls inside a predefined range. On these days, the note will typically offer a preassigned spread over the relevant treasury bond. When Libor is outside the range, the payout is zero. The note effectively provides a way for investors to sell volatility, but the binary structure protects them from the unlimited downside that would accompany similar strategies, such as writing a floor and cap on the range. Corridor products offer investors enhanced yield if they have a strong view that rates will stay within a range, and often they are structured to reflect an investor's view that is contrary to a particular forward-rate curve. In its simplest form, the payoff of the corridor bond can

be seen as the sum of the payoffs of digital options expiring on successive days.

Payoff

Let t be the current time (measured in years) and let $0 = T_0 < t < T_1, \dots, T_j, \dots, T_n$ be the payment dates of the coupons $\phi(T_j)$ (T_0 is the last date at which a payment occurred). Let $D(T_j, T_{j+1})$ be the number of days in the coupon period and let $T_{j,i}$ be the date corresponding to i days after date T_j , that is, $T_{j,i} = T_j + i/365$, $i = 1, \dots, D(T_j, T_{j+1})$. Let x_l and x_u be the lower and upper bound of the range (the prespecified range for each observed date can vary daily or across different compounding periods). Finally let $X(t)$ be the value of the reference index at time t . Sometimes, X represents a stock index or a foreign currency rate, and sometimes is taken to be a LIBOR rate of a preassigned tenor (in this case $X(t) = L(t, t + \theta)$, where L is the LIBOR rate and θ is its tenor) or the spread of two swap rates with different maturities.

The range note can have a fixed and a floating version. For a range note, the value of the coupon paid at time T_{j+1} is equal to

$$\phi(T_{j+1}) = C_{j+1} \times \frac{H(T_j, T_{j+1})}{D(T_j, T_{j+1})} \quad (1)$$

where C_{j+1} represents the annual coupon rate for the $(j+1)$ th compounding period and is given by

$$C_{j+1} = \begin{cases} C & \text{fixed range note,} \\ X(T_j) + \Delta & \text{delayed floating range note,} \end{cases} \quad (2)$$

where C is a constant and Δ is the spread to be added to the reference rate, and

$$H(T_j, T_{j+1}) = \sum_{i=1}^{D(T_j, T_{j+1})} 1_{[x_l, x_u]}(X(T_{j,i})) \quad (3)$$

where $1_A(x)$ is the indicator function of the set A , that is, $1_A(x) = 1$ if $x \in A$, otherwise $1_A(x) = 0$. Here the term *delayed* refers to the fact that the option maturity (or reset date) T_j anticipates the payment date T_{j+1} . Sometimes, instead of having the delayed floating range note we have the *in-arrears* floating range note where the coupon is set equal to

$$C_{j+1} = X(T_{j+1}) + \Delta \quad (4)$$

that is, the coupon payment depends on the level of the reference rate at the current coupon payment date (maturity and payment date coincide).

Sometimes, a minimum coupon clause is also included, so that the coupon amounts to

$$\phi(T_{j+1}) = \max\left(C_{j+1} \times \frac{H(T_j, T_{j+1})}{D(T_j, T_{j+1})}, K\right) \quad (5)$$

The standard contract is the fixed rate range note if the underlying is a stock index or a foreign currency and the delayed floating range note if the underlying is a LIBOR rate.

Pricing

In this section, we discuss the pricing problem of the corridor contracts described earlier.

Underlying is a Stock Index

In this case, we model the underlying according to the Geometric Brownian Motion (GBM) model, that is,

$$dX(t) = (r - q)X(t) dt + \sigma X(t) dW(t), X(t) = x \quad (6)$$

where

r : instantaneous risk-free rate,
 q : instantaneous dividend yield,
 σ : percentage volatility,
 x : initial underlying price.

An analytical formula for pricing fixed range notes is promptly available, resorting to the fact that

$$\begin{aligned} & \mathbb{E}_t(1_{[x_l, x_u]}(X(T))) \\ &= \mathbb{E}_t(1_{(-\infty, x_u]}(X(T)) - 1_{(-\infty, x_l]}(X(T))) \\ &= \mathcal{N}(d_{T-t}^{x_u}) - \mathcal{N}(d_{T-t}^{x_l}) \end{aligned}$$

where

$$\begin{aligned} d_{T-t}^w &= \frac{\ln \frac{x}{w} + (r - q)(T - t) - \frac{1}{2}\sigma^2(T - t)}{\sqrt{\sigma^2(T - t)}} \\ \mathcal{N}(x) &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{u^2}{2}} du \end{aligned} \quad (7)$$

Therefore, for a fixed-rate range note, we have

$$\begin{aligned} & \mathbb{E}_t(\phi(T_{j+1})) \\ &= \frac{C_j}{D(T_j, T_{j+1})} \sum_{i=1}^{D(T_j, T_{j+1})} \left(\mathcal{N}(d_{T_{j,i}-t}^{x_u}) - \mathcal{N}(d_{T_{j,i}-t}^{x_l}) \right) \end{aligned} \quad (8)$$

and the price of the fixed range note is

$$\sum_{j=0}^n P(t, T_{j+1}) \mathbb{E}_t(\phi(T_{j+1})) + P(t, T_n) \quad (9)$$

where $P(t, T)$ refers to the price of a zero-coupon bond expiring in T .

From a pricing perspective, the case of the fixed range note with a minimum coupon provision appears more interesting. Indeed, in this case, the pricing formula requires the distribution of the occupation time of the range $[x_l, x_u]$. If the random variable $H(T_j, T_{j+1})/D(T_j, T_{j+1})$ in equation (3) is replaced by its continuously monitored version

$$h(T_j, T_{j+1}; x_l, x_u) = \int_{T_j}^{T_{j+1}} 1_{[x_l, x_u]}(X(s)) ds \quad (10)$$

few analytical results are available. In particular, the distribution of $h(T_j, T_{j+1}; x_l, x_u)$ when $x_l = -\infty$ (or $x_u = \infty$) is obtained in [1], exploiting the Feynman–Kac formula. Related results are presented in [4, 5, 7, 10, 12, 16, 17]. Owing to the stationarity of the Brownian motion, we observe that the distribution of $h(T_j, T_{j+1})$ is the same as the distribution of $h(0, T_{j+1} - T_j; x_l, x_u)$, and this law (when $x_l = -\infty$) is strictly related to the law of the occupation time in the time interval $[0, \tau]$ as

$$Y_{0,x}(u, \tau) = \int_0^\tau \mathbf{1}_{(-\infty, u]}(\delta s + W(s)) ds, W(0) = x \quad (11)$$

where $\delta = (r - q - \sigma^2/2)/\sigma$. Fusai [8] provides the pricing formula in the case of finite values of x_l and x_u , obtaining the Laplace transform in time of the characteristic function of $Y_{0,x}(u, \tau)$.

The real-life case of discrete monitoring is discussed in [9] using Monte Carlo simulation and finite difference methods. In particular, the authors stress that the price of the contract with continuous time

monitoring is the highest (lowest) when the index is inside (outside) the band. This is due to the nature of the contract: if the index is inside the band, and we assume continuous time monitoring, then the passage of time will increase the value of the contract until the moment in which the index crosses the barriers. Instead, if we assume discrete time monitoring, we cannot exploit the passage of time completely: we register the position of the index only at discrete dates and if they are quite distant (e.g., a month), it is possible that the index at the reset date will move outside the band and so the occupation time does not increase. In this case, the time between two monitoring dates is entirely lost. *Vice versa*, in the discrete case, if we are outside the band, and between two monitoring dates the index moves inside the band, then the occupation time increases by the entire time distance between monitoring dates. Instead, with continuous time monitoring we miss every instant before the process crosses the barrier. So the continuous time formula will overvalue (undervalue) the discrete time formula when the index is inside (outside) the band.

We have not discussed here the pricing of the floating range notes with a stock index as underlying because they are not very common. However, using the stock as numéraire and the tower property (to take into account the delay between maturity date and payment date) analytical formula are promptly available. In the case of a minimum coupon, we need the joint law of Brownian motion and its occupation times. Useful formulas for this case are provided in [2, 10, 12].

Underlying is an Interest Rate

In this case, the underlying variable $X(t)$ of the range note is a simple compounded interest rate with tenor θ defined according to the formula

$$1 + X(t)\theta = \frac{1}{P(t, t+\theta)} \quad (12)$$

The pricing of range notes, with the underlying being an interest rate, has begun with Turnbull [18], who assumes that the interest rate dynamics is well represented by a one factor Gaussian Heath–Jarrow–Morton (HJM) model, that is, the dynamics of the price of a zero-coupon bond $P(t, T)$ is given by

$$\frac{dP(t, T)}{P(t, T)} = r(t) dt + \sigma(t, T) dW(t) \quad (13)$$

where $\sigma(t, T)$ is deterministic.

In particular, Turnbull [18] considers the Ho and Lee model ($\sigma(t, T) = \sigma$, constant) and the Hull and White model ($\sigma(t, T) = \sigma e^{-\lambda(T-t)}$, $\lambda > 0$) and obtains a closed form formula for the range note (fixed rate and delayed floating case). A simpler and more intuitive derivation than [18] and for a more general volatility function (albeit still deterministic) is obtained, using the change of numéraire technique, in [14].

The multifactor Gaussian HJM

$$\frac{dP(t, T)}{P(t, T)} = r(t) P(t, T) dt + \sigma(t, T)' \cdot dW(t) \quad (14)$$

where $\cdot$ denotes the inner product in R^n and $W(t) \in R^n$ is an n -dimensional standard Brownian motion as considered in [15]. Such extension is important because it enhances the term structure model calibration to the interest rates covariance matrix “observed” in the market, which, along with the term structure of interest rates, will ultimately determine the price of the range notes under analysis. In fact, in order to price and hedge range notes consistently with the market prices of related plain-vanilla interest rate options (such as caps and/or European swaptions), it is essential to use an interest rate model that is analytically tractable and that provides a good fit to the term structures of interest rates, volatilities, and correlations observed in the market.

Reference [6] further extends these results to a multivariate Lévy term structure model, an extension of a Gaussian HJM model with jump processes.

The main limit of these models is that the rate $X(t)$ can attain negative values with positive probability, which may cause some pricing error in many cases.

An extension to the class of affine term structure model, which encompasses both Gaussian and non-Gaussian models such as Cox–Ingersoll–Ross (CIR) square-root models is introduced in [11]. The extension is useful in ensuring the positivity of the interest rate; moreover, Jangy and Yoon [11] have also consider the pricing spread range notes. The

limit of their analysis is that they consider as underlying asset a continuously compounded interest rate of a given tenor rather than the corresponding simple compounded interest rate. On one hand, this allows to get (i) analytical formulas for a more general class of multifactor models and (ii) positive interest rates. On the other hand, the pricing formulas are not immediately adaptable to real-life contracts because the spread is usually between swap rates of different tenors.

A Libor Market Model is instead adopted in [19]. This has the advantage of enhancing the model calibration to the interest rate covariance matrix observed in the market, and, in addition, it guarantees the positivity of interest rates. However, in this model no analytical formulas are available for floating range notes, which need to be priced by Monte Carlo simulation. However, freezing the drift of forward rates in order to have a dynamics of the LIBOR rate with deterministic drift and volatility, Wu and Chen [19] are able to provide approximate pricing formulae.

Finally, we remark that, with an interest rate as underlying, no pricing formula has so far been made available in the literature concerning the pricing of a range note with a minimum coupon provision.

Related Payoff

Exotic options related to corridor options are quantile options, introduced in [13], and studied in more detail in [1, 4]. Step options studied in [12] are contracts related to range notes, as an alternative to standard barrier options. Barrier options have the drawback of losing all value at the first touch of the barrier. Step options lose value more gradually. The option value decreases as the underlying asset spends more time at lower levels. Another example is the Parisian option (see **Constant Maturity Swap**). A Parisian out option with window D , barrier L , and maturity date T will lose all value if the underlying price has an excursion of duration D above or below the barrier L during the option's life. If the loss of value is prompted by an excursion above (below) the barrier, the option is said to be an up-and-out (down-and-out) Parisian option. Parisian contractual forms were introduced and studied by Chesney *et al.* [3]. Contracts of this type are more robust to eventual price manipulations. The pricing formulas in [3, 12] involve inverse Laplace transforms.

End Notes

^aThe fairway in golf is like the index or interest rate range. The outlook is positive if the ball lands on the fairway. If, however, a ball lands in the rough, the outlook is negative. Source: <http://www.investopedia.com/terms/f/fairwaybond.asp> as of January 2009.

^bThe German noun hamster has the same meaning as the English noun hamster: it is the name of a small rodent. But HAMSTER is also an acronym standing for Hoffnung Auf MarktStabilität in Einer Range (literally: Hope on market stability in a given range). It really is a pun as in German the verb 'hamstern' has the meaning of 'to hoard'. HAMSTER options hoard the fixed amount one gets for each day; the underlying stays in the prespecified range. What is earned cannot be lost any more. Source <http://www.margrabe.com/Dictionary/DictionaryGJ.html#sectH> as January 2009.

Lookback Options

Lookback options are path-dependent options, introduced at first in [25] and [26], characterized by having their settlement based on the minimum or the maximum value of an underlying index as registered during the lifetime of the option. At maturity, the holder can “lookback” and select the most convenient price of the underlying that occurred during this period: therefore they offer investors the opportunity (at a price, of course) of buying a stock at its lowest price and selling a stock at its highest price. Since this scheme guarantees the best possible result for the option holder, he or she will never regret the option payoff. As a consequence, a lookback option is more expensive than a vanilla option with similar payoff function. However, these options do not offer a natural hedge for typical business and are used mainly by speculators. To mitigate their cost, sometimes the lookback feature is mixed with an average feature: for example, the payoff is the best or the worst of past average prices and they are offered as investment product under names such as *Everest*, *Napoleon*, and *Altiplano*.

In the section Payoff Function, we describe lookback options payoff. In the section Pricing, we illustrate the pricing of these options in the Black–Scholes setting and some results on the hedging problem. Thereafter, in the section Non-Gaussian Models, we consider the pricing problem under non-Gaussian models. Finally, in the section Related Payoff, we present payoffs related to lookback options.

Payoff Function

A lookback option can be structured as a put or call. The strike can be either fixed or floating. We now consider two lookback options written on the minimum value achieved by the underlying index during a fixed time window:

- *A fixed strike lookback put* The payoff is given by the difference, if positive, between the strike price and the minimum price over the monitoring period. Therefore, the buyer of this option can sell the asset at the minimum price receiving the strike K .
- *A floating strike lookback call* The payoff is given by the difference between the asset price at the option maturity, which represents the floating strike, and the minimum price over the monitoring period. Therefore, the buyer of this option can buy the underlying asset paying the minimum price.

Notice that floating strike options will always be exercised. Formulae for the payoffs are provided in Table 1, as well as versions involving the maximum and variants denominated *partial price* or *partial time*.

Pricing

In this section, we discuss the pricing problem under the geometric Brownian motion (GBM) assumption, that is,

$$dS(t) = (r - q)S(t)dt + \sigma S(t)dW(t), \quad S(0) = S_0 \quad (1)$$

where r is the instantaneous risk-free rate; q is the instantaneous dividend yield; σ is the percentage volatility; S_0 is the initial underlying price; and we are interested in the distribution of the minimum $m(T)$ and maximum $M(T)$

$$M(T) = \max_{0 \leq u \leq T} S(u), \text{ and } m(T) = \min_{0 \leq u \leq T} S(u) \quad (2)$$

Figure 1 illustrates a simulated path of the underlying asset according to the dynamics in equation 1 and the corresponding trajectories for the maximum and minimum price.

Analytical Solution

Under the GBM assumption, the distribution law of $m(T)$ (as well as the joint density of $m(T)$ and $S(T)$) is known in closed form. This allows one to obtain an analytical solution for standard lookback options as expected value of the discounted payoff; see, for example, [25, 26], and [15]. Therefore, we obtain the following pricing formula for the floating strike lookback call:

$$\begin{aligned} & \mathbb{E}_{t, S_t} e^{-r(T-t)} (S(T) - m(T)) \\ &= S_t e^{-q(T-t)} - e^{-r(T-t)} \mathbb{E}_{t, S_t} m(T) \\ &= S_t e^{-q(T-t)} \mathcal{N}(d_2) \end{aligned}$$

Table 1 Lookback option payoff function

Generic lookbacks			
	Minimum $m(T) = \min_{0 \leq u \leq T} S(u)$	Maximum $M(T) = \max_{0 \leq u \leq T} S(u)$	Range $M(T) - m(T)$
Standard lookbacks			
	Floating strike	Fixed strike	Reverse strike
Call	$(S(T) - m(T))^+$	$(M(T) - K)^+$	$(m(T) - K)^+$
Put	$(M(T) - S(T))^+$	$(K - m(T))^+$	$(K - M(T))^+$
Nonstandard lookbacks			
	Partial price	Partial time	conditions
Call	$(S(T) - \lambda m(T))^+$	$(S(T_2) - m(T_1))^+$	$\lambda \geq 1, T_1 < T_2$
Put	$(\gamma M(T) - S(T))^+$	$(M(T_1) - S(T_2))^+$	$\mu \leq 1, T_1 < T_2$

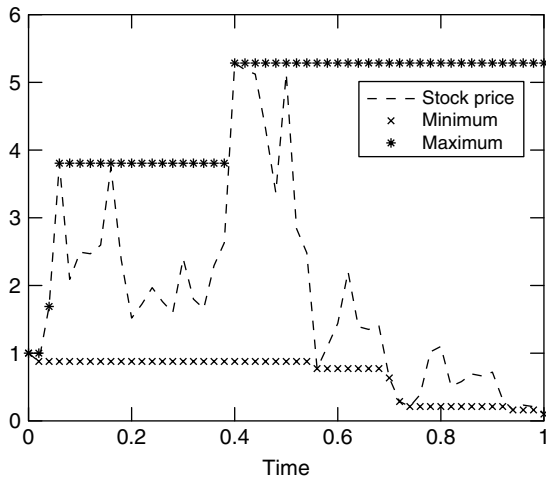

Figure 1 Geometric Brownian motion and its maximum and minimum to date

$$\begin{aligned}
 & -e^{-r(T-t)} m_t \mathcal{N}(d_2 - \sigma \sqrt{T-t}) \\
 & + \frac{\sigma^2 S_t}{2r} \left[e^{-r(T-t)} \left(\frac{S_t}{m_t} \right)^{-2r/\sigma^2} \mathcal{N}(d_3) \right. \\
 & \left. - e^{-q(T-t)} \mathcal{N}(-d_2) \right] \quad (3)
 \end{aligned}$$

with

$$\begin{aligned}
 d_2 = & \frac{1}{\sqrt{\sigma^2(T-t)}} \left(\ln \left(\frac{S_t}{m_t} \right) + (r-q)(T-t) \right. \\
 & \left. + \frac{1}{2} \sigma^2 (T-t) \right),
 \end{aligned}$$

$$d_3 = -d_2 + \frac{2(r-q)}{\sigma} \sqrt{T-t},$$

$$\mathcal{N}(x) = \int_{-\infty}^x e^{-\frac{u^2}{2}} du \quad (4)$$

Notice that the formula above admits a simplification when $t = 0$: indeed, in this case, we have $S(0) = m(0)$. Formula 3 suggests that the lookback call value is given by the sum of the premium of a plain vanilla call with strike equal to the current minimum and the premium of a so-called strike bonus option. This is the expected value of the cash flows necessary to exchange the initial option position for options with successively more favorable strikes. In other words, it measures the potential decrease in the price at which the option allows its holder to buy the security, if and when the security price attains a new minimum.

For pricing the fixed strike put option, we have

$$\begin{aligned}
 & \mathbb{E}_{t, S_t} e^{-r(T-t)} (K - m(T))^+ \\
 & = \mathbf{1}_{(K < m_t)} \left\{ -S_t \mathcal{N}(-d) + e^{-r(T-t)} \right. \\
 & \quad \times K \mathcal{N}(-d + \sigma \sqrt{T-t}) + \left(\frac{\sigma^2}{2r} \right) S_t \\
 & \quad \times \left[e^{-r(T-t)} \left(\frac{S_t}{K} \right)^{-2r/\sigma^2} \mathcal{N}(d_1) - \mathcal{N}(-d) \right] \Big\} \\
 & + \mathbf{1}_{(K \geq m_t)} \left\{ e^{-r(T-t)} (K - m_t) - S_t \mathcal{N}(-d_2) \right\}
 \end{aligned}$$

$$+ e^{-r(T-t)} m_t \mathcal{N}(-d_2 + \sigma \sqrt{T-t}) + \left(\frac{\sigma^2}{2r} \right) S_t \\ \times \left[e^{-r(T-t)} \left(\frac{S_t}{m_t} \right)^{-2r/\sigma^2} \mathcal{N}(d_3) - \mathcal{N}(-d_2) \right] \} \quad (5)$$

with

$$d = \frac{1}{\sqrt{\sigma^2(T-t)}} \left(\ln \left(\frac{S_t}{K} \right) + (r-q)(T-t) \right. \\ \left. + \frac{1}{2} \sigma^2 (T-t) \right), \\ d_1 = \frac{-d + 2(r-q)\sqrt{T-t}}{\sigma} \quad (6)$$

Lookback options on the maximum can be priced by exploiting the relation between maximum and minimum operators.

An important feature of lookbacks is the frequency of observation of the underlying assets for the purpose of identifying the best possible value for the holder. For example, the above expressions are consistent with the assumption that the underlying asset is monitored continuously. Instead, discrete monitoring refers to updating the maximum/minimum price at fixed times (e.g., daily, weekly, or monthly). In this case, we have to replace $M(T)$ and $m(T)$ by $\hat{M}(T)$ and $\hat{m}(T)$, defined as

$$\hat{M}(T) = \max_{0 \leq i \leq n} S(i\Delta), \text{ and } \hat{m}(T) = \min_{0 \leq i \leq n} S(i\Delta) \quad (7)$$

where n is the number of monitoring dates and Δ is the time distance between monitoring dates; with $n\Delta = T$. Nearly all closed-form expressions available for pricing path-dependent options are based on continuous-time paths, but many traded options are based on discrete price fixings. In general, a higher maximum/lower minimum occurs as long as the number n of monitoring dates increases. As noted by Heynen and Kat [29] and Aitsahlia and Leung [1], the discrepancy between option prices under continuous and discrete monitoring of the reference index may have significant effect on the prices of lookback options, but does not introduce new hedging problems. Indeed, the slow convergence of the discrete scheme to the continuous one as the number n of monitoring dates increases is well known. This figure is quantified in an order of proportionality of approximately $1/\sqrt{n}$.

For example, setting $r = 0.1$, $q = 0$, $\sigma = 0.2$, $T = 1$, $S_0 = 100$, the continuous formula returns 19.6456. Assuming a year consists of 250 days and that 10 monitoring dates are available (i.e., monitoring occurs approximately once a month), the discrete formula gives 17.0007: a percentage difference about 15% with respect to the continuous case. Using 10 000 monitoring dates (i.e., monitoring occurs once every 36 minutes), the discrete formula returns 19.5523, a small but still appreciable difference with respect to the continuous case.

Few papers have investigated the analytical pricing of discretely monitored lookback options. A correction to the continuously monitored formula based on the Riemann zeta function is given in [12]. The Riemann zeta function enters indeed in the computations of the moments of the discrete maximum/minimum; see, for example, [23, 27, 31, 32, 34], for different derivations and improvements of the above correction. New results for discrete options have been recently obtained exploiting the Wiener–Hopf factorization and the Spitzer’s identity. For example, [5] and [27] present an exact analytical formula showing how to cast the pricing problem in terms of an integral equation of the Wiener–Hopf type. This equation can be solved in closed form in the Gaussian case. The computational cost is linear in the number of monitoring dates. A related approach based on the Spitzer’s identity (the probabilistic interpretation of the solution of a Wiener–Hopf equation) has been advanced by Borovkov and Novikov [9] and by Petrella and Kou [39]. They propose an algorithm with a computational cost that is quadratic in the number of monitoring dates but has the advantages of being simply adapted to non-Gaussian models provided that they have independent identically distributed (i.i.d.) increments and the pricing formula of plain vanilla calls and puts are available.

Other approaches are mainly numerical and briefly detailed in the following subsections.

Finite Difference Method

The numerical solution of the partial differential equation (PDE) satisfied by the lookback option price is discussed for example in [42] and a detailed treatment for the discrete case is given in [3]. Since lookback options are path-dependent options, their value V does not depend only on the current spot

price and time, but also on the current realized minimum or maximum, and we can write $V = V(S, m, t)$ for options on the minimum (similar discussion holds for lookback on the maximum). Applying Ito's lemma and equating the expected return on the option to the return on a risk-free investment, it can be shown that V solves the following PDE:

$$\frac{\partial V}{\partial t} + (r - q)S \frac{\partial V}{\partial S} + \frac{\sigma^2}{2} S^2 \frac{\partial^2 V}{\partial S^2} = rV \quad (8)$$

which has to be solved for $S \geq m$ and $T \geq t \geq 0$. The above PDE is the standard Black–Scholes PDE, with the change of the domain from $S \geq 0$ to $S \geq m$. Here m appears as parameter delimiting the domain of the spot price. This implies that a boundary condition at $S = m$ is needed. The important point is the observation that when the spot price is near to the running minimum, the probability that at expiry the minimum will be equal to the current minimum m is zero and therefore changes in m do not affect the option value. This allows one to set the boundary condition at $S = m$:

$$\frac{\partial V(S, m, t)}{\partial m} = 0 \text{ when } S = m \quad (9)$$

Together with the payoff condition at $t = T$, equations (8) and (9) allow us to fully characterize the lookback option premium. For discretely monitored lookback options, with monitoring at dates $t_i = i\Delta$ the PDE (8) remains unchanged, while the boundary condition (9) does not apply anymore. Indeed, between monitoring dates, the spot price can freely move in $(0, +\infty)$ and at monitoring dates, the solution is updated according to the rule

$$V(S, m, t_i^+) = V(S, \min(S, m), t_i^-) \quad (10)$$

Equation (8) can be solved numerically using an appropriate numerical scheme such as the Crank–Nicolson one (see **Crank–Nicolson Scheme**). However, exploiting a change of numeraire, the PDE (8) can be simplified to a single state variable [3].

Monte Carlo Simulation

Discretely monitored lookback options can be easily priced by standard Monte Carlo (MC) simulation. The underlying price is simulated at all monitoring

dates exploiting the exact solution of the stochastic differential equation (1):

$$S^{(j)}((i+1)\Delta) = S^{(j)}(i\Delta)e^{(r-0.5\sigma^2)\Delta + \sigma\sqrt{\Delta}\epsilon_i^{(j)}} \quad (11)$$

where $\epsilon_i^{(j)}$ is a standard normal random variate and $S^{(j)}(i\Delta)$ is the spot price at time $t_i = i\Delta$ as sampled in the j th simulation.

The corresponding minimum price $m^{(j)}(i\Delta)$ over the time interval $t_{(i-1)\Delta}, t_{i\Delta}$ is updated at each monitoring date according to the rule

$$\hat{m}^{(j)}(i\Delta) = \min(S^{(j)}(i\Delta), \hat{m}^{(j)}((i-1)\Delta)) \quad (12)$$

with a starting condition $m_0^{(j)} = S_0$. The MC price for a lookback is given by the average of the discounted payoff computed over J simulated sample paths. For a lookback option with fixed strike K , the MC price is

$$e^{-rt_n} \frac{1}{J} \sum_{j=1}^J (K - \hat{m}^{(j)}(n\Delta))^+ \quad (13)$$

Similarly, for a floating strike lookback option, the MC price is

$$e^{-rt_n} \frac{1}{J} \sum_{j=1}^J (S^{(n\Delta)} - \hat{m}^{(j)}(n\Delta)) \quad (14)$$

Unfortunately, the procedure cannot be immediately applied to continuously monitored options shrinking the time step Δ . Indeed, owing to fact that we can only sample at discrete times, we lose information about the parts of the continuous-time path that lie between the sampling dates. This procedure will be systematically biased in the sense that the continuous minimum (maximum) will be always overestimated (underestimated). Andersen and Brotherton-Ratcliffe [4] show that for a one-year lookback with 256 discrete monitoring points this bias is around 5% of the option price and suggest a procedure to correct it.

Binomial and Tree Methods

As for PDEs, the implementation of a tree for path-dependent options involves two state variables and the need to keep track of current extreme values will cause the number of calculations to grow substantially faster than the number of nodes. However, under the GBM assumption and exploiting

a change of numeraire, the pricing of lookback options can be reduced to one-state binomial model (having a reflecting barrier at 0); see, for instance, [6] and [14], as well as **Tree Methods**. Using such models cuts the amount of computation remarkably and also makes it straightforward to deal with the early exercise feature.

Hedging

We conclude this section, mentioning the hedging problem of lookback options. When $r = q + \sigma^2/2$, lookback options can be exactly replicated using a self-financing strategy based on straddles (an ordinary put plus an ordinary call) with an exercise price equal to the initial extremum (maximum or minimum) [25]. If, over the life of the option, the stock price never rises above or falls below its initial value, the initial straddle would exactly satisfy the writer's terminal obligation. When the stock price is at an extremum and then achieves a new maximum or minimum, the straddle should be sold and a new portfolio established, a straddle with exercise price equal to the new maximum (minimum). This strategy is self-financed and replicates the lookback option. However, in general, the replicating strategy requires the computation of the Δ coefficient, that is, units of stocks needed to replicate the contingent claim, by taking the derivative of the pricing formula with respect to the current spot price. An alternative method is put forward by the use of the Malliavin calculus approach, and the main component for this method to work is a sort of representation theorem, called the *Clark–Ocone formula*. This formula allows us to identify a formal expression for the replicating portfolio of basically any contingent claim. This has been exploited in [8] to obtain the replicating portfolio.

A different approach is taken in [30] that finds bounds on the prices of the lookback option, in terms of the (market) prices of call options. This is achieved without making explicit assumptions about the dynamics of the price process of the underlying asset, but rather by inferring information about the potential distribution of asset prices from the call prices. Thus the bounds and the associated hedging strategies are model independent and represent limits on the possible price of the lookback, which are necessary for the absence of arbitrage.

Non-Gaussian Models

The GBM model in equation (1) is one of the most successful and widely used models in financial economics. Unfortunately, deviations between the model and empirical evidence are well known in literature and therefore offer new opportunities for the development of more-realistic models and pricing formulas for exotic options. With reference to lookback options, extensions have been obtained replacing the GBM model by the constant elasticity of variance (CEV) model (see **Constant Elasticity of Variance (CEV) Diffusion Model**) or by an exponential Lévy model (see **Exponential Lévy Models**). In the following sections we discuss such extensions.

CEV

The study of lookback options in the CEV model has started with [10] and [11]. Their approach consists in approximating the CEV process by a trinomial lattice and uses it to value barrier and lookback options numerically. A binomial tree is also used in [16]. While these approaches are purely numerical, in [20] closed-form solutions for the Laplace transforms of the probability distributions of the maximum and minimum are obtained. Lookback prices are recovered by inverting the Laplace transforms and integrating against the option payoff. An analytical inversion of the Laplace transforms for lookback options in terms of spectral expansions associated with the infinitesimal generator of the CEV diffusion is given in [36]. All these studies point out that the differences in prices of these exotic options under the CEV and geometric Brownian motion assumptions can be far more significant than the differences for standard European options.

Lévy Processes

Lookback options have been priced also under Lévy processes. For example, in [13] a very powerful algorithm is proposed that can be adapted for pricing discrete lookback under a jump-diffusion model. For more general Lévy processes, very efficient algorithms have been proposed in [22, 39] and [24]. An analytical expression in terms of the Laplace transform is found for continuously monitored options, under a double-exponential model, in [35].

Related Payoff

Several exotic options can be thought of as a modification of lookback options. We have mentioned a few of them here.

In *partial lookback* options, the lookback feature is limited to only the first (for entry timing) or the last (for exit timing) part of the options' life. This product, even with a relatively short lookback periods, appears to offer a good solution to most timing problems at a reasonable price. Kat and Heynen [33] provide closed-form pricing formulas for such options. Analysis shows how the prices of such "partial lookback options" respond to a change in the monitoring period.

Quanto lookback refers to a payoff structure where the terminal payoff of the quanto option depends on the realized extreme value of a stock denominated in a foreign currency but the payoff is paid in a domestic currency. These contracts have been studied in [18].

Double lookbacks or *Range options* include calls and puts with the underlying being the difference between the maximum and minimum prices of one asset over a certain period, and calls or puts with the underlying being the difference between the maximum prices of two correlated assets over a certain period. Analytical expressions of the joint probability distribution of the maximum and minimum values of two correlated geometric Brownian motions are derived in [28] and used in the valuation of double lookbacks. An option on the spread between the maximum and minimum price of a single stock over a given interval of time captures the idea of an option on price volatility; see, for example, the related literature on financial econometrics devoted to estimate the volatility using range estimators. Therefore, such an option might be of interest to traders who want to bet on price volatility or hedge an existing position that is sensitive to price volatility.

Quantile options have a payoff at maturity depending on the order statistics of the underlying asset price. The j -quantile process $q(n, j)$ is defined as the level at which the return process stays below for j periods out of n . In particular, we have $q(n, n) = \hat{M}(n\Delta)$ and $q(n, 0) = \hat{m}(n\Delta)$. The quantile payoff is obtained replacing the extreme appearing in Table 1 by the quantile $q(n, j)$. These options can be priced by making use of what is known as the *Dassios–Port–Wendel identity* [19], that allows one

to write the quantile as sum

$$q(n, j) \stackrel{d}{=} \hat{m}((n - j)\Delta) + \hat{M}(j\Delta) \quad (15)$$

where $\stackrel{d}{=}$ means equality in distribution and $\hat{m}((n - j)\Delta)$ and $\hat{M}(j\Delta)$ are independent processes. From this identity, it follows that the density of the quantile is the convolution of the densities of $\hat{m}((n - j)\Delta)$ and $\hat{M}(j\Delta)$ and, at the issue date of the contract, the quantile price can be obtained as expected discounted payoff under the risk-neutral measure; see [5] and [19] for details. Another way of exploiting the Dassios–Port–Wendel identity consists in, conditioning on the minimum, representing the quantile option price as average of lookback option prices written on the maximum and with random strike. The average is taken with respect to the density of the discrete minimum. Finally, we remark that the pricing off the inception date is not straightforward, because the quantile process is non-Markovian. A discussion can be found in [19]. Other relevant references are [2, 38], and [7].

A *drawdown (drawup) option* is defined as the drop (increase) of the asset price from its running maximum (minimum), $D(t) = M(t) - S(t)$, ($U(t) = S(t) - m(t)$). Maximum drawdown $MDD(t)$ is defined as the maximal drop of the asset price from its running maximum over a given period of time:

$$MDD(t) = \max_{0 \leq s \leq t} D(s) \quad (16)$$

In a similar manner, we can define the maximum drawup. Maximum drawdown measures the worst loss of an investor who enters the market at a certain point and leaves it at some following point within a given time period; this means that he or she buys the asset at a local maximum and sells it at the subsequent lowest point, and this drop is the largest in the given time period. A derivative contract on the maximum drawdown, introduced in [41], can serve as an important risk measure indicator: when the market is in a bubble, it is reasonable to expect that the prices of drawdown contracts would be significantly higher. On the other hand, when the market is stable, or when it exhibits mean reversion behavior, the prices of drawdown contracts would become cheaper. When the market experiences a crash, the lookback option may expire close to worthless if the final asset value is near its running maximum. Momentum traders believe

that the realized maximum drawdown (maximum drawup) will be larger than expected, and thus they are natural buyers of this contract. On the other hand, selling the (unhedged) contract is equivalent to taking the opposite strategy, namely, buying the asset when it is setting its new low. This is known as *contrarian trading*. Contrarian traders believe that the realized maximum drawdown (maximum drawup or range) will be smaller than expected, and they are natural sellers of this contract. The distribution of the maximum drawdown of Brownian motion is studied in [37].

Russian options are perpetual American Options with lookback payoff, introduced in [40]. Russian options can be regarded as a kind of perpetual American fixed strike lookback option with zero strike price and their pricing can be derived by using a probability approach [21], or a PDE approach [17].

Finally, we mention the class of structures named *mountain options*, having names such as Himalaya, Everest, Altiplano and so on (see **Atlas Option**; **Himalayan Option**; **Altiplano Option**). Here, the extrema over a given period of a given asset is replaced by the best or the worst performer over different periods of assets in a given basket. Sometimes, a global floor on the return of the product is also introduced. It is clear that MC simulation is needed to be able to price this type of products, that, in general, are very sensible to the crosscorrelation of the assets. In addition, the Greeks of these contracts can change markedly as the trade progresses.

Parisian Option

Parisian options are barrier options that are activated or canceled—depending on the type of option—if the underlying asset has been continuously traded above or below the barrier level long enough. A down-and-out Parisian option denotes a contract that expires worthless if the underlying asset reaches a prespecified level L and remains constantly below this level for a time interval longer than a fixed number D , called the *window*. Its price (for a call option) at time 0 is given by

$$\phi(T, K) := e^{-rT} \mathbb{E} \left[(S_T - K)^+ \mathbb{1}_{T_L^{D,-}(S) > T} \right] \quad (1)$$

where $T_L^{D,-}(S)$ is the first time the asset S makes an excursion longer than D below L . Parisian-style options are mostly encountered in convertible bonds with “soft-call” provision for conversion. For example, the bond’s specifications may be such that conversion will be allowed if and only if the share price remains above a theoretical price for a given amount of time, for example, 20 business days prior to the conversion date (this is Parisian option). Other covenants stipulate that the average share price trades for n days above the trigger level. While the latter does not correspond *sensu stricto* to a Parisian option, the motivation is similar: to render the conversion rule more stable—and less prone to manipulation—basing it on the behavior of the stock price over a window of time as opposed to basing it on the (more volatile) spot price. The pioneer paper on that topic is owed to Chesney *et al.*, [5]. Pricing Parisian options is a challenging issue and several methods have been proposed in the literature: Monte Carlo simulations, Laplace transforms, lattices, and partial differential equations.

Monte Carlo Method

As for standard barrier options, using simulations leads to a biased problem, owing to the choice of the discretization time step in the Monte Carlo algorithm. Baldi *et al.*, [3] have developed a method based on sharp large deviation estimates, which improves the usual Monte Carlo procedure. It consists in providing an approximation of p^ϵ —the probability that a Brownian bridge reaches a time-dependent barrier

over a time of length ϵ —by studying its asymptotic behavior when ϵ tends to 0. They derive precise estimates of $g_{L,t}^S := \sup\{u \leq t | S_u = L\}$, which is, for a down-and-out Parisian option, related to $T_L^{D,-}(S)$ by the following formula: $T_L^{D,-}(S) := \inf\{t > 0 : (t - g_{L,t}^S) \mathbb{1}_{S_t < L} > D\}$. This procedure still works when the asset follows a diffusion process with general coefficients.

Laplace Transforms

The idea of using Laplace transforms for pricing Parisian options is owed to Chesney *et al.*, [5]. By using the Brownian excursion theory, they get closed formulas for

$$\int_0^\infty dt e^{-\lambda t} \phi(t, K) \quad (2)$$

the Laplace transform of the price with respect to the maturity time.

For models with constant parameters, when considering a down and in call option, one rewrites $\phi(T, K)$ as

$$e^{-\left(r + \frac{m^2}{2}\right)T} \mathbb{E}_{\mathbb{P}} \left(\mathbb{1}_{T_b^{D,-} < T} (xe^{\sigma Z_T} - K)^+ e^{mZ_T} \right) \quad (3)$$

where Z is a $\mathbb{P}$ -Brownian motion, m depends on r and σ , and $T_b^{D,-} := T_b^{D,-}(Z)$ is the first time Z makes an excursion below $b := \frac{1}{\sigma} \log(L/S_0)$ longer than D . By using the Brownian motion excursion theory, notably the Azéma martingale and the Brownian meander, the density of $Z_{T_b^{D,-}}$ can be obtained and it can be shown that $T_b^{D,-}$ and $Z_{T_b^{D,-}}$ are independent. There is no explicit formula for the density of $T_b^{D,-}$, but we only know its Laplace transform. The strong Markov property enables to introduce $Z_{T_b^{D,-}}$ in equation (3). We rewrite equation (3) as

$$\int_{-\infty}^\infty \mathbb{E}_{\mathbb{P}} (\mathbb{1}_{T_b^{D,-} < T} \mathcal{P}_{T-T_b^{D,-}}(f_x)(z)) v^-(dz) \quad (4)$$

where v^- denotes the law of $Z_{T_b^{D,-}}$, $f_x(z) = e^{-(r+m^2/2)T} e^{mz} (xe^{\sigma z} - K)^+$, and $\mathcal{P}_t(f_x)(z) = 1/\sqrt{2\pi t} \int_{-\infty}^\infty f_x(u) \exp(-(u-z)^2/2t) du$. It remains to compute the Laplace transform of equation (4) with respect to the maturity. A change of variables

introduces the Laplace transform of $T_b^{D,-}$, which is explicitly known. This leads to a closed formula.

We refer the reader to [1] for the description of a fast and accurate numerical inversion of the Laplace transforms. By studying the regularity of the Parisian option prices with respect to the maturity time, Labart and Lelong [9] justify the accuracy of the numerical inversion. Except for particular values of the barrier, the prices are of class C^∞ . Their study relies on the existence and the regularity of a density for the Parisian time $T_b^{D,-}$.

This algorithm is implemented in [4] and is compared to a procedure for approximating a general Laplace transform with one that can be easily inverted. The Laplace transform approach is very specific to the problem, but practically we see that the lack in the flexibility of the method is compensated by its accuracy and computational speed.

Lattices

Costabile [6] presents a discrete time algorithm to evaluate Parisian options. The evaluation method is based on a combinatorial approach used to count the number of trajectories of a particle which, moving in a binomial lattice, remains constantly above an upper barrier for time intervals strictly smaller than a prespecified window period. Once this number has been computed, it can be used to derive a binomial algorithm, based on the Cox–Ross–Rubinstein (CRR) model (*see Binomial Tree or Tree Methods*). It enables to evaluate Parisian options with a constant or an exponential barrier. Avellaneda and Wu [2] model and price Parisian-style options by a trinomial lattice method, which changes with the value of the asset with respect to the barrier.

Partial Differential Equations

Pricing of Parisian options can be done using partial differential equations. Let τ define the time the underlying asset has continuously spent in the excursion. For a down Parisian option, $\tau := t - \sup\{t' \leq t | S_{t'} \geq L\}$. The dynamics of τ is

$$d\tau_t = \begin{cases} dt & \text{if } S_t < L, \\ -\tau_t & \text{if } S_t = L, \\ 0 & \text{if } S_t < L \end{cases} \quad (5)$$

The new state variable τ can be viewed as a clock that starts ticking as soon as the share price crosses the barrier level and is immediately reset when the share price returns above L . We assume that the asset follows a log normal Brownian motion given by $dS_t = \mu S_t dt + \sigma S_t dW_t$. The option price is a function of S, t, τ . If $S \geq L$, the governing equation is the standard Black Scholes equation:

$$\frac{\partial V}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} - rV = 0 \quad (6)$$

If $S \leq L$, τ is ticking. The new governing equation is

$$\frac{\partial V}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} + \frac{\partial V}{\partial \tau} - rV = 0 \quad (7)$$

The boundary conditions are the following: the path-wise continuity of V in $S = L$ leads to $V(L, t, \tau) = V(L, t, 0)$ for all t , and

$$\begin{aligned} V(S, T, \tau) &= (S_T - K)^+ & \text{if } \tau < D, \\ V(S, T, \tau) &= 0 & \text{otherwise} \end{aligned} \quad (8)$$

In the study of Haber *et al.* [8], the numerical solution to equations (6) and (7) is implemented using an explicit finite difference scheme. In the case of a discrete monitoring of the contract, Vetzal and Forsyth [7] develop an algorithm based on the numerical solution of a system of one-dimensional PDEs. It is assumed that τ only changes at observation dates with the value of S with respect to the barrier. Away from observation dates, the PDE satisfied by V does not depend on τ . Then, the pricing problems consist of a small number of one-dimensional PDEs, which exchange information only at observation dates (we impose the continuity of V).

These methods have one major benefit: they are flexible enough to be easily modified to price more general options, like Parisian (i.e., when the recorded duration is cumulative rather than continuous).

Double Parisian

There exists a double barrier version of the standard Parisian options. Double Parisian options are barrier options that are activated or canceled if the underlying asset continuously remains outside a range

$[L_1, L_2]$ long enough. The price of a double Parisian out call at time 0 is given by

$$e^{-rT} \mathbb{E} \left[(S_T - K)^+ \mathbb{1}_{T_{L_1}^{D,-}(S) > T} \mathbb{1}_{T_{L_2}^{D,+}(S) > T} \right] \quad (9)$$

These double Parisian options can be priced using the Monte Carlo procedure improved with the sharp large deviation method proposed by Baldi, Caramellino, and Iovino [3]. Labart and Lelong [9] give analytical formulas for the Laplace transforms of the prices with respect to the maturity time.

Cliquet Options

Cliquet options can be broadly characterized as contracts whose economic value depends on a series of periodic settlement values. Each settlement period has an associated strike whose value is set at the beginning of the period. This periodic resetting of the strike allows the cliquet option to remain economically sensitive across wide changes in market levels.

The Market for Cliquet Options

The early market in cliquet options featured vanilla contracts that were simply a series of forward starting at-the-money options. Rubinstein [4] provided pricing formulae for forward-start options in a Black–Scholes framework resulting in Black–Scholes pricing for vanilla cliquets. Cliquet products now trade on exchanges and the fore-runner to these listings were reset warrants, whose first public listings in the United States appeared in 1993 [5] and 1996 [1, 2]. Cliquet options are equally effective in capturing bullish (call) and bearish (put) market sentiments.

The current market for cliquet options accommodates a rich variety of features, which are sometimes best illuminated in discussions of pricing methods [6, 7]. The most actively traded cliquets are return-based products that accumulate periodic settlement values and pay a cash flow at maturity. The return characteristics and the price appeal of a cliquet can be tailored by adding caps and floors to the period returns and by introducing a strike moniness factor different from one. Defining the i th settlement value, R_i , in a call style cliquet by

$$R_i = \text{Max} \left(\text{floor}_i, \text{Min} \left(\frac{S_i}{S_i^0} - k_i, \text{cap}_i \right) \right) \quad (1)$$

where floor_i is the one-period(local) return floor for period i ; cap_i is the one-period(local) return cap for period i ; S_i is the market level on the settlement date for period i ; S_i^0 is the market level on the strike setting date for period i ; and k_i is a strike moniness factor for period i .

The payoff at maturity is given by

$$\text{payoff} = \text{Notional} \cdot \text{Max} \left(GF, \text{Min} \left(\sum_i^n R_i, GC \right) \right) \quad (2)$$

where GF is a global floor; GC is a global cap; and notional is the principal amount of the investment.

The investor forgoes returns above the local cap and is protected against returns below the local floor. For the same investment cost, investors can participate in more of the upside return by raising the local cap at the expense of a lowered local floor and the increased exposure to downside returns.

Applications of Cliquet Options

The periodic strike setting feature of a cliquet enables an investor to implement a strategy consistent with rolling options positions but without exposure to volatility movements. For example, an investor could buy a cliquet to implement a rolling three-month put strategy and be immunized against the future increase in options premiums that would accompany increases in volatility throughout the life of the strategy. Hence a cliquet provides cost certainty, whereas the rolling put strategy does not.

Cliquet products are often embedded in principal-protected notes, which combine certain aspects of fixed-income investing with equity investing. These notes guarantee the return of principal at maturity with the investment upside provided by the cliquet return. Retail notes would generally base investment gains on a broad market index such as the S&P 500 index. Principal-protected notes may further guarantee a minimum investment yield, which compounds to the value of the global floor at maturity. The guaranteed yield may be considered as part of the equity return, as it is in equation (2), or it can be considered as part of the fixed-income return. In the latter case, the equity payoff in equation (2) would be modified as in equation (3):

$$\text{payoff} = \text{Notional} \cdot \text{Max} \left(0, \text{Min} \left(\sum_i^n R_i, GC \right) - GF \right) \quad (3)$$

where the global floor now sets a strike on the sum of periodic returns.

Summary

We have discussed the general characteristics of cliquet options and illustrated the payoff for one commonly traded type of the cliquet. Numerous variations

exist and can be tailored to give very different risk-reward profiles. Some are distinguished in the market by specific names, for example reverse cliquets [3]. The customizability of cliquet options likely means we will continue to see product innovation in this area in the future.

RICK L. SHYPIT

Basket Options

Equity basket options are derivative contracts that have as underlying asset a basket of stocks. This category may include (broadly speaking) options on indices as well as options on exchange-traded funds (ETFs), as well as options on bespoke baskets. The latter are generally traded over the counter, often as part of, or embedded in, structured equity derivatives.

Options on broad market ETFs, such as the Nasdaq 100 Index Trust (QQQQ) and the S&P 500 Index Trust (SPY), are the most widely traded contracts in the US markets. As of this writing, their daily volumes far exceed those of options on most individual stocks. Owing to this wide acceptance, QQQQ and ETF options have recently been given quarterly expirations in addition to the standard expirations for equity options. Options on sector ETFs, such as the S&P Financials Index (XLF) or the Merrill Lynch HOLDR (SMH), are also highly liquid.

If we denote by B the value of the basket of stocks at the expiration date of the option, a basket call has payoff given by $\max(B - K, 0)$ and a basket put has payoff $\max(K - B, 0)$, where K is the strike price. Most exchange-traded ETF options are physically settled. Index options tend to be cash settled. Over-the-counter basket options, especially those embedded in structured notes, are cash settled.

The fair value price of a (bespoke) basket option is determined by the joint risk-neutral distribution of the underlying stocks. If we write the value of the basket as

$$B = \sum_{i=1}^n w_i S_i \quad (1)$$

where w_i , S_i denote respectively the number of shares of the i th stock and its price, the returns satisfy

$$\frac{dB}{B} = \sum_{i=1}^n \frac{w_i S_i}{B} \frac{dS_i}{S_i} = \sum_{i=1}^n p_i \frac{dS_i}{S_i}, \quad \text{with} \quad p_i \equiv \frac{w_i S_i}{B} \quad (2)$$

Here, p_i represents the instantaneous capitalization weight of the i th stock in the basket, that is, the percentage of the total dollar amount of the

basket associated with each stock. If we assume that these weights are approximately constant which is reasonable, it follows that the volatility of the basket and the volatilities of the stocks satisfy the relation

$$\sigma_B^2 = \sum_{i,j=1}^n p_i p_j \sigma_i \sigma_j \rho_{ij} \quad (3)$$

where σ_B is the volatility of the basket, σ_i are the volatilities of the stocks, and ρ_{ij} is the correlation matrix of stock returns. If we assume lognormal returns for the individual stocks, then the probability distribution for the price of the basket is not lognormal. Nevertheless, the distribution is well approximated by a lognormal and equation (3) represents the natural approximation for the implied volatility of the basket in this case.

The notion of *implied correlation* is sometimes used to quote basket option prices. The market convention is to assume (for quoting purposes) that $\rho_{ij} \equiv \rho$, a constant. It then follows from equation (1) that the implied correlation of a basket option is

$$\begin{aligned} \rho &\equiv \frac{\sigma_B^2 - \sum_{i=1}^n p_i^2 \sigma_i^2}{\sum_{i \neq j} p_i p_j \sigma_i \sigma_j} = \frac{\sigma_B^2 - \sum_{i=1}^n p_i^2 \sigma_i^2}{\left(\sum_{i=1}^n p_i \sigma_i \right)^2 - \sum_{i=1}^n p_i^2 \sigma_i^2} \\ &\approx \frac{\sigma_B^2}{\left(\sum_{i=1}^n p_i \sigma_i \right)^2} \end{aligned} \quad (4)$$

Implied correlation is the market convention for quoting the implied volatility of a basket option as a fraction of the weighted average of implied volatilities of the components.

For example, if the average implied volatility for the components of the QQQQ for the December at-the-money options is 25% and the corresponding QQQQ option is trading at an implied volatility of 19%, the implied correlation is $\rho \approx (19/25)^2 = 58\%$.

This convention is sometimes applied to options that are not at the money as well. In this case, in the calculation of implied correlation for the basket option, the implied volatilities for the component stocks are usually taken to have the same moneyness as the index in percentage terms. Other

2 Basket Options

conventions for choosing the volatilities of the components, such as equal-delta or “beta-adjusted” money, are sometimes used as well. Since the corresponding implied correlations can vary with strike price, market participants sometimes talk about the *implied correlation skew* of a series of basket options.

Call Spread

A call spread is an option strategy with limited upside and limited downside that uses call options of two different strikes but the same maturity on the same underlying. More details and pricing models can be found in [1]. Market considerations can be found in [3–5]. The call spread produces a structure that at maturity pays off only in scenarios where the price of the underlying is above the lower strike. One can think of this strategy as buying a low-strike call option and financing part of the upfront cost by selling a higher strike call option. The effect of selling the higher strike option is to limit the upside potential, but reduce the cost of the structure. It should be used for expressing a bullish view that the underlying will rise in price above the lower strike. As with all options, choosing the strike and maturity will depend on one's view of how much the underlying will move and how quickly it will move there. An example is shown, in detail, in Figure 1.

In the example shown in Figure 1, we look at a 790/810 call spread on the S&P 500 index, SPX. With the underlying SPX index at 770 and with three months to expiration, a 790 strike call price is 49.44 and an 810 strike call price is 41.79. The spread cost is $49.44 - 41.79 = 7.65$. Thus, the cost for a call spread is significantly reduced from the outright cost of a call option with the same strike. This upfront cost for the call spread is the most one can lose in a call spread. We subtract this initial investment from all other valuations, as shown in Figure 1, to get a total value. On the other hand, if both options expire in the money, one will earn $20 = 810 - 790$ on the call spread. Then the maximum profit is the spread minus the initial cost, or $20 - 7.65 = 12.35$.

Note that with three months to expiration, the call spread value is fairly insensitive to the underlying price. However, as the option gets closer to expiration, the sensitivity of the price of the call spread becomes greater, especially in the range of the spread itself. This sensitivity to underlying price or delta (*see Delta Hedging*) is illustrated in Figure 2.

The delta of the call spread stays relatively flat until relatively close to expiration of the option. When the call spread is close to expiration, the delta is very unstable around the two strikes.

Another important consideration is the volatility implied by the market (*see Implied Volatility: Market Models*). When the strikes are out of the money, the call spread price increases when volatility increases because the probability of finishing in the money increases. On the other hand, when the strikes are in the money, the call spread price decreases when volatility increases because the probability of finishing out of the money increases. This is illustrated in Figure 3.

The Relationship with Digital Options and Skew

The value of a European call spread structure can be written in terms of the difference of two call options. If we let $p(S)$ denote the probability distribution of the underlying at the time of option expiry, then we have

$$\begin{aligned} CallSpread &= e^{-r\tau} \int_{K_1}^{\infty} (S - K_1) p(S) dS - e^{-r\tau} \\ &\quad \times \int_{K_2}^{\infty} (S - K_2) p(S) dS \end{aligned} \quad (1)$$

$$\begin{aligned} CallSpread &= e^{-r\tau} \int_{K_2}^{\infty} (K_2 - K_1) p(S) dS + e^{-r\tau} \\ &\quad \times \int_{K_1}^{K_2} (S - K_1) \cdot p(S) dS \end{aligned} \quad (2)$$

If we now take the strikes very close to each other, the second term becomes insignificant. Next, if we lever up by $1/(K_2 - K_1)$, the payoff approximates the payoff of a digital option, which pays one if the underlying at termination is greater than the strike and zero otherwise. In this case,

$$\begin{aligned} DigitalOption &= e^{-r\tau} \int_K^{\infty} p(S) dS \\ &= e^{-r\tau} (1 - \Phi(K)) \end{aligned} \quad (3)$$

where $\Phi(K)$ is the cumulative probability distribution at termination of the underlying. For the original paper, see [6]. Also see [2, 7, 8] for more details. We can state equation (3) in words as follows. The

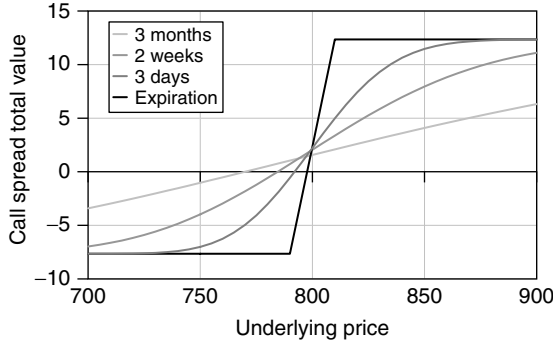

Figure 1 The value of a call spread at various times before expiration

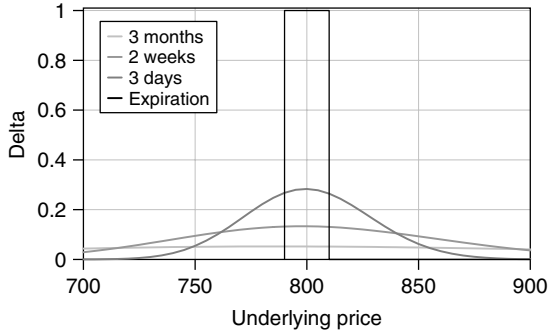

Figure 2 The delta of a call spread at various times before expiration

probability distribution function of the underlying at termination can be inferred from market prices as the derivative of digital options prices with respect to the strike. As these digital option prices come from call spreads with close strikes, we can conclude that the probability distribution function can be inferred from vanilla option prices.

Equation (2) shows that for close strikes or long expiries, the value of a call spread is approximately the strike difference times the probability that the underlying finishes above the spread:

$$CallSpread \approx e^{-r\tau} (K_2 - K_1) \cdot (1 - \Phi(K_2)) \quad (4)$$

This can be used as a crude first-order estimate for the value of a call spread. The second term in equation (2) can be approximated as (similar to the

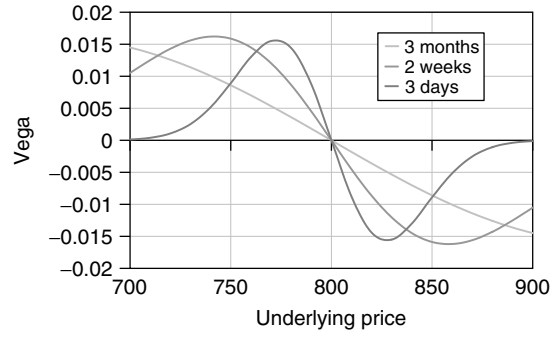

Figure 3 The vega of a call spread at various times before expiration

area of a triangle)

$$e^{-r\tau} \int_{K_1}^{K_2} (S - K_1) p(S) dS \approx e^{-r\tau} \frac{(K_2 - K_1)}{2} \times (\Phi(K_2) - \Phi(K_1)) \quad (5)$$

This gives a better approximation

$$CallSpread \approx e^{-r\tau} (K_2 - K_1) \times \left(1 - \frac{\Phi(K_1) + \Phi(K_2)}{2} \right) \quad (6)$$

This is a very intuitive formula as it is just the payoff of the call spread times the “average” probability the call spread finishes in the money.

ERIC LIVERANCE

Butterfly

A butterfly spread is an option strategy with limited upside and limited downside that uses call options of three different strikes but the same maturity on the same underlying. Specifically, a butterfly is a structure that is a long position in 1 low-strike call, a short position in 2 midstrike calls, and a long position in 1 high-strike call. More details and pricing models can be found in [2]. Market considerations can be found in [4–6]. The butterfly spread produces a structure that at maturity pays off only in scenarios where the price of the underlying is between the lowest and highest strikes. One can think of this strategy as buying an option on the underlying being in a range. The butterfly has limited upside potential, but a significantly reduced cost compared to that of an outright call option. It should be used for expressing a bullish view that the underlying will trade in a range. As with all options, choosing the strike and maturity will depend on one's view of how much the underlying will move and how quickly it will move there. An example is shown in detail in Figure 1.

In the example shown in Figure 1, we look at a 780/800/820 butterfly on the S&P 500 index, SPX. With the underlying SPX index at 770 and with three months to expiration, the butterfly cost is close to 1.00. The call option with the 800 strike is 70.14; thus, the cost for a butterfly is significantly reduced from the outright cost of a call option with the same strike. This upfront cost for the butterfly is the maximum that this butterfly position can lose. We subtract this initial investment from all other valuations, as shown in Figure 1, to get a total value. If the underlying is exactly 800 at expiration, the position will earn 20 on the butterfly from the low-strike option. The maximum position profit then is the strike spread minus the initial cost, or $20 - 1.00 = 19.00$.

Note that with three months to expiration, the butterfly value is fairly insensitive to the underlying price and is difficult to distinguish from the x -axis. However, as the option gets closer to expiration, the sensitivity of the price of the call spread becomes greater, especially in the range of the butterfly strikes. This sensitivity to underlying price or delta (*see Delta Hedging*) is illustrated in Figure 2.

The delta of the butterfly stays relatively flat until relatively close to expiration of the option. When the butterfly is close to expiration, the delta is very unstable around the three strikes.

Another important consideration is the volatility implied by the market (*see Implied Volatility: Market Models*). The vega profile of a butterfly is shown in Figure 3. When the underlying is close to the strikes, the vega is negative because when volatility increases the probability that the underlying expires out of the money increases. For this reason, it is common to use a butterfly with relatively long expiries and with strikes centered around at-the-money to take a view that implied volatility will decline while still holding a position with relatively small delta (insensitive to changes in the underlying). When the underlying is away from the money, the butterfly is long vega because when volatility increases, the probability that the underlying finishes in the money increases.

The Relationship with Distribution of the Underlying

A butterfly can be thought of as a long call spread plus a short call spread, with overlapping strikes and the same strike spread. An approximation for the value of a call spread can be found in **Call Spread**:

$$\text{Call Spread} \approx e^{-r\tau} (K_2 - K_1) \cdot \left(1 - \frac{\Phi(K_1) + \Phi(K_2)}{2} \right) \quad (1)$$

where $\Phi(x)$ is the cumulative distribution function of the underlying. Applying equation (1) to a butterfly, we have

$$\begin{aligned} \text{Butterfly} &\approx e^{-r\tau} (K_2 - K_1)^2 \left[\frac{\Phi(K_3) - \Phi(K_1)}{K_3 - K_1} \right] \\ &\approx e^{-r\tau} (K_2 - K_1)^2 p(K_2) \end{aligned} \quad (2)$$

where $p(x)$ is the probability distribution function of the underlying at option expiration and is the derivative of $\Phi(x)$ (Figure 4).

We can apply this formula in the following way. We convert the triangle in the lower part of Figure 3 to a square. Then we let the value of the payoff of the

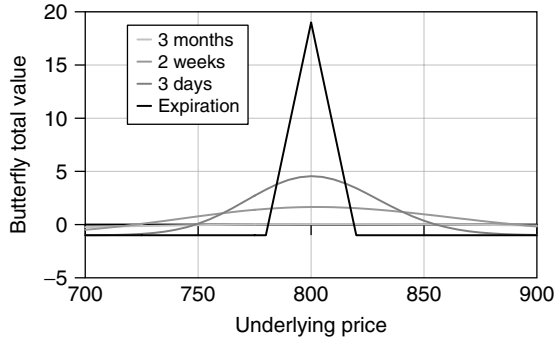

Figure 1 The value of a butterfly at various times before expiration

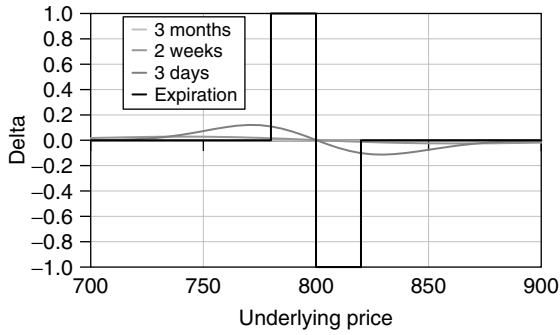

Figure 2 The delta of a butterfly at various times before expiration

butterfly to be represented as the probability times the area of the square, as in equation (2). Then turning around equation (2), we have

$$\text{prob}(K_a < S < K_b) \approx e^{r\tau} \frac{\text{Butterfly}}{(K_2 - K_1)} \quad (3)$$

The relationship between option prices and the distribution of the underlying was first pointed out in [1], but see also [3, 7]. The use of call spreads and butterflies to impute the market-implied underlying probability distribution can be related to taking derivatives with respect to the strike of the call price. A call spread is like a first derivative and a butterfly is like a second derivative. Formally, we have

$$\text{Call} = e^{-r\tau} \int_K^\infty (S - K) p(S) dS \quad (4)$$

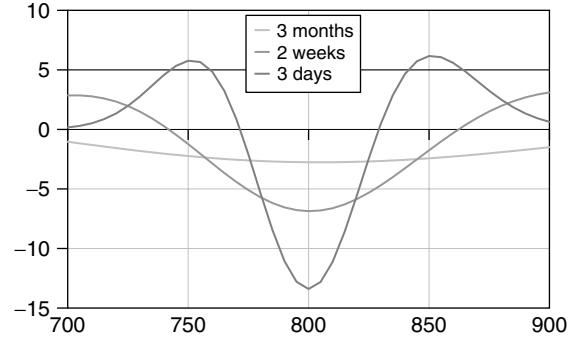

Figure 3 The vega of a butterfly at various times before expiration

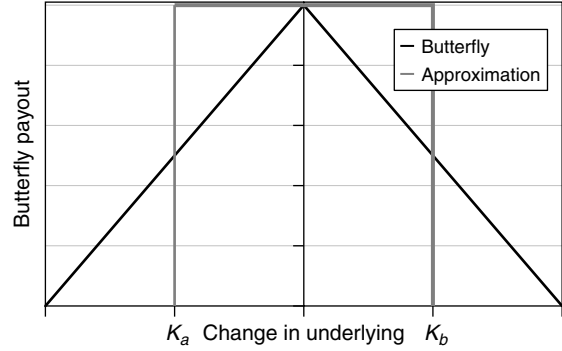

Figure 4 Using a butterfly to infer the underlying probability distribution

$$\frac{\partial}{\partial K} \text{Call} = -e^{-r\tau} \int_K^\infty p(S) dS \quad (5)$$

$$\frac{\partial^2}{\partial K^2} \text{Call} = -e^{-r\tau} p(K) \quad (6)$$

Gamma Hedging

Why Hedging Gamma?

Gamma is defined as the second derivative of a derivative product with respect to the underlying price. To understand why gamma hedging is not just the issue of annihilating a second-order term in the Taylor expansion of a portfolio, we review the profit and loss (P&L)^a explanation of a delta-hedged self-financing portfolio for a monounderlying option and its link to the gamma.

Let us consider an economy described by the Black and Scholes framework, with a riskless interest rate r , a stock S with no repo or dividend whose volatility is σ , and an option O written on that stock.

Let Π be a self-financing portfolio composed at t of

- the option O_t ;
- its delta hedge: $-\Delta_t S_t$ with $\Delta_t = \frac{\partial O}{\partial S}$; and
- the corresponding financing cash amount $-O_t + \Delta_t S_t$.

We note $\delta\Pi$ the P&L of the portfolio between t and $t + \delta t$ and we set $\delta S = S_{t+\delta t} - S_t$. Directly, we have that the delta part of the portfolio P&L is $-\Delta_t \delta S$ and that the P&L of the financing part is $(-O_t + \Delta_t S_t)r\delta t$. Regarding the option P&L, δO , we have, by a second-order expansion,

$$\delta O \approx \frac{\partial O}{\partial t} \delta t + \frac{\partial O}{\partial S} \delta S + \frac{1}{2} \frac{\partial^2 O}{\partial^2 S} (\delta S)^2 \quad (1)$$

Furthermore, the option satisfies the Black and Scholes equation (see **Black–Scholes Formula**):

$$\frac{\partial O}{\partial t} + rS \frac{\partial O}{\partial S} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 O}{\partial^2 S} = rO \quad (2)$$

Combining these two equations and writing the P&L of the portfolio as the sum of the three terms, we get

$$\delta\Pi \approx \frac{1}{2} S^2 \frac{\partial^2 O}{\partial^2 S} \left(\left(\frac{\delta S}{S} \right)^2 - \sigma^2 \delta t \right) \quad (3)$$

where $\partial^2 O / \partial^2 S$ is the gamma of the option part of the portfolio (in terms of definition, $S^2(\partial^2 O / \partial^2 S)$ is called the *cash gamma* because it is expressed

in currency and can be summed over several stock positions, whereas the direct gamma cannot).

As no condition was put on the relation of the volatility to time and space, equation (3) is easily extended to a local volatility setting (see **Local Volatility Model**). Practitioners call this equation the *breakeven relation* and $\sigma\sqrt{\delta t}$ the *breakeven* for it represents the move in performance the stock has to make in the time δt to ensure a flat P&L (e.g., if we consider that a year is composed of 256 open days, a stock having an annualized volatility of 16% needs to make a move of 1%, at which the delta is rebalanced, to ensure a flat P&L between two consecutive days). Figure 1 shows the portfolio P&L for a position composed of an option with a positive gamma.

Equation (3) leads to two important remarks. First, it is a local relation, both in time and space, and the fact that the gamma is gearing the breakeven relation implies that the global P&L of a positive gamma position, hedged according to the Black and Scholes self-financing strategy, can very well be negative if a stock makes large moves in a region where the gamma is small and makes small moves in a region where the gamma is maximum, even if the realized variance of the stock is higher than the pricing variance σ^2 . Secondly, in the long run, the realized variance is usually smaller than the implied variance, which can lead practitioners to build negative gamma positions. Yet, Figure 1 shows that a positive gamma position is of finite loss and possibly infinite gain, whereas it is the opposite for a negative gamma position. Practically, this is why traders tend naturally to a gamma neutral position.

A specific aspect of the equity market is the presence of dividends. One can wonder if, on the date the stock drops by the dividend amount, a positive gamma position is easier to carry than a negative gamma position. It is, of course, linked to the dividend representation chosen in the stock modeling. It can be shown that the only consistent way of representing the dividends is the one proposed in **Dividend Modeling**, where the stock is modeled as in Black and Scholes between two consecutive dividend dates. It is the only representation in which equation (3) stands (on the dividend date, the P&L term coming from the cash dividend part is offset by a term arising from the adapted Black and Scholes equation). In others, either the gamma carries a dividend part (dividend yield models) that leads to a

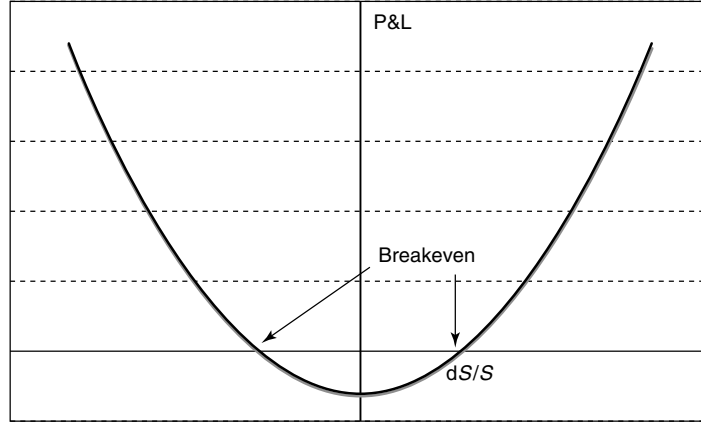

Figure 1 The P&L of a self-financing portfolio composed of an option with a positive gamma in the interval δt

false breakeven on the dividend date or equation (3) is not associated with the stock but with the variable that is stochastic (model in which the stock is described as a capitalized exponential martingale minus a capitalized dividend term, for example). This is why practitioners use the model proposed in **Dividend Modeling** rather than any other. This is also why it is, indeed, a general framework we put ourselves in by excluding dividends and repo (which is usually represented by a drift term whose P&L impact is also offset by a term arising from the adapted Black and Scholes equation) in our analysis.

Practical Gamma Hedging

We have seen why traders usually try to build a gamma-neutral portfolio. Yet, there is no pure gamma instrument in the market, and neutralizing the gamma exposure always brings a vega exposure to the portfolio. Without trying to be exhaustive, we briefly review here some natural gamma hedging instruments.

Hedging Gamma with Vanilla Options

European calls and puts have the same gamma (and the same vega). Hence, they are equivalent hedging instruments. Figure 2 shows the gamma of a European option for two different maturities and Figure 3 shows the compared evolutions with respect to the maturity of the gamma and of the vega.

These two figures show that, to efficiently hedge his or her gamma exposure, a trader would rather use a short-term option to avoid bringing too much vega to his or her position. Moreover, the gamma of an “at-the-money” option is increasing as one gets closer to the maturity, whereas the gamma of an “out-of-the-money” option is decreasing.

The Put Ratio Temptation

As equation (3) shows, the gamma and the theta (first derivative of a derivative product with respect to time) of a portfolio are of opposite signs. Moreover, in the equity market, the implied volatility is usually described by a skew, meaning that if we consider two puts P_1 and P_2 for the same maturity T , having two strikes K_1 and K_2 with $K_1 < K_2$, we classically have $\sigma_{K_1} > \sigma_{K_2}$. If we now build a self financing portfolio Π that is composed of $P_2 - \alpha P_1$ with $\alpha = \Gamma_2 / \Gamma_1$, the ratio of the two gammas, we get from equation (3) that $\delta \Pi \approx \frac{1}{2} S^2 \Gamma_2 (\sigma_{K_1}^2 - \sigma_{K_2}^2) \delta t > 0$.

This result is not in contradiction with arbitrage theory; it only demonstrates that equation (3) is strictly a local relation. As shown by Figure 2, to keep this relation through time, the trader would have to continuously sell the put P_2 , as α increases as time to maturity decreases, and, in case of a market drop down, he or she would find himself in a massive negative gamma situation. Still, practitioners commonly use put ratios to improve the breakeven of their position.

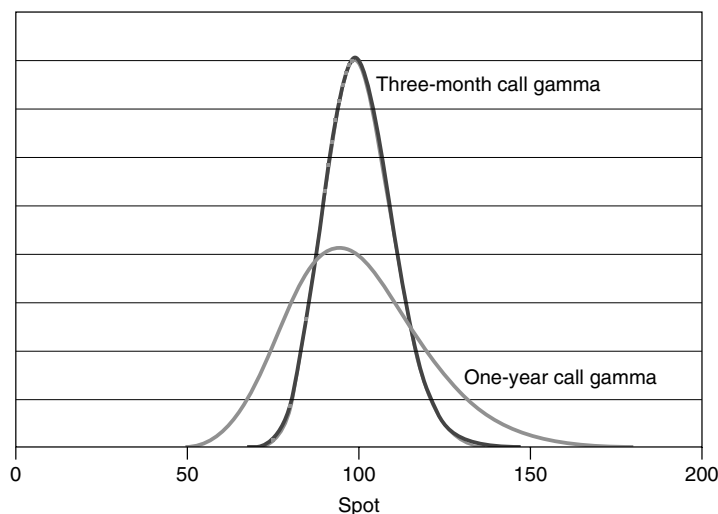

Figure 2 Gamma of a European call as a function of the spot for two maturities (strike is equal to 100)

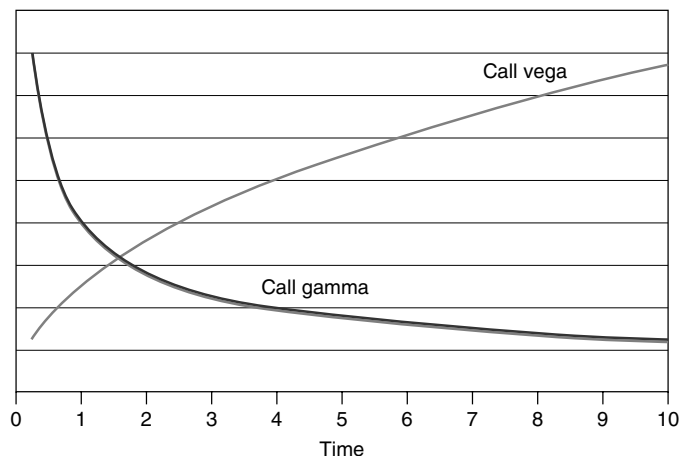

Figure 3 Compared evolution of the gamma and vega of an at-the-money European call as a function of maturity (scales are different)

Hedging Gamma with a Variance Swap or a Gamma Swap

As explained in **Variance Swap** a variance swap is equivalent to a log contract. Hence, its cash gamma is constant. It is therefore an efficient gamma hedging instrument for a portfolio whose gamma is not particularly localized (as opposed to a portfolio of vanilla options whose gamma is locally described by Figure 2). Gamma swaps (*see* **Gamma Swap**) have the same behavior. Their specificity is to have a constant gamma.

Extending the Definition of Gamma

In the market, the implied volatility changes with the spot moves (*see* **Implied Volatility Surface**). It is in contradiction with the use of a Black and Scholes model whose volatility is constant, but, to avoid the multiplicity of risk sources, and to keep them observable, traders tend to rely on that model, nonetheless (and therefore hedge their vega exposure). Nevertheless, to take this dynamics into consideration, some traders incorporate a “shadow” term into their sensitivities. The shadow gamma [1]

is defined as

$$\frac{\partial^2 O}{\partial^2 S} + \frac{\partial}{\partial S} \left(\frac{\partial O}{\partial \sigma} \frac{\partial \sigma}{\partial S} \right) \quad (4)$$

The second term, the shadow term, depends on the chosen dynamics of the implied volatility.

The problem with the shadow approach is that we cannot rely anymore on a self-financing strategy in the Black and Scholes framework to define the breakeven. One solution, in order to build a self-financing strategy that incorporates volatility surface into the dynamics, is to use a stochastic volatility model (see **Heston Model**) instead of a Black and Scholes model. For example, one can use the following model:

$$\begin{aligned} dS &= rS dt + \sigma S dW_t^1 \\ d\sigma &= \mu dt + \nu dW_t^2 \\ d\langle W^1, W^2 \rangle_t &= \rho dt \end{aligned} \quad (5)$$

Using the same arguments as in the Black and Scholes framework, the P&L of a delta-hedged self-financing portfolio (now with a first-order hedge for the volatility factor using a volatility instrument like a straddle, for example) in this model is

$$\begin{aligned} \delta \Pi &\approx \frac{1}{2} S^2 \frac{\partial^2 O}{\partial^2 S} \left(\left(\frac{\delta S}{S} \right)^2 - \sigma^2 \delta t \right) \\ &+ \frac{1}{2} \frac{\partial^2 O}{\partial^2 \sigma} ((\delta \sigma)^2 - \nu^2 \delta t) \\ &+ S \frac{\partial^2 O}{\partial S \partial \sigma} \left(\left(\frac{\delta S}{S} \right) \delta \sigma - \rho \sigma \nu \delta t \right) \end{aligned} \quad (6)$$

Two other “gamma” terms appear in this equation, which proves that incorporating the dynamics of the volatility is not as simple as the addition of a shadow term in the Black and Scholes breakeven relation. It also shows that controlling the P&L leads to a more complex gamma hedge, as it is now necessary to annihilate two more terms (the second and third ones, for which natural hedging instruments are strangles and risk reversals).

Another popular way of integrating the volatility surface dynamics in the model is to use Levy processes (see **Exponential Lévy Models**). We do not give the P&L explanation in that case, but, like in the stochastic volatility framework, it is the sum of the term presented in equation (3), for the Brownian

part, and of a term coming from the pure jump part. The hedge of the latter is very complex because it is not localized in space (one needs to use a strip of gap options, e.g., to control it).

Finally, a possible way of controlling the volatility surface dynamics is to make no assumption on the volatility except that it is bounded. This framework is known as *uncertain volatility modeling* and is presented in **Uncertain Volatility Model**. The analysis leads to the conclusion that instead of one breakeven volatility, there are, in fact, two: the upper bound for positive gamma regions and the lower bound for negative gamma ones. In that case, and supposing that the effective realized volatility stays locally between these two bounds, gamma hedging is not necessary, as the P&L of the delta-hedged self financing portfolio is naturally systematically positive.

Multiunderlying Derivatives

We consider a multidimensional Black and Scholes model of N stocks S_i with volatility σ_i . ρ_{ij} represents the correlation between the Brownian motions controlling the evolution of S_i and S_j . We do not discuss the issue of multicurrency (see **Quanto Options**) and, using the same mechanism as in the monounderlying framework, we can express the P&L of a delta-hedged self-financing portfolio as

$$\begin{aligned} \delta \Pi &\approx \frac{1}{2} \sum_{i=1}^N S_i^2 \frac{\partial^2 O}{\partial^2 S_i} \left(\left(\frac{\delta S_i}{S_i} \right)^2 - \sigma_i^2 \delta t \right) \\ &+ \sum_{i < j} S_i S_j \frac{\partial^2 O}{\partial S_i \partial S_j} \left(\left(\frac{\delta S_i}{S_i} \right) \left(\frac{\delta S_j}{S_j} \right) - \rho_{ij} \sigma_i \sigma_j \delta t \right) \end{aligned} \quad (7)$$

The first term can be controlled by the hedging instruments we have previously reviewed. The cross ones, which incorporate the “cross gammas”, can also be controlled, using so-called correlation swaps (typically, a basket option minus the sum of the individual options).

Conclusion

Controlling the gamma exposure of a position is one of the main concerns of traders. Hedging instruments

are common options but it is not possible to simply hedge the gamma without modifying the vega exposure of the position. Also, integrating the volatility surface dynamics in the model leads to a more complex gamma-hedging issue than in a Black and Scholes model, but it still can be addressed. Moreover, we remark that although we have considered the equity market in our study, this analysis can easily be extended to other complete markets in which there is no arbitrage and where the price process is modeled by a Brownian motion of any dimension.

End Notes

^aP&L stands for “profit and loss” and represents the evolution of the portfolio value between two dates due to time and to the market activity between these dates.

Delta Hedging

The delta of an asset or a portfolio broadly means net market exposure to an asset class. This may be for a single asset, like an option, or for a portfolio, like an S&P 500 benchmarked mutual fund. Delta hedging is the process of reducing the size of this exposure to a target level to reduce the amount of risk exposure due to the delta present in the portfolio.

Delta hedging is a term used in two broad categories: delta hedging of investment portfolios and delta hedging of financial derivatives.

Delta Hedging of Investment Portfolios

The delta of a portfolio is determined based on the assets in the portfolio. For equity portfolios, it may mean net equity exposure, for fixed income portfolios it may mean portfolio duration, while for commodity portfolios it could be exposure to the underlying commodity such as bushels of corn or barrels of oil. To delta hedge a portfolio, the portfolio manager determines what target net delta level is desired for the portfolio and uses a broad market instrument like a futures or swaps to achieve that desired level of delta. In addition, some portfolio managers might be more precise by hedging sensitivity to one factor (beta hedging) or multiple factors.

Delta Hedging of Financial Derivatives

Financial derivatives provide linear or nonlinear exposure to an underlying asset price level. While it is possible that both the buyer and the seller of a specific derivative are interested in identically opposite exposures, it is more common that one of the parties to the transaction is a financial intermediary or market maker that plans to hedge or reduce some of the risks of the transaction.

Delta hedging is the simplest form of hedging financial derivatives. This hedging aims to neutralize the direct exposure to the underlying asset, or delta, while maintaining second-order exposures to convexity, volatility, and time. In this discussion, we assume that a market maker enters into a financial derivative transaction and decides to hedge the delta

arising from the transaction. If the net delta exposure between the financial derivative and the hedge is zero, the position is said to be *delta neutral*.

The Process of Delta Hedging

The process of delta hedging incorporates some or all of the following steps.

Calculation of Delta

Typically, this is based on risk neutral valuation of the product. As a result the delta may vary depending on the underlying model used in the valuation. This variation may be small for simple products but may result in material differences for complex products. For example, a vanilla equity call option at-the-money (ATM) might have a similar delta based on Black–Scholes [1] inputs or a local volatility model, while a knock-out put, might have materially different deltas if measured by the two models above.

Determining the Appropriate Hedging Instrument

Entering into a hedge has various costs, the key aspects of which are mentioned below:

1. **Liquidity of the hedging instrument**

It is ideal that the hedging instrument is easily tradable with a low bid/ask spread. For derivatives, where the underlying is less liquid or there might be some market impact in executing the hedge, the price of the financial derivative is based on the average realized execution price level of the hedge.

2. **Basis risk in the hedging instrument**

In practice, some of the hedging instruments may have a small basis risk *versus* the actual underlying, which needs to be hedged. This usually happens when the actual underlying has significant transaction or liquidity costs and the basis tracking risk is low.

3. **Financing costs**

There might be costs associated with going long or short an asset as a hedge or entering into a financial swap transaction (e.g., the cost of posted collateral).

4. **Stability of the hedge**

If the hedge involves going long an asset or entering into a long-term linear over the counter (OTC)

derivative, the hedge is considered stable. However, if the market maker requires to borrow the hedge to go short (e.g., short stocks or bonds), then the hedge may be subject to a lack of availability to borrow in the marketplace.

Incorporating the Cost of Hedging into the Price of the Financial Derivative

1. Market makers who seek to hedge a position may incorporate the cost of hedging using adjustments to the financing rates, expected loss owing to basis risk, or future rollover costs of short-term hedges (like futures) into the pricing of the derivative.
2. In addition, the market maker may seek contractual obligations to ensure that if he is unable to hedge the contract, he has a right to unwind the derivative at fair market price.

Examples of Delta Hedging

Below are some examples of delta hedging.

Example 1. Listed put option on S&P 500 index.

Market Maker Derivatives Inc. (MMDI) sells an exchange listed put on the S&P 500 (SPX) Index on a \$100mm notional with a strike price of \$1350 and one year expiration to a client when the SPX is trading at \$1400. The Black–Scholes model calculates the delta of the position at 38.5%. To delta hedge and neutralize the position to P&L swings from changes in the level of the SPX, MMDI needs to sell \$38.5mm of SPX Index. MMDI can do one of the following to achieve this:

1. Sell \$38.5mm in SPX index futures (1100 futures at \$1400 with a 250 multiplier). Since these futures expire every three months, the market maker needs to roll this exposure into a new contract every three months.
2. Sell \$38.5mm of a one-year swap on the SPX Index with another counterparty for one year or enter into an OTC put/call combo transaction (buying a put and selling a call with the same strike price to replicate a forward using put–call parity) for \$38.5 mm notional. This is done in the OTC market place and appropriate International Swaps and Derivatives Association, Inc. (ISDA) (<http://www.isda.org/>) documents and collateral agreements need to be in place before this is done.

3. Sell \$38.5mm a basket of stock that comprises S&P 500 index, paying a borrowing fee and executing stock orders on the exchange.

Example 2. Long total return swap on XYZ commodity index.

MMDI sold a five-year total return swap on the XYZ commodity index to a client for \$10mm notional, which has a delta of \$10mm. To hedge the position, MMDI can do one of the following:

1. Buy an equal and offsetting swap with another client or market counterparty or a basket of commodities swaps for each of the components of the XYZ index from another counterparty which is the perfect hedge (assuming no counterparty risk).
2. Hedge the XYZ index with a much more actively traded index like the CRB index taking into account the tracking risk and weighting differences of the components between the two indices.
3. Maintain a portfolio of long futures on commodities, which compromises the XYZ index and rolling futures on the position for the next five years. The market maker assumes the risk of rolling the futures positions to changes in the shape of the commodity forward curve.

Rehedging Delta with Time, Spot Moves

The delta of a financial product may change with time or the levels of the different market parameters such as volatility, underlying price, interest rates, or skew. It is then necessary to periodically adjust the size of the hedge to maintain the delta at a preset level. The rate of change of the delta is proportional to the gamma (*see Gamma Hedging*).

Dispersion Trading

Dispersion trading refers to the practice of selling index variance while buying variance of its constituents at the same time. The reverse strategy (buying index variance while selling constituents variance) can also be employed, but it is not as popular.

To understand dispersion trading, consider the index as a basket of stocks:

$$S_I = \sum_{i=1}^n w_i S_i \quad (1)$$

where w_i is the weight of S_i in the basket.

The variance of the index is related to that of the individual stocks by

$$\sigma_I^2 = \sum_{i=1}^n w_i^2 \sigma_i^2 + 2 \sum_{i=1}^n \sum_{j>i}^n \rho_{ij} w_i w_j \sigma_i \sigma_j \quad (2)$$

The variance is defined as

$$\sigma_i^2 = \frac{1}{T} \sum_{t=1}^T (S_i^t - \bar{S}_i)^2 \quad (3)$$

with $\bar{S}_i = \frac{1}{T} \sum_{t=1}^T S_i^t$, and the correlation ρ_{ij} is defined as

$$\rho_{ij} = \frac{1}{T} \sum_{t=1}^T (S_i^t - \bar{S}_i)(S_j^t - \bar{S}_j) / (\sigma_i \sigma_j) \quad (4)$$

If we hold the realized variances of every component stock constant, the maximum for the index variance is reached when the correlation between all the components is 100%. If the correlation between stocks is not perfectly 100%, the index variance is lower. The more “dispersed” the stocks are, the lower is the index variance.

A measure of dispersion—the dispersion spread—can be defined as

$$D = \sqrt{\left(\sum_{i=1}^n w_i \sigma_i \right)^2 - \sigma_I^2} \quad (5)$$

or, alternatively, it has also been defined as

$$D = \sum_{i=1}^n w_i \sigma_i - \sigma_I \quad (6)$$

$D = 0$ corresponds to the case when there is no dispersion—all correlations are 100%.

So, to long dispersion is equivalent to be short correlation and *vice versa*.

To characterize the correlation between the constituents, one can define the average correlation as if the correlation is the same between every pair of stocks in the basket

$$\bar{\rho} = \frac{\sigma_I^2 - \sum_{i=1}^n w_i^2 \sigma_i^2}{2 \sum_{i=1}^n \sum_{j>i}^n w_i w_j \sigma_i \sigma_j} \quad (7)$$

However, sometimes, it is easier to calculate the less accurate “correlation proxy,” which is defined as

$$\tilde{\rho} = \frac{\sigma_I^2}{\left(\sum_{i=1}^n w_i \sigma_i \right)^2} \quad (8)$$

This correlation proxy can be interpreted as the “average” of all correlations between all pairs of stocks in the index including a stock with itself (which we know should be 100%). When the number of stocks in the index n is high, it can be seen that $\sum_{i=1}^n w_i^2 \sigma_i^2$ is much less compared to the retained terms:

$$\sum_{i=1}^n w_i^2 \sigma_i^2 \ll \sigma_I^2 \quad (9)$$

$$\sigma_I^2 \simeq \sigma_I^2 - \sum_{i=1}^n w_i^2 \sigma_i^2 \quad (10)$$

$$2 \sum_{i=1}^n \sum_{j>i}^n w_i w_j \sigma_i \sigma_j \simeq 2 \sum_{i=1}^n \sum_{j>i}^n w_i w_j \sigma_i \sigma_j + \sum_{i=1}^n w_i^2 \sigma_i^2 \quad (11)$$

The correlation proxy and correlation are very close to each other. The implied correlation can be simply inferred from the ratio of average volatilities. Sometimes it is also convenient to calculate the mean variance ratio that is more directly related to the trade profit/loss (P/L).

By definition, realized correlation is the correlation calculated using realized volatilities, and implied correlation is the correlation calculated using implied volatilities. Implied volatilities decide the price of the traded instruments like vanilla options and variance swaps.

The success of dispersion trades relies on the fact that statistically the realized correlation tends to be below the implied correlation. Historically, if one were long dispersion, on average, one made more money than the amount one lost. There are many different reasons for this phenomenon, for example, one may argue that there is more market demand for index volatility than that of the individual stock, which means usually there is more premium for equity stock volatility. More importantly, correlation jumps to a very high level when extreme market conditions exist, namely, global recession and market crash, while it stays low in a normal and uneventful market.

To long the volatility of each component stock, and short the index volatility, one can either trade vanilla options or variance swaps. The variance swaps provide direct exposure to variance without the unnecessary cost and hassle of hedging against daily stock movements.

One issue in dispersion trade is to decide the relative weight for index and constituents variances. There is no single “correct” relative weight to use. For example, vega neutral weights aim to make the sum of constituents vega and index vega zero, so that the trade is hedged against fluctuations in level of volatility. “Premium neutral” weights make the initial premium of buying constituents and selling index cancel each other.

In reality, it is impractical to trade all constituents. Often, a selection of names in the index (or even those not in the index) is used. This is called a *proxy basket*. One can build the proxy basket by selecting, for example, the names that have the largest weights in the index, or the names that are judged relatively “cheap”, or the names that are mostly likely to “disperse” against each other, or simply by the stock fundamentals.

Correlation Swap

A correlation swap is a type of exotic derivative security that pays off the observed statistical correlation between the returns of several underlying assets, against a preagreed price. At the time of writing, it is traded over-the-counter (OTC) on equity and foreign exchange derivatives markets. This article focuses on equity correlation swaps, which appeared in the early 2000s, as a means to hedge the parametric risk exposure of exotic trading desks to changes in correlation.

Payoff

Similar to **variance swaps**, the correlation swap payoff involves a notional (the amount to be paid/received per *correlation point*^a), a realized correlation component (the formula used to calculate the level of observed statistical correlation between the underlying assets), and a strike price:

$$\begin{aligned} \text{Correlation swap payoff} &= \text{notional} \\ &\times (\text{realized correlation} - \text{strike}) \end{aligned}$$

For example, a one-year correlation swap contract on the constituents of the Dow Jones Euro Stoxx 50 index would include the following terms:

- underlying assets—each of the 50 constituent stocks denoted by $S_1, \dots, S_N$ ($N = 50$);
- notional—€100 000 per *correlation point*;
- realized correlation— $\frac{2}{N(N-1)} \sum_{1 \leq i < j \leq N} \rho_{i,j}$, where $\rho_{i,j} = \frac{\text{Cov}(X_i, X_j)}{\sqrt{\text{Var}(X_i) \times \text{Var}(X_j)}} \times 100$ is the familiar pairwise coefficient of correlation between the time series X_i and X_j of daily log returns observed in the year following the trade date;
- strike—52.0 *correlation points*.

Thus, if after one year the arithmetic average of pairwise correlation coefficients between the 50 underlying assets is equal to 58.3 *correlation points*, the swap seller will pay a net cash flow of €630 000 to the swap buyer.

Realized Correlation

There are mainly two types of realized correlation formulas currently found on over-the-counter (OTC) markets:

- equally weighted realized correlation—the formula used in the above example;
- weighted realized correlation— $\frac{\sum_{1 \leq i < j \leq N} w_i w_j \rho_{i,j}}{\sum_{1 \leq i < j \leq N} w_i w_j}$,

where $w_1, \dots, w_N$ are preagreed positive weights summing to 1. In the above example, one would typically take the “index weights” as of the trade date, that is, the stock quantities that a portfolio manager would invest in to track one unit of the Dow Jones Euro Stoxx 50 index.

Several technical reports have investigated how the above weighted realized correlation (WRC) formula relates to other proxy formulas that are popular in econometrics, when the underlying assets and weights correspond to an equity index. Tierens–Anadu [4] give empirical evidence that in the case of the S&P 500 index,

$$WRC \approx \frac{\sum_{i < j} w_i w_j \text{Cov}(X_i, X_j)}{\sum_{i < j} w_i w_j \sqrt{\text{Var}(X_i) \text{Var}(X_j)}} \quad (1)$$

In addition, Bossu [1, 2] derives the following limit-case proxy formula, subject to some conditions on the weights:

$$\begin{aligned} &\frac{\sum_{i < j} w_i w_j \text{Cov}(X_i, X_j)}{\sum_{i < j} w_i w_j \sqrt{\text{Var}(X_i) \text{Var}(X_j)}} \\ &\stackrel{N \rightarrow \infty}{\sim} \frac{\text{Var}\left(\sum_{i=1}^N w_i X_i\right)}{\left(\sum_{i=1}^N w_i \sqrt{\text{Var}(X_i)}\right)^2} \quad (2) \end{aligned}$$

The proxy formula on the right-hand side is remarkable because we can interpret the numerator as “index variance” and the denominator as “average constituent variance”, which is more straightforward than the average of $N \times (N - 1)/2$ pairwise correlation coefficients.

Fair Value

At the time of writing, little is known about the “fair value” of correlation swaps. Owing to the typically large number of underlyings, the popular Monte Carlo engine with or without local volatility surfaces requires an $N \times N$ correlation matrix as additional input parameter. There are two problems with this approach: a practical one and a theoretical one. The practical problem is that individual correlation coefficients cannot be implied from listed option markets.^b The theoretical problem is that, even if one could come up with a sensible implied correlation matrix, a meaningful dynamic replication strategy for the correlation swap payoff would still be missing.^c

Ongoing research (see, e.g., the working papers of Bossu [1] and Jacquier [3]) aims to identify the linkages between **dispersion trading** and the dynamic hedging of correlation swaps, especially when the underlying assets are the constituent stocks of an equity index. This approach exploits the proxy formulas above to rewrite the correlation swap payoff as a function of tradable variance swaps; in this framework the correlation swap becomes a multiasset volatility derivative (see **Realized Volatility Options**), rather than a classical multiasset derivative.

End Notes

^aIn market jargon, a *correlation point* is equal to 0.01. With this convention, the value of a correlation coefficient is comprised between -100 and $+100$ correlation points.

^bTo imply the value for $\rho_{i,j}$, one needs three option prices: a vanilla option on S_i , a vanilla option on S_j and, for

example, a vanilla option on a portfolio made of 50% S_i and 50% S_j . The former two options are listed, the latter is not.

^cFor example, in a two-asset extension of the Black–Scholes model with instantaneous correlation ($d\ln S_i^1)(d\ln S_j^2) = \rho dt$, the forward value of an equally weighted correlation swap is simply $\rho - \text{strike}$, which would be hedged purely with cash!

Stock Pinning

Stock pinning, or simply *pinning*, is formally the occurrence of a closing stock print, on option expiration day, which exactly matches the denominated value of a strike price. As an example, let stock XYZ have strikes 30, 32.5, 35, and 40. If on Friday, May 16, 2008 at 4:00 pm EDT (USA), the third Friday of the month and thus an expiration day for listed

options, the closing print of XYZ is \$35, then stock XYZ is said *to pin*. Prices of \$34.27, \$31.60, or even \$32.48, are said not to have pinned. Figure 1 is a tick price graph of KO (Coca Cola Corporation) showing the last several days prior to a pinning expiration.

As a practical matter, it may be useful experimentally to consider pinning to have occurred if the stock expires within a certain interval of a strike price. There are several reasons for this looser definition. Empirically there may be several “closing prints”

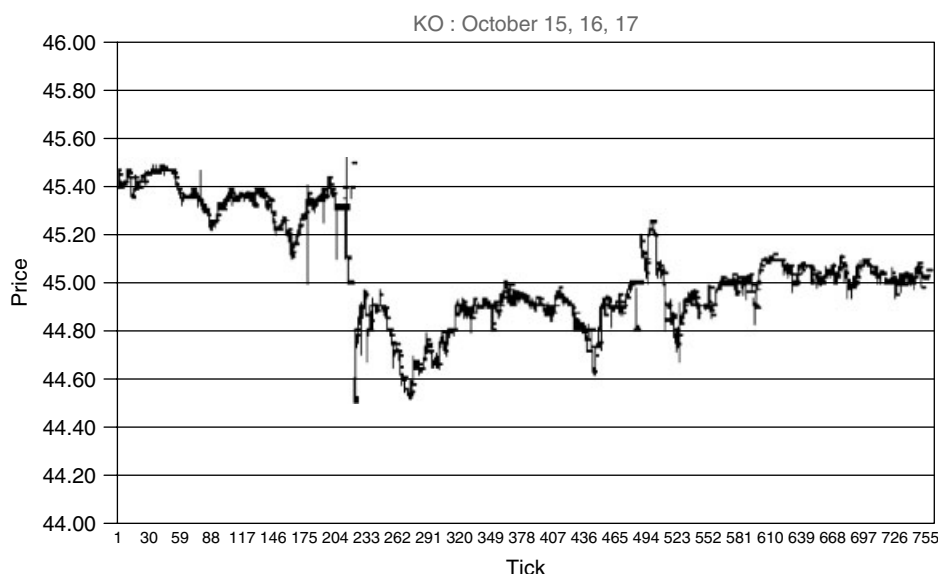

Figure 1 KO (Coca Cola) tick data for a pinning expiration, October 17, 2003

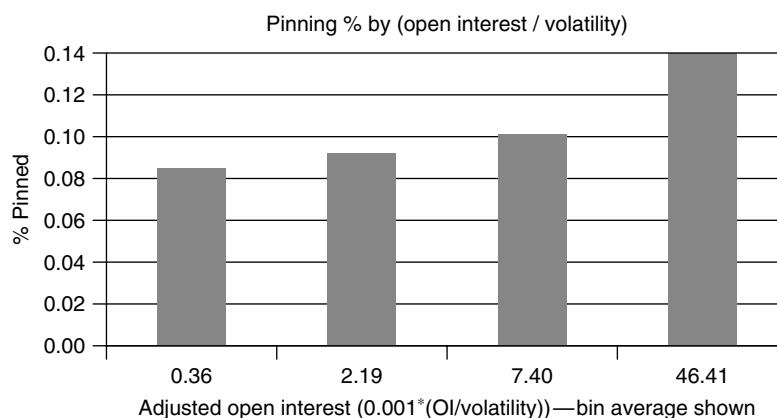

Figure 2 All optionable stocks in 2002 divided into quartiles by pinning strength, β . As predicted, the probability of pinning increases with beta. (Pinning criteria \$0.15, courtesy Bart Rothwell)

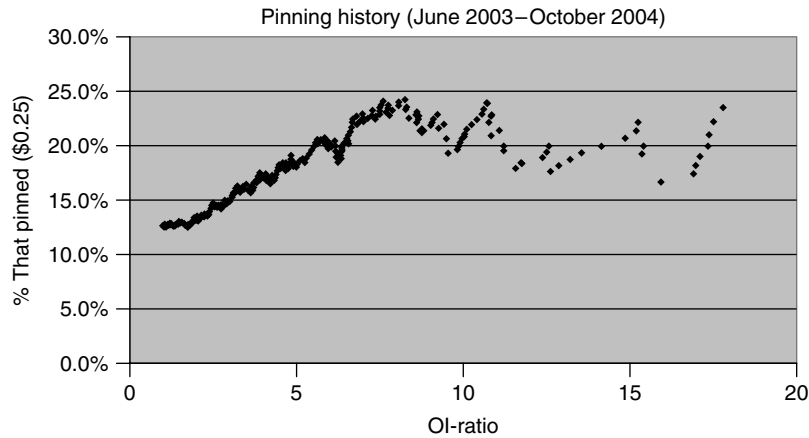

Figure 3 Cumulative distribution function of pinning of stocks, which are within \$1 of a strike with 1 week to go to expiration as a function of the parameter, β . (Courtesy Tom MacFarland)

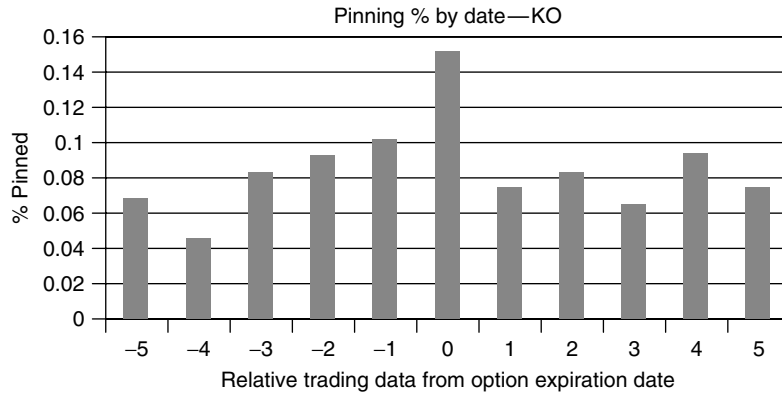

Figure 4 The percentage of days KO closed within \$0.15 of a strike in a 10-year period January 1, 1996 to January 1, 2005. 0 is expiration day, negative integers are days prior to expiration, positive integers are days following expiration. (Courtesy Bart Rothwell)

making a choice of the closing price arbitrary. Tick data shows that a stock may be effectively *pinned* over the last several minutes before expiration but then have a closing print just off the strike. In the first example, this might happen if the last quote were \$34.98 bid, at \$35.01, and the closing price stayed in the interval but was not precisely \$35.

Two additional reasons for a looser definition are the automatic exercise conditions mandated by the OCC (Options Clearing Corporation) and the consequent *pin risk*, which attends expiring short positions on the (nearly) pinned strike. The OCC has traditionally fixed an interval about a strike

outside of which in-the-money puts and calls would be automatically exercised by the clearing process; options within the interval would require *exercise notice* by the holder. Over time, the OCC has reduced the interval to the current \$0.01 (from \$0.05 before June 2008 expiration); traders will declare a stock to have pinned if it falls within the OCC interval. Pin risk attends to any short position inside this interval because an uncertain number of options may be assigned and thus an uncertain postexpiration stock position exists in the positions of those short the expiring at-the-money options.^a

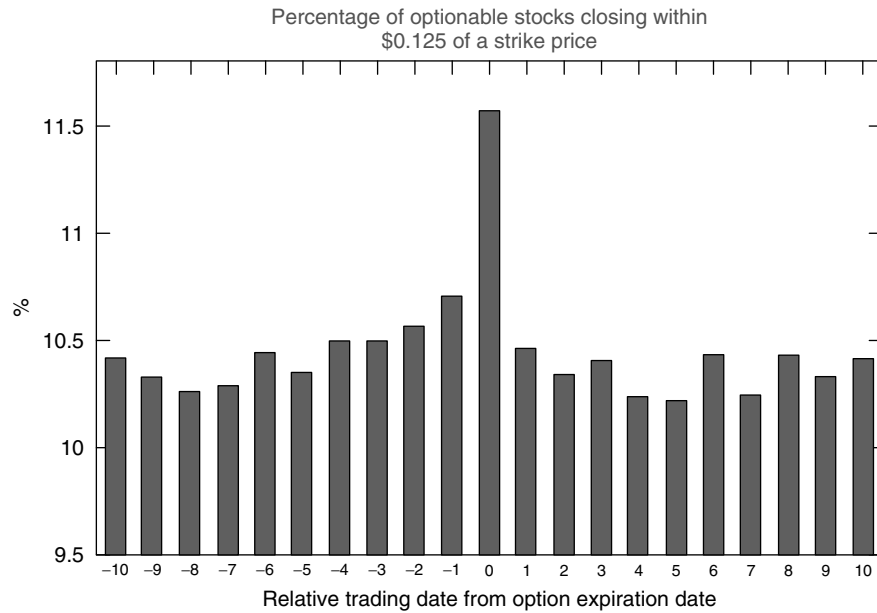

Figure 5 All stocks, January 1996 to September 2002 [Reproduced with permission from Stock price clustering on option expiration dates, Ni *et al.*, Journal of Financial Econometrics, © Elsevier 2005.]

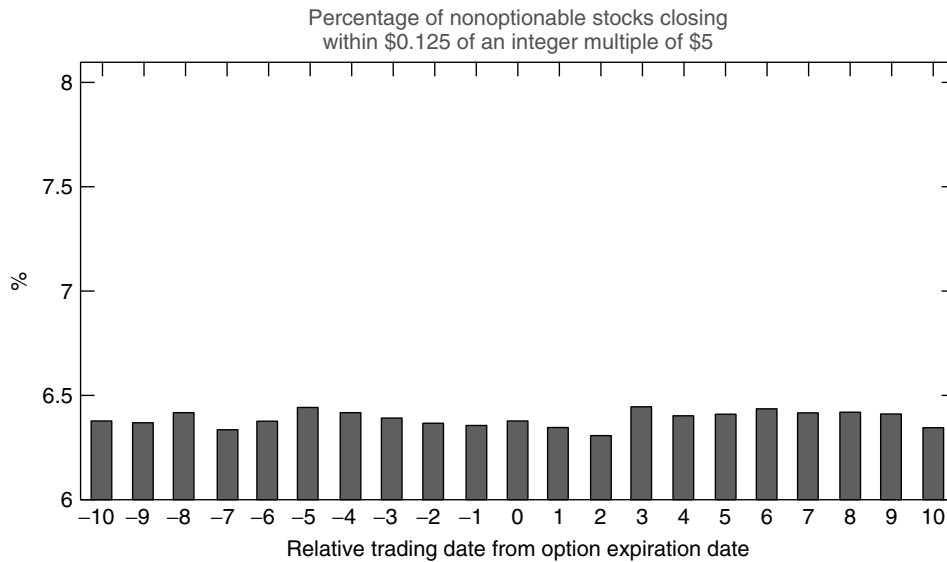

Figure 6 Nonoptionable stocks do not pin, January 1996 to September 2002 [Reproduced with permission from Stock price clustering on option expiration dates, Ni *et al.*, Journal of Financial Econometrics, © Elsevier 2005.]

So far we have defined a single instance of pinning. Complementing the notion of an individual instance of stock pinning is an ensemble assertion

of stock pinning. In this perspective, a stock, or stocks, is said to pin if, no matter how small an interval one chooses about a strike price, there

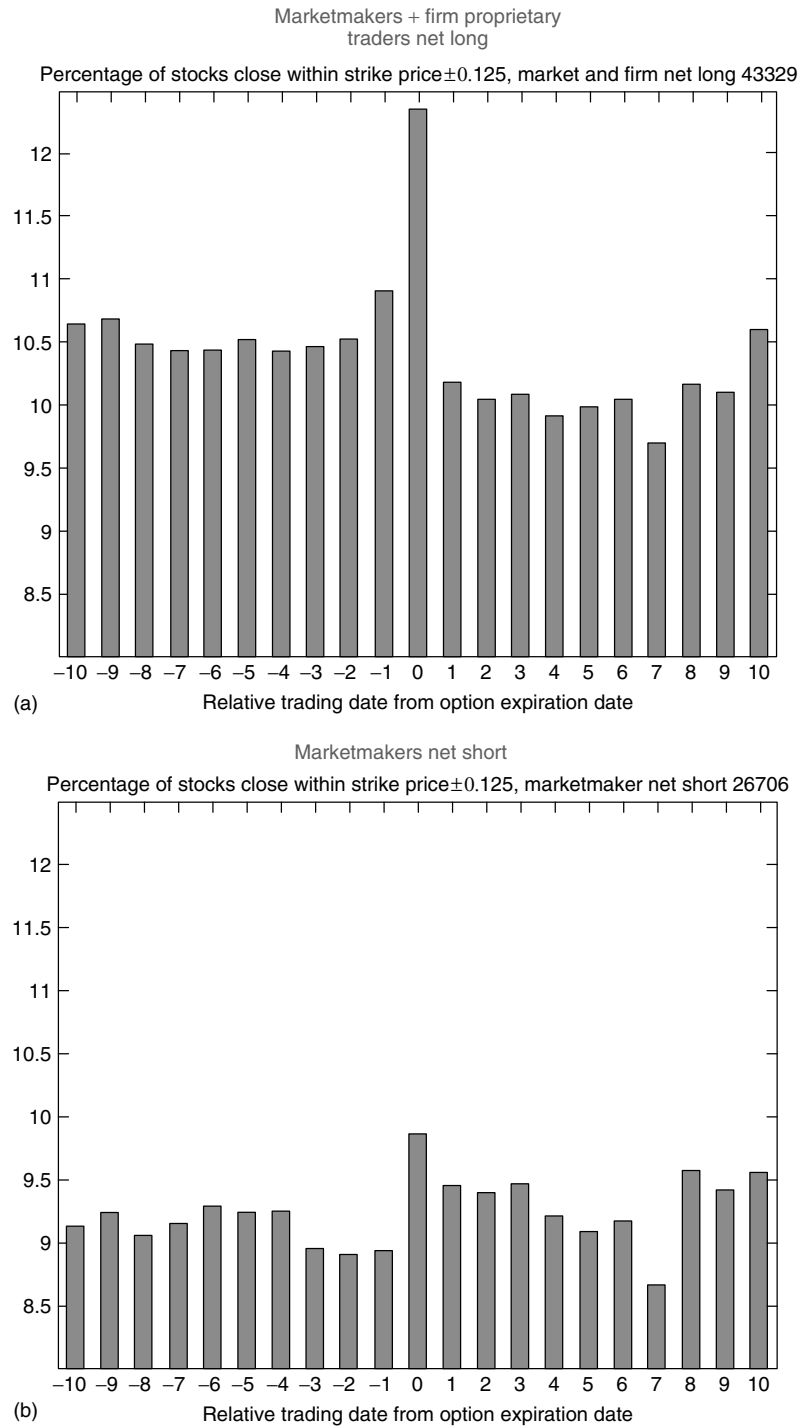

Figure 7 All optionable stocks, January 1996 to September 2002. (Pinning criterion \$0.125): pinning when professional traders are (a) long and (b) short the expiring at-the-money strike

is a finite probability of finding closing prints within the interval. To compute this limit, expressed mathematically as

$$\lim_{\varepsilon \rightarrow 0} P(|S-K| \leq \varepsilon) > 0 \quad (1)$$

where ε is an interval about (any) strike K , S is the stock price at expiry, and P is the probability among all expiration closes, one can do empirical experiments or theoretical calculations. It is important to note that standard models of option pricing such as Black–Scholes, Heston, SABR, and stochastic volatility models, in general, cannot exhibit pinning mathematically.

Although traders had long believed pinning to be a real phenomenon, little theoretical or experimental effort was made to examine the subject through the 1990s. Krishnan and Nelkin [3] looked at the data set of MSFT (Microsoft Corporation) expirations and found evidence of pinning. They proposed a model that combined a Gaussian random walk with a Brownian bridge process in order to force pinning to a strike. The model *perforce* guaranteed pinning, but suffered from many obvious weaknesses: stocks do not always pin; they can pin at many possible strikes; and the choice of the amount of Brownian bridge component was exogenously (and arbitrarily) imposed.

Then Avellaneda and Lipkin [1], and nearly simultaneously, Ni *et al.* [4], produced theoretical and experimental arguments for pinning. In the former work, Avellaneda and Lipkin proposed an asymmetric hedging strategy for professional traders—aggressive hedging of long gamma positions and weak hedging of short gamma positions. This hedging strategy coupled with a stock impact function (simplistically assumed to be linear^b) led directly to pinning (with nonzero probability), which depended naturally and endogenously on the option open interest, the intrinsic stock volatility, the (logarithmic) distance to the strike and the time to expiration. In dimensionless form, the *strength parameter*, β , is proportional to the open interest and inversely proportional to the volatility. Figures 2 and 3 show, experimentally, the monotonic growth of pinning probability with β .

Ni *et al.* used the IVY® and CBOE databases to check pinning frequencies. Figures 4 and 5, typical Ni *et al.* graphs, indicate the excess clustering

of stock prices near a strike on expiration days for KO and for the entire market over extended periods. Figure 6 demonstrates the absence of pinning in nonoptionable stocks. Finally, Ni *et al.* lent support for the hedging assumptions of Avellaneda and Lipkin. Figure 7(a,b) shows the difference between pinning when professional traders are long (a) and short (b) the expiring at-the-money strike.

Since 2004, other research groups, for example, Jeannin, *et al.* [2], have continued to explore the details of pinning.

End Notes

^a. Practitioners define *pin risk* as the uncertain deltas which an otherwise balanced position might have postexpiration due to the assignment of calls or puts on a near pinning strike. For example, a position long 50 calls and short 50 puts on the \$25 strike, for a stock which expires near \$25, may be assigned from 0 to 5000 shares of stock due to the uncertain number of puts which may have been exercised. This amount of stock thus assigned is independent of the number of calls the trader chooses to exercise himself.

^b. Following the initial 2003 work, Gennady Kasyan (with Avellaneda and Lipkin, unpublished) showed that any impact function stronger than square-root would result in pinning. This suggests that weaker impact functions may be contradicted by the extensive market evidence of stock pinning.

Variance Swap

Definition

A variance swap is a volatility derivative that pays off on realized volatility of some underlying:

$$\text{Payoff} = (\sigma_R^2 - K_{\text{var}}) \times N \quad (1)$$

where σ_R^2 is the realized variance, K_{var} is the fair value of the realized variance at inception, and N is the notional amount, a leverage factor. The realized variance may be defined differently in different markets depending not only on the “default model” but also on specific contract specifications. One standard way for stocks [9] is to define realized variance as

$$\sigma_R^2 = \frac{252}{n} \sum_{i=1}^n u_i^2, \quad u_i = \ln(S_i / S_{i-1}) \quad (2)$$

This requires $n + 1$ observations of the daily closing stock price S_i . The factor 252 is the approximate number of business days in a year, which gives an annualized variance. Also note that this formula assumes the mean of the returns to be zero. This means that it is distinct from the statistical variance of the returns. The mean of returns is typically small and setting it to zero makes returns on variance swaps additive over time. Using log returns to measure variance makes this formula compatible with the standard Black–Scholes option pricing formula.

The long position in a variance swap receives N dollars for every point by which the stock’s realized variance σ_R^2 has exceeded the inception fair value K_{var} . See [6] for one of the earliest, but most comprehensive, references on variance swaps. In this reference, the authors discuss replication problems due to strike spacing and gapping of the underlying, for example.

It is market practice to define the variance notional in volatility terms:

$$\text{Variance Notional} = \frac{\text{VegaNotional}}{2 \times \sigma_{\text{strike}}} \quad (3)$$

where the strike volatility σ_{strike} is equal to the square root of the strike variance K_{var} . With this adjustment, if the realized volatility is 1 percentage point above

σ_{strike} at maturity, the payoff is approximately equal to the vega notional.

Uses of variance swaps include trading the level of volatility (variance swaps are a more pure way to do this compared to straddles), trading the realized/ implied vol spread, hedging of volatility exposures, or trading volatility on a forward basis via forward variance swaps. See [1] for more details about variance swaps, market practices, and their use in vol spread trading and correlation trading.

Fair Value and Skew

In [6], it is shown that a variance swap can be statically replicated with calls, puts, and a forward contract. The payoff for the variance swap then comes from delta hedging of this portfolio of options with the underlying. The fair value is determined by the cost of the replicating portfolio of options. The payoff in terms of realized volatility is achieved by delta hedging with the underlying. If the realized vol is exactly equal to the expected vol at inception, the hedging profits will be exactly equal to the cost of the option portfolio and the payout will be zero. As the portfolio of options (in theory) includes option of every strike, the fair value cost is affected significantly by the skew. The skew is defined to be the way the implied volatility changes as the strike changes, all else being equal.

The fair value can be derived using the volatility formula discussed in [4]. In this reference, the authors show the remarkable formula that the expected value of any smooth payoff function $f(S_T)$ in terms of the terminal stock price S_T can be written in terms of stock and option prices.

$$\begin{aligned} E_t[f(S_T)] &= f(\kappa)B_0 + f'(\kappa)[C_t(\kappa) - P_t(\kappa)] \\ &\quad + \int_{-\infty}^{\kappa} f''(s)P_t(s)ds \\ &\quad + \int_{\kappa}^{\infty} f''(s)C_t(s)ds \end{aligned} \quad (4)$$

An application of Ito’s lemma to the usual Black diffusion yields the variance differential:

$$2 \left[\frac{dS_t}{S_t} - d(\log S_t) \right] = \sigma^2 dt \quad (5)$$

Applying equation (4) to the log contract [11] in equation (5) shows that the replicating portfolio

consists of out-of-the-money calls and puts of all strikes K , where each option has the weight $1/K^2$ plus a dynamic delta hedge using a forward contract on the stock. The fair value of the variance strike is

$$K_{\text{var}} = \frac{2}{T} \left[rT - \left(\frac{S_0}{S_*} e^{rT} - 1 \right) - \log \frac{S_*}{S_0} \right. \\ \left. + e^{rT} \int_0^{S_*} \frac{1}{K^2} P(K) dK \right. \\ \left. + e^{rT} \int_{S_*}^{\infty} \frac{1}{K^2} C(K) dK \right] \quad (6)$$

Here, $C(K)$ and $P(K)$ are the prices of the call and put, respectively, with strike K .

In [6], we find the following formulas for fair value in terms of simple skew models. For the skew that is linear in the strike,

$$\sigma(K) = \sigma_{\text{ATM}} - b \frac{K - S_F}{S_F} \quad (7)$$

the fair value is

$$K_{\text{var}} = \sigma_{\text{ATM}}^2 (1 + 3Tb^2 + \dots) \quad (8)$$

For the skew that is linear in the delta (here Δ_p is the put delta),

$$\sigma(\Delta_p) = \sigma_{\text{ATM}} + b \left(\Delta_p + \frac{1}{2} \right) \quad (9)$$

the fair value is

$$K_{\text{var}} = \sigma_{\text{ATM}}^2 \left(1 + \frac{1}{\sqrt{\pi}} b \sqrt{T} + \frac{1}{12} \frac{b^2}{\sigma_{\text{ATM}}^2} + \dots \right) \quad (10)$$

In [7], we have a particularly elegant formula for the fair value given directly in terms of the skew. Denote

$$z(k) = d_2 = -\frac{k}{\sigma_{\text{BS}}(k)\sqrt{T}} + \frac{\sigma_{\text{BS}}(k)\sqrt{T}}{2} \quad (11)$$

Intuitively, z measures the log-moneyness of an option in implied standard deviations. Then

$$K_{\text{var}} = \int_{-\infty}^{\infty} dz \cdot N'(z) \sigma_{\text{BS}}^2(z) T \quad (12)$$

Market Risk

In [5], the authors derive general results on market risk for variance swaps. Because variance is additive, a variance swap partway through its life is valued partly by realized vol (already observed) and partly by unrealized/implied vol, which is yet to be observed.

$$V(t_0, T)(T - t_0) = \underbrace{V(t_0, t)(t - t_0)}_{\text{Realized}} \\ + \underbrace{V(t, T)(T - t)}_{\text{Unrealized}} \quad (13)$$

It follows from this that at time t a variance swap with notional N has value

$$M(t) = N e^{-rT} [\lambda(V(t_0, t) - K_0) \\ + (1 - \lambda)(K_t - K_0)], \\ \lambda = (t - t_0)/(T - t_0) \quad (14)$$

The first piece is just the time-weighted value of realized variance against the strike. The second piece is the time-weighted difference of fair value variance strikes. The same formula can be used to decompose the daily price change into three risk components: gamma, and theta:

$$\Delta M(t) = M(t + \Delta t) - M(t) \\ = N \left(\underbrace{\frac{1}{\tau} V(t, t + \Delta t) \Delta t}_{\text{Gamma}} \right. \\ \left. + \underbrace{(1 - \lambda_{t+\Delta t}) \cdot \Delta K}_{\text{Vega}} - \underbrace{\frac{1}{\tau} K_t \Delta t}_{\text{Theta}} \right) \quad (15)$$

The biggest independent risk is in the fair value of the strike, which we have put in the vega component. This component also entails the skew risk.

Volatility Swaps

Although variance swaps can be statically replicated, volatility swaps (*see Volatility Swaps*) cannot. In [3], the authors show that there is an approximate dynamic replicating strategy for volatility

swaps. Before this, volatility swap valuation had been thought to be highly model dependent [2]. See also [8, 10], where the authors give a closed formula for valuing vol swaps using a GARCH model.

ERIC LIVERANCE

Volatility Swaps

Volatility swaps are very similar to variance swaps, both in concept and in application. Like variance swaps, volatility swaps can be used by hedge funds to speculate on volatility movements or by portfolio managers to hedge other products against volatility fluctuations. Since their introduction in 1998, they have seen rapid growth and there is currently a sizable market in both the equity and foreign exchange markets. Volatility swaps are also traded in interest rate and commodity markets.

Technically speaking, a volatility swap is not really a swap, but a forward contract on the realized volatility. At maturity, the buyer receives from the seller the difference between the realized volatility and the fixed strike amount, multiplied by the dollar notional (quoted in dollar per volatility point):

$$\text{Volatility swap} = \text{Notional} \times (\sigma_{\text{realized}} - K) \quad (1)$$

while

$$\text{Variance swap} = \text{Notional} \times (\sigma_{\text{realized}}^2 - K^2) \quad (2)$$

The fixed strike payment is usually referred to as the *fixed leg* of the swap and the realized volatility is referred to as the *floating leg*. The swap contract contains the detailed specifications on how the volatility is calculated. Typically, the floating leg is calculated as

$$\sqrt{\text{Annualization} \times \sum_{i=1}^N \left(\ln \frac{S_i}{S_{i-1}} \right)^2} \quad (3)$$

where S_i should be adjusted by discrete dividends across dividend payment days. In the most accepted convention, the floating leg is reset and computed daily.

Besides variance swaps, another product closely related to volatility swaps is the VIX contract, which is written as the square root of the sum of expected future variances.

Because variance is the square of volatility, the payoff of a variance swap is convex in volatility while the payoff of a volatility swap is linear in volatility. A volatility swap is thus cheaper than the corresponding variance swap. More specifically, the fair strike for

the volatility swap is slightly lower than that of a variance swap. The difference between the two is known as the *convexity adjustment* and gets larger as volatility of volatility gets larger. The convexity adjustment can be calculated, for example, in the Heston model.

The variance swap is preferred in the equity market due to the fact that it can be replicated with a linear combination of vanilla options and a dynamic position in futures (*see Variance Swap*; [2]). In other markets, the volatility swap is actually more liquid than the variance swap. Although a position in variance swap can be replicated, a position in volatility swap cannot. This means that different models that correctly calibrate to the vanilla option surface will give the same price for variance swaps but not for the volatility swaps. In other words, the price of a variance swap is model independent, but the price of volatility swap is not. In practice, the volatility swap and variance swap admit almost equal pricing for short-term maturities. Recent research also suggest that the model dependence is not as large as it is commonly believed and volatility swaps can also be approximately replicated by trading vanilla options (*see Volatility Index Options; Realized Volatility Options*; [1]). Newer models have been developed that can price volatility derivatives including volatility swaps, while remaining consistent with the entire volatility surface [3].

Static Hedging

Liquid traded put and call options can be used as hedge instruments for over-the-counter traded products. Barrier options are the most common exotic options, and, for these contracts, static hedging works out particularly well. In the Black–Scholes model there are simple methods (conceptually straightforward and/or closed form) for constructing replicating portfolios that do not require dynamic trading; they are set up at initiation of the barrier option, and liquidated at either knockout or expiry. They are, thus, static hedges. Inspired by Allen and Padovani [1], we describe how to find static hedges for barrier options in the Black–Scholes model in a way that encompasses both Derman’s [6] intuitive calendar-spread algorithm and Carr’s [4] strike-spread hedges stemming from put–call symmetry.

Construction of Static Hedges

Unless we explicitly say otherwise, we consider a Black–Scholes model throughout this article. This means that the interest rate is constant, and all options are written on some underlying asset S that follows a geometric Brownian motion. A zero-rebate, knockout barrier option is a contract that pays off as a plain vanilla option if S stays within a specified barrier for the whole life of the barrier option, but becomes worthless if the barrier is hit or crossed (*see also Barrier Options*). Recurrent examples are the down-and-out call and the up-and-out call. The value of a still-alive barrier option is of the form $F(S_t, t)$, where the function F solves the Black–Scholes partial differential equation with 0 as boundary condition along the barrier (*see Finite Difference Methods for Barrier Options*). This is illustrated in Figure 1, which is useful to keep in mind when the method for constructing static hedges is described in the following.

Construction of Static Hedges

A portfolio of puts and calls that (approximately) replicates the barrier option can be found as the solution to a linear system of equations, and constructing it does not require knowledge/implementation of barrier option valuation formulas. The idea

is to match the barrier option’s value at expiry and along the barrier.

To illustrate, consider a down-and-out call with strike K , expiry T , and barrier B . (An up-and-out call is treated similarly, except strike-above-the-barrier calls are used as hedge instruments.) Let Put , $Call$ (spot, time | strike, expiry) denote put and call values.

Suppose that we have specified a grid of time points $0 = t_0 < t_1 < \dots < t_n = T$, and n pairs of put with strikes $K_j \leq B$ and expiries $T_j \leq T$. Find the solution α to

$$A\alpha + u = 0 \quad (1)$$

where A is an $n \times n$ matrix with entries $A_{i,j} = Put(B, t_i | K_j, T_j)$ and u is an n -vector with entries $Call(B, t_i | K, T)$. A portfolio with the (K, T) -call and α_j in the (K_j, T_j) -put then matches the barrier option’s zero value at the t_i -points along the barrier, and its expiry payoff above the barrier. So the barrier option is—to a good approximation when the match points, the t_i ’s, are close—replicated buying this portfolio at time 0 and selling it either when the barrier option is knocked out (because sample paths are continuous, this can only happen if the barrier is actually hit) or when it expires. In other words, this represents a static hedge. There is freedom of choice regarding strikes and expiries of the hedge instruments. Derman [6] suggests calendar-spread hedging with strikes along the barrier, that is, using $T_j = t_{j-1}$ and $K_j = B$. This makes the A -matrix triangular so that we can solve for α_j ’s in one easy-to-explain backward-working pass. Another choice—closely related to Carr’s work [4]—is to use strike spreads, that is, $T_j = T$ for all j and K_j ’s that are different and below the barrier.

Example 1. Table 1 gives a numerical comparison of the performance of different hedge portfolios for three-month barrier options; a typical lifetime of a barrier option in foreign exchange markets. Looking at the results in Table 1 for the down-and-out call, we see the appeal of using options as hedge instruments; very few options are needed in the static hedges to achieve a hedge quality that is several orders of magnitude better than usual dynamic Δ -hedging. The numbers for the up-and-out call demonstrate one problem that static hedging does not immediately solve: the up-and-out call is a *reverse* or *live-out* option meaning that the underlying call is in the money when the barrier option knocks out. This

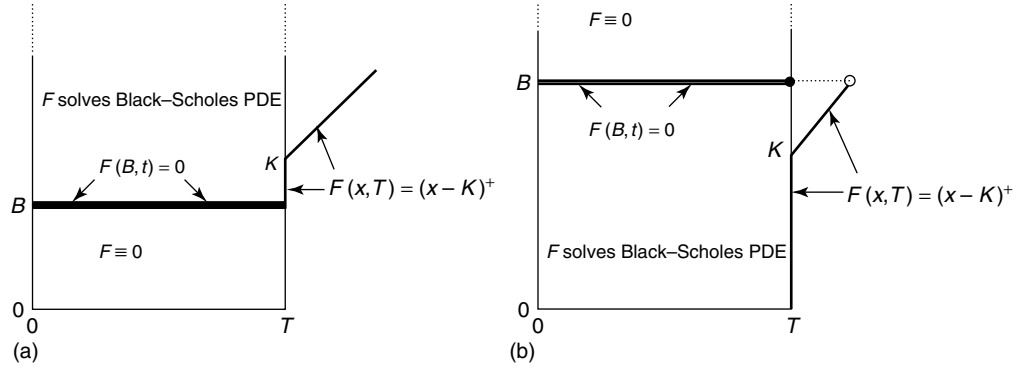

Figure 1 The PDEs for (a) down-and-out and (b) up-and-out call options

Table 1 Performance of dynamic and static hedge strategies in the Black–Scholes with 15% volatility and zero interest rate and dividends. The columns show the initial price of the hedge portfolio and the standard deviation of the benchmarked discounted hedge error, that is, the value of hedge portfolio at liquidation minus barrier option payoff relative to the initial value of the barrier option. All static hedges use three options besides the (K, T) -call. The time points for value matching, the t_i s, and the expiries for the calendar spreads are from the list $(0, 1/12, 2/12, 3/12)$. The strike spreads use calls with strikes $(110, 112, 114)$ for the up-and-out case, and puts with strikes $(90.25 = B^2/K, 88.25, 86.25)$ for the down-and out case. The Δ -hedge is adjusted daily and all portfolios are continuously monitored

Hedge method	Barrier option type			
	Down-and-out call $K = 100, T = 1/4, B = 95$		Up-and-out call $K = 100, T = 1/4, B = 110$	
	Cost	Standard deviation (%)	Cost	Standard deviation (%)
Dynamic; Δ	2.6964	11	1.0358	81
Static; strike spreads	2.6964	0	1.0674	19
Static; calendar spreads	2.6704	1.0	1.3468	94

discontinuity creates a large gap risk, and hedge quality deteriorates. To alleviate this, a number of regularization techniques have been suggested, for instance [10] using singular value decomposition when solving equation (1).

Beyond Black–Scholes Dynamics

Constructing static hedges by solving linear equations like equation (1) goes well beyond the Black–Scholes model. For constant elasticity of variance (asset volatility $\sigma S_t^{\gamma-1}$) and local volatility (asset volatility of the form $\sigma(S_t, t)$) models, the system carries over verbatim; the entries of the A -matrix are just calculated with a different formula/method. For jump-diffusion models [2], one needs to extend the grid of match points to space points beyond the barrier, and for stochastic volatility models [8], an extra

dimension is needed to match different volatility levels at knockout. By using both strike and calendar spreads, asymptotically perfect static hedges can be found in these two cases. It should be stressed that the static hedges are model and parameter dependent, but experimental and empirical evidence [7, 9] suggests a high degree of robustness to model risk.

Put–Call Symmetry and Static Hedges

In a number of papers [3–5], Peter Carr and coauthors have derived put–call symmetries and shown how they can be used to create static hedges for barrier options. In its basic form [4] [page 1167], the put–call symmetry states that in the zero-dividend, zero-interest rate Black–Scholes

model, we have

$$\begin{aligned} \text{Call}(S_t, t|K, T) &= (K/S_t) \times \text{Put}(S_t, t|S_t^2/K, T) \\ &\text{for all } S_t, t, K, \text{ and } T \end{aligned} \quad (2)$$

So a down-and-out call is replicated by buying one strike- K call, selling K/B puts with strike B^2/K , liquidating this position the first time that $S_t = B$, and if that does not happen, holding it until the options expire. More general symmetry relations enable one to find static hedges for such contracts as up-and-out calls, barrier options with rebates, lookback options, and double barrier options ([11] is a survey). Those static hedges will typically involve a continuum of plain vanilla options. Put–call symmetries also exist in models with nonzero interest rates and dividends, and more general dynamics than geometric Brownian motion (see [5]). Note that the strike-spread approach from the previous section finds the symmetry-based static hedges without explicit knowledge of closed-form results, and that the perfect replication of the down-and-out call in Table 1—where the strike- B^2/K put is included as a hedge instrument—demonstrates the basic put–call symmetry.

Corridor Variance Swap

A corridor variance swap, with corridor C , on an underlying Y is a *weighted variance swap* on $X := \log Y$ (unless otherwise specified), with weight given by the corridor's indicator function:

$$w(y) := \mathbb{1}_{y \in C} \quad (1)$$

For example, one may define an *up*-variance swap by taking $C = (H, \infty)$ and a *down*-variance swap by taking $C = (0, H)$, for some agreed H .

In practice, the corridor variance swap monitors Y discretely, typically daily, for some number of periods N , annualizes by a factor such as $252/N$, and multiplies by notional, for a total payoff

$$\text{Notional} \times \text{Annualization} \times \sum_{n=1}^N \mathbb{1}_{Y_n \in C} \left(\log \frac{Y_n}{Y_{n-1}} \right)^2 \quad (2)$$

If the contract makes dividend adjustments (as typical for contracts on single stocks but not on indices), then the term inside the parentheses becomes $\log((Y_n + D_n)/Y_{n-1})$, where D_n denotes the dividend payment, if any, of the n th period.

Corridor variance swaps accumulate only the variance that occurs while price is in the corridor. The buyer therefore pays less than the cost of a full variance swap. Among the possible motivations for a volatility investor to accept this trade-off and to buy up (or down) variance are the following. First, the investor may be bullish (bearish) on Y . Second, the investor may have the view that the market's downward volatility skew is too steep (flat), making down-variance expensive (cheap) relative to up-variance. Third, the investor may be seeking to hedge a short volatility position that worsens as Y increases (decreases).

Model-free Replication and Valuation

The continuously monitored corridor variance swap admits model-free replication by a static position in options and dynamic trading of shares, under conditions specified in **Weighted Variance Swap**, which include all positive continuous semimartingale

share prices Y under deterministic interest rates and proportional dividends.

Explicitly, one replicates using equation (7) of that article, with λ derived in [3]:

$$\lambda(y) = \int_{K \in C} \frac{2}{K^2} \text{Van}(y, K) dK \quad (3)$$

where $\text{Van}(y, K) := (K - y)^+ \mathbb{1}_{K < \kappa} + (y - K)^+ \mathbb{1}_{K > \kappa}$ for an arbitrary put/call separator κ .

Therefore, in the case that the interest rate equals the dividend yield (otherwise, *see Weighted Variance Swap*), a replicating portfolio statically holds $2/K^2 dK$ vanilla calls or puts at each strike K in the corridor C . The corridor variance swap model-independently has the same initial value as a claim on the time- T payoff $\lambda(Y_T) - \lambda(Y_0)$. Additionally, the replication strategy trades shares dynamically according to a “zero-vol” delta-hedge, meaning that its share holding equals the negative of what would be the European portfolio's delta under zero volatility.

For corridors of the type $C = (0, H)$ or $C = (H, \infty)$ where $H > 0$, taking $\kappa := H$ in equation (3) yields

$$\lambda(y) = (-2 \log(y/H) + 2y/H - 2) \mathbb{1}_{y \in C} \quad (4)$$

This λ , with H chosen arbitrarily, is also valid for the variance swap $C = (0, \infty)$

Further Properties

1. For a small interval $C = (a, b)$, the corridor variance swap approximates a contract on local time, in the following sense. Corridor variance satisfies

$$\begin{aligned} V_T^{(a,b)} &:= \int_0^T \mathbb{1}_{X_t \in (\log a, \log b)} d\langle X \rangle_t \\ &= \int_{\log a}^{\log b} L_T^x dx \end{aligned} \quad (5)$$

by the occupation time formula, where L_T^x denotes (an x -cadlag modification of) the *local time* of X . Therefore, at any point a ,

$$\frac{1}{\log b - \log a} V_T^{(a,b)} \longrightarrow L_T^a \quad \text{as } b \downarrow a \quad (6)$$

2. Corridor variance can arise from imperfect replication of variance. The replicating portfolio for

a standard variance swap holds options at all strikes $K \in (0, \infty)$. In practice, not all of those strikes actually trade. If we truncate the portfolio to hold only the strikes in some interval C , then the resulting value does not price a full variance swap but rather a C -corridor variance swap. (Moreover, in practice not even an interval of strikes actually trade, but rather a finite set, which can replicate instead a strike-to-strike notion of corridor variance, as shown in [1].)

3. In the case $C = (H, \infty)$, where $H > 0$, we rewrite equation (4) as

$$\lambda(y) = \frac{2}{H}(y - H)^+ - 2(\log y - \log H)^+ \quad (7)$$

Thus, the replicating portfolio is long calls on Y_T and short calls on $\log Y_T$.

Let F_{X_T} be the characteristic function of $X_T = \log Y_T$. Then techniques in [4, 5] price the calls on Y_T and $\log Y_T$, respectively. Specifically, assuming zero interest rates and dividends, we have the following semiexplicit formula for the corridor variance swap's fair strike:

$$\begin{aligned} \mathbb{E}\lambda(Y_T) - \lambda(Y_0) &= \frac{2}{H\pi} \int_{0-\alpha i}^{\infty-\alpha i} \operatorname{Re} \left(\frac{F_{X_T}(z-i)}{iz-z^2} e^{-iz \log H} \right) dz \\ &\quad + \frac{2}{\pi} \int_{0-\beta i}^{\infty-\beta i} \operatorname{Re} \left(\frac{F_{X_T}(z)}{z^2} e^{-iz \log H} \right) dz - \lambda(Y_0) \end{aligned} \quad (8)$$

for arbitrary positive α, β such that $\alpha + 1, \beta < \sup\{p : \mathbb{E}Y_T^p < \infty\}$, where $\mathbb{E}$ denotes expectation with respect to martingale measure.

In the case $C = (0, \infty)$, equation (4) implies the fair strike formula

$$\begin{aligned} \mathbb{E}\lambda(Y_T) - \lambda(Y_0) &= -2\mathbb{E} \log(Y_T/Y_0) \\ &= 2i F'_{X_T}(0) + 2 \log Y_0 \end{aligned} \quad (9)$$

In the case $C = (H_1, H_2)$, where $0 \leq H_1 < H_2$, subtract the formula for $C = (H_2, \infty)$ from the formula for $C = (H_1, \infty)$.

In the case of nonzero interest rates or dividends, add to equation (8) a correction involving payoffs at all expiries in $(0, T)$, as specified in equation (7a) in **Weighted Variance Swap**, and in equation (9) replace Y_0 by the forward price.

4. With discrete monitoring, the question arises, how to define up-variance and down-variance, and in particular how much variance to recognize, given a discrete move that takes Y across H . Definition (2) recognizes the full square of each move that ends in the corridor. Alternatively, the contract specifications in [2] treat the movements of Y across H by recognizing a fraction of the squared move. The fraction is defined in a way that admits approximate discrete hedging, in the sense that the time-discretized implementation of the continuous replication strategy has in each period a hedging error of only third order in that period's return.

ROGER LEE

Gamma Swap

A gamma swap on an underlying Y is a *weighted variance swap* (see **Weighted Variance Swap**) on $\log Y$, with weight function

$$w(y) := y/Y_0 \quad (1)$$

In practice, the gamma swap monitors Y discretely, typically daily, for some number of periods N , annualizes by a factor such as $252/N$, and multiplies by notional, for a total payoff

$$\text{Notional} \times \text{Annualization} \times \sum_{n=1}^N \frac{Y_n}{Y_0} \left(\log \frac{Y_n}{Y_{n-1}} \right)^2 \quad (2)$$

If the contract makes dividend adjustments (as typical for single-stock gamma swaps but not index gamma swaps), then the term inside the parentheses becomes $\log((Y_n + D_n)/Y_{n-1})$, where D_n denotes the dividend payment, if any, of the n th period.

Gamma swaps allow investors to acquire variance exposures proportional to the underlying level. One application is dispersion trading of a basket's volatility against its components' single-name volatilities; as a component's value increases, its proportion of the total basket value also increases and, hence, so does the desired volatility exposure of the single-name contract. This variable exposure to volatility is provided by gamma swaps, according to point 1 of the "Further Properties" below. A second application is to trade the volatility skew; for example, to express a view that the skew slopes too steeply downward, the investor can go long a gamma swap and short a variance swap, to create a weighting $y/Y_0 - 1$, which is short downside variance and long upside variance. A third application is to trade single-stock variance without the caps often embedded in variance swaps to protect the seller from crash risk; in a gamma swap, the weighting inherently dampens the downside variance, so caps are typically regarded as unnecessary.

Model-free Replication and Valuation

The continuously monitored gamma swap admits model-free replication by a static position in options

and dynamic trading of shares, under conditions specified in **Weighted Variance Swap**, which include all positive continuous semimartingale share prices Y under deterministic interest rates and proportional dividends.

Explicitly, one replicates by using equation (7) of the above article, with

$$\begin{aligned} \lambda(y) &= \frac{2}{Y_0} [y \log(y/\kappa) - y + \kappa] \\ &= \int_0^\infty \frac{2}{Y_0 K} \text{Van}(y, K) dK \end{aligned} \quad (3)$$

where $\text{Van}(y, K) := (K - y)^+ \mathbb{1}_{K < \kappa} + (y - K)^+ \mathbb{1}_{K > \kappa}$ for an arbitrary put/call separator κ . Forms of this payoff were derived in, for instance, [2, 3].

Therefore, in the case that the interest rate equals the dividend yield (otherwise, see the weighted variance swap article), a replicating portfolio statically holds $2/(Y_0 K) dK$ vanilla calls or puts at each strike K . The gamma swap model independently has the same initial value as a claim on the time- T payoff $\lambda(Y_T) - \lambda(Y_0)$. Additionally, the replication strategy trades shares dynamically according to a "zero-vol" delta-hedge, meaning that its share holding equals the negative of what would be the European portfolio's delta under zero volatility.

Further Properties

Points 2–5 follow from equation 3. Point 1 uses only the definition 1.

1. For an index $Y_t := \sum_{j=1}^J \theta_j Y_{j,t}$, let $\alpha_{j,t} := \theta_j Y_{j,t} / Y_t$ be the fraction of total index value due to the quantity θ_j of the j th component $Y_{j,t}$. Define the cumulative *dispersion* D_t by

$$dD_t = \sum_{j=1}^J \alpha_{j,t} d[\log Y_j]_t - d[\log Y]_t \quad (4)$$

Going long $\alpha_{j,0}$ gamma swaps (non-dividend-adjusted) on each Y_j and short a gamma swap on Y creates the payoff

$$\begin{aligned} &\sum_{j=1}^J \alpha_{j,0} \int_0^T \frac{Y_{j,t}}{Y_{j,0}} d[\log Y_j]_t - \int_0^T \frac{Y_t}{Y_0} d[\log Y]_t \\ &= \int_0^T \frac{Y_t}{Y_0} dD_t \end{aligned} \quad (5)$$

as noted in [2]. Hence, a static combination of gamma swaps produces cumulative index-weighted dispersion.

2. By Corollary 2.7 in [1], if the implied volatility smile is symmetric in log-moneyness, and the dividend yield equals the interest rate ($q_t = r_t$), and there are no discrete dividends, then a gamma swap has the same value as a variance swap.
3. Assuming that $Y_T = Y_t R_{t,T}$ for all t , where the time- t conditional distribution of each $R_{t,T}$ does not depend on Y_t , the gamma swap has time- t gamma equal to a discounting/dividend-dependent factor times

$$\frac{2}{Y_0} \mathbb{E}_t \left(\frac{\partial^2}{\partial y^2} \Big|_{y=Y_t} y R_{t,T} \log(y R_{t,T}) \right) = \frac{2 \mathbb{E}_t R_{t,T}}{Y_0 Y_t} \quad (6)$$

where $\mathbb{E}$ denotes expectation with respect to martingale measure. Therefore, the *share gamma*, defined to be Y_t times the gamma, does not depend on Y_t . This property motivates the term *gamma swap*.

4. Within the family of weight functions proportional to $w(y) = y^n$, the gamma swap takes $n = 1$. In that sense, the gamma swap is intermediate between the usual logarithmic variance swap (which takes $n = 0$) and an arithmetic variance swap (which, in effect, takes $n = 2$). Expressed in terms of put and call holdings, the replicating portfolios in these three cases

hold, at each strike K , a quantity proportional to K^{n-2} . The gamma swap $O(1/K)$ is intermediate between logarithmic variance $O(1/K^2)$ and arithmetic variance $O(1)$.

5. Let F be the characteristic function of $\log Y_T$. If $\mathbb{E} Y_T^p < \infty$ for some $p > 1$ then

$$\mathbb{E} Y_T \log Y_T = -i F'(-i) \quad (7)$$

Gamma swap valuations are therefore directly computable in continuous models for which F is known, such as the Heston model (*see Heston Model*).

Atlas Option

In late 1990s, Societe Generale introduced a series of options on baskets of assets which are now commonly referred to as “Mountain Range” options [2]. They were introduced in part to replicate certain portfolio strategies and in part to extend single-name options to portfolios. What these options share is a strong dependence on the correlation structure of the assets, brought about by their nonlinear and path-dependent payoffs. But beyond this similarity, each type has its own distinct payoff tailored to its own risk profile and usage, making each deserving a study of its own. In a series of three articles, we look at the three commonly traded types of Mountain Range options—the Atlas option, the Himalayan option, and the Altiplano option.

We start with the Atlas option, which being the only non-path-dependent option in this group, is somewhat easier to analyze than the other two. This article is organized as follows. We first provide a description of the Atlas option and discuss the financial motivations for and strategies of its usage. We then discuss modeling, valuation, and risk issues that Atlas options share with all Mountain Range options, and conclude with a brief analysis of the risk profile that is unique to it. We remark that although the following discussion holds for a wide class of assets, such as foreign exchange (FX) and commodities, these options are traded mostly on baskets of stocks.

Contract Description

The payoff of the Atlas option is simply a call (or a put) option on the performance of a portfolio at maturity with the best and worst performing names removed. More precisely, given a portfolio, or basket of n stocks, let $S_i(t)$ be the price of the stock $i = 1, \dots, n$ at time t , with 0 being the start of the option and T its maturity. Furthermore, assume that the indices are such that $S_1(T)/S_1(0), \dots, S_n(T)/S_n(0)$, that is, the performance of the stocks is in increasing order. Given a strike K , the number of underperforming assets w and outperforming ones b to be removed,

the payoff of the Atlas option is

$$\max \left(\frac{1}{n - (w + b)} \sum_{i=1+w}^{n-b} \frac{S_i(T)}{S_i(0)} - K, 0 \right) \quad (1)$$

with the obvious condition that $b + w < n$.

If $b < w$, with b possibly 0, or if $b > w$ with w possibly 0, then this option becomes the best of or worst of option, respectively. On the other hand, if $b = w$, with equal number of underperforming and outperforming stocks removed, this option becomes, in effect, a “middle of the road” or an “average of averages” option. By removing the outliers, we are removing extreme risk and lowering the premium, while making it more favorable to risk-averse customers. For example, it can provide protection against defaults for the price of missing out on top performers.

Modeling

In the simplest of implementations, as in single-name options, the asset price processes are modeled as lognormal processes but with a correlation matrix. In more advanced implementations, to account for the volatility smile, some versions of stochastic volatility models are often used. One may even model some form of default component. However, in these more complex models, the modeling of correlation and its estimation become more complex as well.

Valuation and Risk

The number of assets in Mountain Range options generally ranges from a low of 4 or 5 to a high of about 20. Owing to their complex payoff and path-dependency, idiosyncratic characteristics of each asset need to be taken into account. Hence one cannot assume homogeneity of assets for neither small nor large baskets, making any closed-form approximation (especially in light of path dependence) intractable. Consequently, Mountain Range options, even the non-path-dependent Atlas options, are calculated using Monte Carlo simulation [1]. Monte Carlo methods, especially for high-dimensional payoffs with large number of assets, are slow to converge, and usually one or more variance-reduction techniques are employed. This problem is exacerbated further when calculating first and second order Greeks.

But even in the simple lognormal model, the sheer size of the correlation matrix can become a challenge. Since for n assets there can be $n(n-1)/2$ distinct correlations, even for a modest basket of 10 assets, 45 different correlations are possible. Moreover, it is not clear how one can obtain the correlation numbers themselves. If, theoretically speaking, there existed $n(n-1)/2$ traded spread options on each pair, their implied correlations could be used with the spread options as hedges. However, it is unlikely that every pair of assets in a basket would have a traded spread option. Even if they did, their sheer number would make transaction costs prohibitive, even for moderate bid-ask spreads. Hence historical correlations are more often used, even though as with all historical estimates, they are hard to hedge and can change with macro- and microeconomic shifts. When all assets belong to the same sector, a single correlation number is commonly used. This high amount of asset interdependence makes cross-gammas (*see* **Gamma Hedging**) important, adding further to the hedging complexity.

Risk Profile

When $w = b = 0$, the Atlas option is simply a call option on the average performance of a basket. As in a vanilla call on a single stock, the higher the volatility, the higher the price. But the analysis gets more interesting when we start removing good and bad performers at maturity.

For simplicity, we look at a homogeneous portfolio with identical pairwise correlations given by a single number in a simple lognormal model. For very high correlations, the basket behaves as a single asset—thus removing assets has a small effect on

the option payoff. Since it behaves as a single asset, as in single-asset calls, the option's payoff generally increases with volatility.

For low correlations, on the other hand, the basket has a high dispersion at maturity—on average, a few stocks will have a high price and the rest low—and higher the volatility, the higher the dispersion. Since the expectation of the sum of asset prices at maturity is independent of both volatility and correlation, having a few high asset prices implies that many others are very low in most paths. But it is precisely these high-contribution assets that are removed from the basket, leaving the basket with low-priced assets, thus reducing the price of the option. So for low correlation, with $b \neq 0$, increasing volatility does not necessarily increase the price. We remind the reader that this simple analysis applies to a homogeneous basket. Individual volatilities, dividends, and a non-constant correlation can affect the payoff in ways not always easily explained.

REZA K. GHARAVI

Himalayan Option

In the late 1990s, Societe Generale introduced a series of options on baskets of assets that are now commonly referred to as *Mountain Range* options [2]. They were introduced in part to replicate certain portfolio strategies and in part to extend single-name options to portfolios. What these options share is a strong dependence on the correlation structure of the assets, brought about by their nonlinear and path-dependent payoffs. But beyond this similarity, each type has its own distinct payoff tailored to its own risk profile and usage, making each deserving a study of its own. In this second of three articles on Mountain Range options, we look at the Himalayan option. Unlike Atlas options, Himalayans are path dependent, and are usually longer dated than Atlas options.

This article is organized as follows. We first provide a description of the Himalayan option and discuss the financial motivations for and strategies of its usage. We then discuss modeling, valuation, and risk issues that Himalayan options share with all Mountain Range options, and conclude with a brief analysis of the risk profile that is unique to it. We remark that although the following discussion holds for a wide class of assets, such as foreign exchange (FX) and commodities, these options are traded mostly on baskets of stocks.

Contract Description

The payoff of the Himalayan option is best described in words. Given n assets and contractual times $T_1, \dots, T_n$ (usually yearly), at first time T_1 we take the best performing stock, record its performance, and then remove it from the basket. We continue until at maturity T_n we are left with the last stock. The payoff of the option is the sum of the performances on these n contractual times. In some variations, the top two or three are removed at each time.

What this option emulates is the greedy strategy of liquidating a portfolio—the best performing stocks are sold first. Since this is a derivative product, Himalayan options may offer regulatory and tax benefits compared to actual holding of a portfolio.

Modeling

As in single-name options, in the simplest of implementations, the asset price processes are modeled with lognormal processes endowed with a correlation matrix. In more sophisticated implementations, to account for the volatility smile, some versions of stochastic volatility models are often used. One may even include some form of default component in the asset price. However, in these more complex models, the modeling of correlation and its estimation become more complex as well.

Valuation and Risk

The number of assets in Mountain Range options generally ranges from a low of 4 or 5 to a high of about 20. Owing to their complex payoff and path dependency, idiosyncratic characteristics of each asset need to be taken into account. Hence one cannot assume homogeneity of assets for either small or large baskets, making any closed-form approximation (especially in light of path dependence) intractable. As a result, Mountain Range options, specially the path-dependent varieties such as the Himalayan, are calculated using Monte Carlo simulation [1]. In light of their high-dimensional payoffs due to large number of assets and time points, to speed up convergence, specially for first- and second-order Greeks, usually one or more variance-reduction techniques are employed.

The other challenge posed by these options is the correlation. Even in simple lognormal models, the sheer size of the correlation matrix can become a challenge. Since for n assets there can be $n(n-1)/2$ distinct correlations, even for a modest basket of 10 assets, 45 distinct correlations are possible. Moreover, obtaining the pairwise correlations themselves is not straightforward. If, theoretically speaking, there existed $n(n-1)/2$ traded spread options on each pair, their implied correlations could be used with the spread options as hedges. However, it is unlikely that every pair of assets in a basket would have a traded spread option. Even if they did, their sheer number would make transaction costs prohibitive, even for moderate bid–ask spreads. Hence historical correlations are more often used, even though as with all historical estimates, they are hard to hedge

and can change with macro- and microeconomic shifts. When all assets belong to the same sector, a single correlation number is commonly used. This high amount of asset interdependence makes cross-gammas important, adding further to the hedging complexity.

Risk Profile

Payoffs for Himalayan options can be surprising. For simplicity, we look at a homogeneous portfolio with identical pairwise correlations given by a single number in the simple lognormal model. We look at the effects of removing the best performing assets compared to removing assets in a predetermined order. For high correlations, since basket assets move together, the effects of the “greediness” is small—removing the best performing assets leaves the portfolio with similarly performing assets. So compared to removal by some predetermined order, its effects are small. Increasing the volatility increases the dispersion, and as we next see for the case of low-correlation baskets, it may adversely impact the value of the option.

Assets with low correlation, on the other hand, become more disperse as time passes. Since the expected sum of assets at termination of the option is independent of correlation, removing the best

performing asset would in most scenarios leave the worse performing assets, and since no asset is given a chance to grow—it would get removed in the next cut—we are left with increasingly worse performing assets. Thus greediness would actually be a bad strategy compared to some predetermined asset-removal order. Increasing volatility increases this dispersion, further reducing the payoff of the Himalayan. We remind the reader that this simple analysis applies to a homogeneous basket. Individual volatilities, dividends, and a nonconstant correlation can affect the payoff in ways not always easily explained.

REZA K. GHARAVI

Altiplano Option

In the late 1990s, Societe Generale introduced a series of options on baskets of assets that are now commonly referred to as *Mountain Range* options [2]. They were introduced in part to replicate certain portfolio strategies and in part to extend single-name options to portfolios. What these options share is a strong dependence on the correlation structure of the assets, brought about by their nonlinear and path-dependent payoffs. But beyond this similarity, each type has its own distinct payoff tailored to its own risk profile and use, making each deserving of its own study. In this last of three articles on Mountain Range options, we look at the Altiplano option, which can be thought of as an extension of barrier options to baskets.

This article is organized as follows. We first provide a description of the Altiplano option and discuss the financial motivations for and strategies of its usage. We then discuss modeling, valuation, and risk issues that Altiplano options share with all Mountain Range options, and conclude with a brief analysis of the risk profile that is unique to it. We remark that although the following discussion holds for a wide class of assets, such as foreign exchange (FX) and commodities, these options are traded mostly on baskets of stocks.

Contract Description

Like single-name barrier options, Altiplano options have two components—a vanilla-type payoff if a barrier event occurs, and a coupon payoff if it does not. Usually the barrier event is to have at least one stock reach a predetermined barrier.

More precisely, given a portfolio, or a basket of n stocks, let $S_i(t)$ be the price of the stock $i = 1, \dots, n$ at time t , with 0 being the start of the option and T its maturity. The payoff is

$$\max \left(\sum_{i=1}^n \frac{S_i(T)}{S_i(0)} - K, 0 \right) I_B + (1 - I_B)C \quad (1)$$

where I_B is 1 if a barrier event in relation to barrier level B occurs, and is 0 if it does not, in which case the option would pay a coupon C . Here we have used a call option, but, in principle, we could

use any option. As in single-name barriers, there are many possible wrinkles for the barrier event, such as the Parisian type (*see Parisian Option*). But unlike a simple extension from the single-name case where the barrier is triggered by the sum of the portfolio, individual assets can trigger the barriers by themselves. In the example above, all it takes is for one asset to activate a barrier, independently of the level of other assets at the time. This makes the Altiplano sensitive to individual asset moves, rather than the collective sum.

As in single-name barriers, since I_B is always less than 1, the payoff, and thus the risk, are lower than for standard options on baskets, which makes their premiums lower as well (assuming C is small or zero). The lower premium makes it more attractive when used as a hedge, for example.

Modeling

In the simplest of implementations, as in single-name options, the asset price processes are modeled as lognormal processes but with a correlation matrix. In more advanced implementations, to account for the volatility smile, some versions of stochastic volatility models are often used. One may even include some form of default component. However, in these more complex models, the modeling of correlation and its estimation become more complex as well.

Valuation and Risk

The number of assets in Mountain Range options generally ranges from a low of 4 or 5 to a high of about 20. Owing to their complex payoff and path-dependency, idiosyncratic characteristics of each asset need to be taken into account. Hence one cannot assume homogeneity of assets for either small or large baskets, making any closed-form approximation (especially in light of path dependence) intractable. As a result, Mountain Range options, specially the path-dependent varieties such as the Altiplano, are calculated using Monte Carlo simulation [1]. Monte Carlo methods, especially for high-dimensional payoffs with large number of assets and time points, are slow to converge, and usually one or more variance-reduction techniques are employed. Additionally, since the barrier event is binary, the number of simulation paths needed is even greater than those with

continuous payoffs, making first- and second- order Greeks calculations even more noisy. This makes use of variance-reduction methods even more critical.

The other challenge posed by these options is the correlation. Even in the simple lognormal model, the sheer size of the correlation matrix can become a challenge. Since for n assets, there can be $n(n - 1)/2$ distinct correlations, even for a modest basket of 10 assets, 45 distinct correlations are possible. Moreover, it is not clear how one can obtain the pairwise correlations themselves. If, theoretically speaking, there existed $n(n - 1)/2$ traded spread options on each pair, their implied correlations could be used with the spread options as hedges. However, it is unlikely that every pair of assets in a basket would have a traded spread option. Even if they did, their sheer number would make transaction costs prohibitive, even for moderate bid–ask spreads. Hence historical correlations are more often used, even though as with all historical estimates, they are hard to hedge and can change with macro- and microeconomic shifts. When all assets belong to the same sector, a single correlation number is commonly used. This high amount of asset interdependence makes cross-gammas important, adding further to the hedging complexity.

Risk Profile

As in single-asset barrier options, the payoff of an Altiplano option is determined by two competing

terms—the option term and the barrier term. Again, for ease of analysis, we look at a homogeneous portfolio with identical pairwise correlations given by a single number in the simple lognormal model with no coupon payout. For a simple call option on a basket, it is known that high correlation and volatility increase its price. For the barrier event, it depends on the type. If it takes only one asset to hit a barrier, then low correlation and high volatility increase the probability of hitting it. Moreover, depending on the barrier, the paths that lead to higher option prices may make the barrier even more or less likely, leading to possible nonmonotonous behavior. So even in this simple homogeneous case with a single correlation, the behavior is rather complex.

Constant Proportion Portfolio Insurance

Portfolio insurance is a dynamic management technique that aims at giving the investor the ability to limit the downside risk while allowing some participation in the upside market. Option-based portfolio insurance combines a position in the risky asset with a put option on the asset to achieve this goal. In many cases, options on a portfolio may not be available. *Constant proportion portfolio insurance* (CPPI) is an alternative to that approach. CPPI was first introduced by Perold [4] for fixed-income instruments and by Black and Jones [2] for equity instruments.

CPPI utilizes a rule-based strategy to allocate assets dynamically over time. It involves maintaining a dynamic mix of a “riskless” asset (usually treasury bills or liquid money market instruments) and the risky asset, usually a market index. In the case of having more than one risky asset, an index is formed, which would be treated as a single risky asset. The weights in the index do not change during the life of the trade.

The strategy is based on the notion of *cushion*, which is the difference between the current portfolio value and the guaranteed level, called *bond floor*. Obviously, the initial floor F_0 is less than the initial portfolio value V_0 . Define C_t to be t -time value of the cushion, that is

$$C_t = V_t - F_t \quad (1)$$

The final payoff at maturity is the maximum of these two quantities: (i) the value of the portfolio at maturity and (ii) the guaranteed level. In a nutshell, CPPI is a path-dependent, self-financing capital guarantee structured product that has final payoff linked to the performance of a pool of assets.

Throughout the existence of the contract, an amount of wealth is invested into the risky asset. This amount called *exposure* is proportional to the cushion and is calculated by multiplying the cushion by a predetermined *multiple*.

$$e_t = mC_t \quad (2)$$

The remainder of wealth is allocated into the riskless asset. Trivially, the higher the multiple, the more the holder will participate in rising markets and

the faster the portfolio value approaches the bond floor in downturn markets.

Both the bond floor and multiple are specified in the contract and indicate the investor appetite for risk. Assuming Black–Scholes framework for risky asset S_t

$$dS_t = \mu S_t dt + \sigma S_t dW_t \quad (3)$$

and assuming floor evolves as follows:

$$dF_t = r F_t dt \quad (4)$$

the value of the portfolio at time t , as shown in [5] and [3], is

$$V_t(S_t, m) = F_0 \exp(rt) + \alpha_t S_t^m \quad (5)$$

where $\alpha_t = \frac{C_0}{S_0^m} \exp(\beta t)$ and β is given by

$$\beta = r - m \left(r - \frac{1}{2} \sigma^2 \right) - m^2 \frac{\sigma^2}{2} \quad (6)$$

In periods of negative performance, a specified amount of the risky asset, according to a predetermined asset allocation formula, is liquidated and used to purchase riskless assets. On the other hand, when market goes up, a specified amount of riskless assets, according to the formula, is liquidated and proceeds are used to purchase the risky asset. The provider undertakes the risk of managing of the pool of assets (both risk-free and risky assets).

For risk managing of the pool in CPPI, the provider receives an annual fee. The fee is specified in the contract in one of the following ways: (i) as a fixed percentage of the initial notional per annum, (ii) as a fixed percentage of the value of the portfolio per annum (path dependent), and (iii) as a fixed percentage of the value of the equity held in the pool per annum (path dependent). The first two are more common than the third one.

The provider also receives the potential value of dividends on the equity. This amount is also path dependent.

If there is more than one risky asset in the pool, they would be treated like a basket in a basket option, so that in the event of rebalancing the collection of risky assets is treated like a single underlying.

Rebalancing Procedure

The asset allocation formula is a part of the contract. The terms in the formula are negotiated between the

provider and the counterparty before entering into the transaction.

A feature is built into the allocation formula in order to avoid constant rebalancing. Rebalancing occurs where the difference between theoretical equity exposure from the formula and the actual equity allocation is greater than a predefined number of percentage points specified in the contract.

In the case that it is triggered, the provider sells/purchases an amount of equity and purchases/sells risk-free assets to make the actual ratio equal to the number generated by the formula. The timetable for rebalancing is up to the investor, with monthly or quarterly rebalancing being often cited.

Gap Risk

The risk that the value of the portfolio is less or equal to the bond floor is called the *gap risk*.

If there is no drastic jump in the value of the risky asset for the life of the trade, then there is no need for injection of money for rebalancing of the pool. Therefore downfall is lower than the gap risk and the value of the pool would be above the bond floor. In that case, hedging the CPPI trade would be risk free.

There are cases that the value of the pool may go under the bond floor. Either the provider cannot liquidate the risky asset due to illiquidity or the value of the equity asset has dropped so much that proceeds are not sufficient to maintain the value of the portfolio above the floor—the market simply drops by more than the gap risk before a rebalancing can be undertaken. In either case, the provider must make up the shortfalls. Whenever the portfolio value reaches a given floor, the investor receives a given amount. At this point, the entire pool comprises of 100% exposure to riskless asset. The gap risk is presented as basis points per annum.

Modeling Gap Risk

Modeling the gap risk is the main concern in CPPI. It is analogous to a string of one-day out-of-the-money put options.

Using standard Black–Scholes formula would not be ideal for the following two reasons: (i) lack of volatility information on such deep out-the-money

options and (ii) fat-tailed behaviors observed in stock returns distributions.

In [1], the authors apply extreme value theory to determine the multiple. A quantile hedging approach is introduced, which provides an upper bound on multiple. This bound is statistically estimated from the behavior of extreme variations in rates of asset returns. The authors also introduce the distributions of interarrival times of these extreme movements and show their impacts on CPPI.

In [5] the authors analyze the cost of the guarantee and the performance of portfolio based on such a strategy. They provide two extensions. One is based on Levy processes that allow jumps into the dynamics of the underlying asset. Second, they deal with insurance against all hitting times of modified floor.

In [3], Cont and Tankov study the behavior of CPPI strategies in models where the price of the underlying portfolio may experience downward jumps. That allows them to quantify the gap risk while maintaining the analytical tractability of the continuous-time framework. With respect to the work done in [5], in [3] the authors consider various risk measures for the loss and provide an analytical method to compute them.

CPPI techniques have also been applied to credit portfolios (*see Credit Portfolio Insurance*).

Equity Default Swaps

Equity default swaps (EDS) are equity derivatives that are structured as far out-of-the-money American-style binary puts with periodic swap payments rather than an up-front premium. The structure of EDS is similar to **credit default swaps** (CDS) except that the default event is defined in terms of a decline in the share price of the reference entity rather than a credit event experienced by the reference entity. Thus, similar to a CDS, an EDS can be seen in terms of the protection buyer and protection seller counterparties. In the case of an EDS, protection buyers are hedging themselves against a large decline in the share price.

More specifically, the protection buyer in an EDS makes periodic fixed payments to the protection seller. The size of the periodic payments is called the *EDS spread*. In return for the periodic payments, a default payment from the protection seller to the protection buyer is made if the share price of the reference entity declines a prespecified amount from the share price at initiation of the EDS contract. If this equity default event occurs and the default payment is made, then the contract terminates with the protection buyer ceasing to make further payments. If the equity default event never occurs before the maturity of the EDS contract, then no payment is ever made from the protection seller to the protection buyer.

Typically, the prespecified fall in the share price is a 70% decline, so that the equity default event is defined as the first time that the shares of the reference entity trade at 30% of the share price when the EDS contract is entered. The amount of the default payment is fixed when the EDS contract is initiated and computed as

$$N \times (1 - R) \quad (1)$$

where N is the notional value of the contract and R is the recovery rate, which is predetermined and typically set to be 50%. The formulation of the default payment in terms of a recovery rate is to further the analogy to CDS. EDS are usually medium-term contracts with maturities of five years being the most common.

The first EDS were issued in 2004 as a means to allow protection sellers to receive a higher return

than from CDS. A credit event almost certainly implies that an equity default event will occur, but, conversely, an equity default event can occur without a credit event having occurred. This implies that for the same reference entity, the EDS spread must be greater than the CDS spread. Besides, since protection sellers receiving a higher return for EDS, the default event for EDS is easier to define than for CDS. Whether or not the share price has reached a predetermined level is unambiguous, but the various credit events can sometimes cause confusion for counterparties and have led to legal proceedings.

One difference between EDS and most equity derivatives is the swap feature. Not only is there no up-front premium but also upon an equity default event, no further swap payments are made. Gil-Bazo [4] finds the fraction of the EDS spread that is due to this swap feature under the Black–Scholes model, given plausible parameter values.

Applications of EDS

Besides the obvious application of EDS as portfolio protection on long positions in shares, EDS are often used in ways that exploit their similarity to CDS. Two examples are given here: relative value trades in EDS–CDS carry trades and as yield-enhancing replacements for CDS in **collateralized debt obligations** (CDO).

In EDS–CDS carry trades, an investor sells protection with an EDS and buys protection with a CDS. The larger EDS spread is received while the smaller CDS is paid, so that the investor simply collects the positive carry if neither a credit nor an equity default event occurs. In the case that both default events occur, the investor is partially hedged with the effectiveness of the hedge depending on the relative timing of the default events as well as the recovery rate on the credit event. There is a risk of large losses if an equity default occurs without a credit event occurring.

Some CDO were constructed with the reference portfolio including some EDS in addition to CDS. While this increases the risk to the CDO investors, there can be significant yield enhancement. There have even been CDO where the reference portfolio was exclusively composed of EDS.

These are termed *equity collateralized obligations (ECO)*.

EDS as Credit–Equity Hybrids

Since a large fall in the equity price is needed to trigger the payout of an EDS, there are often accompanying credit implications to the firm leading many to refer to EDS as a *credit–equity hybrid instrument*, despite the default event being defined exclusively in terms of the share price.

There is empirical evidence that EDS should not be considered simply as an equity derivative. de Servigny and Jobst [8] assess the relative weighting of debt and equity factors for equity default probabilities. They find that for the typical definition of equity default as 30% of the initial share price, debt factors are more important than equity factors. In addition, Jobst and de Servigny [5] study EDS correlation and EDS–CDS correlation and find that multivariate analyses commonly used for credit are the most appropriate.

EDS Pricing

Consider the problem of finding the fair spread for an EDS that is to be initiated now at time $t = 0$, with the current stock price as S_0 . The default payment in an EDS is made the first time that the share price trades at the prespecified level L where $L < S_0$. In addition to this, the swap payments are made contingent on the share price not being traded at or below the prespecified level. Thus, to price an EDS, the probability distribution of the first passage time of the level L is required. Here, the first passage time of L is defined as

$$\tau_L = \inf\{t > 0; S_t \leq L\} \quad (2)$$

Then, if an EDS with \$1 notional requires a periodic payment of C at times $T_1, \dots, T_n$ the price of the EDS for a protection buyer is

$$\begin{aligned} EDS(S_0; C, R, L) = & -C \sum_{i=1}^n D^{T_i} P(\tau_L > T_i | S_0) \\ & + (1 - R) E[D^{\tau_L} 1_{\{\tau_L \leq T_n\}} | S_0] \end{aligned} \quad (3)$$

where R is the recovery rate, D^t is the discount factor to time t and P and E are probabilities and expectations under the risk-neutral measure. Then, the fair spread for an EDS is the value of C that makes $EDS(S_0; C, R, L) = 0$.

The problem of deriving the first passage time distribution has been solved in several special cases. Albanese and Chen [1] compute the EDS spread under the assumption that the stock price follows a constant elasticity of variance (CEV) process (see **Constant Elasticity of Variance (CEV) Diffusion Model**) and Asmussen *et al.* [2] use the Wiener–Hopf factorization (see **Wiener–Hopf Decomposition**) to compute the EDS spread under the assumption that the stock price follows a Carr–Geman–Madan–Yorr (CGMY) Lévy process (see **Tempered Stable Process**). For models where credit considerations are more explicitly addressed, EDS spreads have been priced using different methods: Albanese and Chen [1] use a credit barrier model with a credit to equity mapping; Campi *et al.* [3] extend the CEV case to include jump to default; Medova and Smith [6] use a structural model of credit risk (see **Structural Default Risk Models**) where the firm’s asset value follows a geometric Brownian motion; and Sepp [7] makes use of an extended structural model where the firm’s asset value can have stochastic volatility (see **Heston Model**) or be a double exponential jump diffusion, with the default barrier being deterministic or stochastic.

Exchange-traded Funds (ETFs)

Exchange-traded funds (ETFs) are indexed products and trade like equities on the main exchanges. Technically, an ETF holder possesses certificates that state legal right of ownership over a portion of a basket of individual stock certificates. It may be tempting to think of ETFs as mutual funds. However, ETFs differ from mutual funds in several ways. One key distinction is that mutual funds only trade at the end of each day at their calculated NAVs while ETFs trade throughout the day at ever-changing prices. Another is that ETFs, unlike mutual funds, can be sold short.

A number of financial entities are required to create and maintain ETFs. Initially, the fund manager submits a detailed plan to SEC as to the ETF's constitution and how it will function. Once the plan is approved, the fund manager enters into an agreement with a market maker or specialist known as the *authorized participant*. The authorized participant, typically by borrowing, begins to assemble a basket of instruments that compose the index the ETF is meant to replicate. Once assembled, the instruments are placed in trust at a custodial bank that, in turn, uses them to form what are known as *creation units*. Each creation unit represents a subset of the basket of instruments. The custodial bank then divides the creation units into (typically) 10 000 to 600 000 ETF shares [5], which are legal claims on the aforementioned instruments, and forwards the shares to the authorized participant. It should be mentioned that this is an in-kind trade (i.e., ETF shares are exchanged for the basket of financial instruments) with no tax implications. The authorized participant subsequently sells the shares in the open market just like shares of stock. The ETF shares then continue to be sold and resold by investors. The instruments underlying the creation units, and therefore the ETF shares, remain in trust with the custodian who is responsible for paying any cash flows (e.g., dividends and coupons) from the instruments to the ETF holders and providing administrative oversight of the creation units themselves.

A long position in an ETF can be unwound two ways. The first is simply to sell the share in the open

market. The second is to purchase enough ETF shares to form a creation unit and then exchange the creation unit for the securities that comprise it. As with the creation of the ETF shares, this second option has no tax implications but is generally only available to large institutional investors.

The financial firms mentioned above are motivated to participate in the ETF space by different profit opportunities. Fund managers and custodial banks each collect a small portion of the fund's annual assets. Investors who loan instruments that compose the aforementioned baskets receive interest fees, while market makers seek to earn both arbitrage (i.e., the difference in price between the ETF and the basket of instruments) and bid/ask-spread profits.

According to a July 2008 Morningstar article, the average ETF charged 54 bps in annual fees [3]. This number was up from 41 bps a year earlier [3]. The average has been raised owing to recently formed exotic, narrowly focused ETFs. However, there are still many broad-market ETFs with annual fees on the order of 10 bps. Furthermore, an ETF's management fee is usually lower than the (approximately) 80 bps charged by the typical mutual fund [2]. Finally, over 90% of US ETFs have bid/ask spreads of fewer than 50 bps (with over half having spreads of fewer than 20 bps) [1], while the expense ratio (which includes management fees, administrative costs, 12b-1 distribution fees, and other operating expenses) for an average mutual fund is 150 bps [4]. Assuming one must transact at the bid (offer) when selling (buying), even ETFs with higher bid/ask spreads have, on average, substantially lower frictional costs than mutual funds (104 bps vs. 150 bps).

There are close to 2000 ETFs trading today, tracking numerous broad-market composites as well as a multitude of sector and geographic indexes. These products cover approximately 40 different investment categories (e.g., Utilities Sector Equity, High Yield Fixed Income, US Real Estate Equity and European Mid/Small Cap Equity) and fall into several investment styles (e.g. equity, fixed income, and alternatives). Furthermore, these funds are offered by a large number of investment banks and investment management companies. Consequently, the ETF market gives investors numerous choices both in terms of the nature of investment and the fund manager.

In conclusion, a number of financial entities are necessary to create and maintain ETFs, indexed products that trade like stocks on major bourses. Furthermore, ETFs differ from mutual funds in that they trade throughout the day, can be shorted, and generally carry lower fees. Finally, the close to 2000 ETFs trading today cover a plethora of different investment categories, offering investors an inexpensive means to construct well-diversified portfolios.

MICHAEL J. TARI

Volume-weighted Average Price (VWAP)

The volume-weighted average price (VWAP) and its close cousin, the time-weighted average price (TWAP), are commonly used measures of the average price of a security over a period of time. VWAP and TWAP are used by traders and other investment professionals as reference prices, an indication of the average transaction price over an interval of time. So, for example, if the TWAP of a security is \$10 on a given day and a trader had bought a sizeable block of shares at \$9.50, we might conclude that the trader had added value in that he or she obtained a better than a naïve program that mechanically sends out orders in the market at a steady rate throughout the day.

Mathematical Definition

More formally, the VWAP of a security over a specified trading horizon (e.g., from market open to close) is defined as the ratio of the total transaction value in that security (i.e., the sum, over all trades in the specified horizon, of the product of each trade's share volume and the corresponding price) to the total volume of shares traded (i.e., the sum of all shares traded in the trading horizon). When the trading horizon is typically a trading day, intraday or multiday VWAP measures are also computed. A related concept is the TWAP, defined as the average price over a particular time interval with no explicit volume weighting. Traders use TWAP over VWAP for securities where the temporal pattern of volume exhibits considerable variation, for example, in less-active securities.

Formally, given N trades in the relevant interval, let $S_1, \dots, S_N$ be the shares transacted with corresponding prices $P_1, \dots, P_N$. Then, we have

$$VWAP = \frac{\sum_{i=1}^N P_i S_i}{\sum_{i=1}^N S_i} \quad (1)$$

$$TWAP = \frac{\sum_{i=1}^N P_i}{N} \quad (2)$$

Subtleties in the computation of VWAP/TWAP include (i) the choice of volume definition (e.g., primary market volume or composite volume), (ii) the treatment of certain trades (e.g., block trades that might be negotiated off market), and (c) the decision whether to include volumes at the open and close of the market.

Uses

VWAP is commonly used as an approximation to the price that could be realized by a trader who passively participates in trading activity. As such, the performance of traders can be measured by their ability to execute orders at prices better than the VWAP benchmark prevailing over the trading horizon.

The computational simplicity of the VWAP is a major factor in its popularity in measuring trade execution, especially in markets where detailed trade level data is difficult or expensive to obtain. VWAP can be misleading as a benchmark in certain situations where the trader's objective is to control the slippage from a given strike or decision price, or where the strategy is not passive. In such cases, for example, if the trader has short-term alpha, the mechanical application of a VWAP strategy (i.e., trading in parallel to historical volume patterns) can lead to significant opportunity costs in terms of slippage. VWAP is not appropriate when the trader's executions are large relative to market volumes. In this case, VWAP might conceal a large price impact because the trader's own trades constitute the bulk of the reported volume. Finally, if traders have discretion over whether to execute or not, the VWAP benchmark can be gamed by selectively timing executions.

An important application is to so-called VWAP strategies, typically algorithmic trading strategies that automatically break up an order and send trades to the market to match the historical volume pattern or profile (see, e.g., [1]) of a security. See, for example, [2] for a discussion of the uses of VWAP in trading strategies and algorithms. The goal of a VWAP strategy is to obtain an execution price close to the VWAP for the day. Some brokers also guarantee VWAP execution, essentially taking on the execution risk for a fee.

Equity Swaps

A swap contract is a bilateral agreement between two parties, known as counterparties, to exchange cash flows at regularly scheduled dates in the future. In an equity swap, some of the cash flows are determined by the return on a stock or an equity index. Typically, one of the parties pays to the other the total return of a stock or an equity index. In exchange, he or she receives from the other a cash flow determined by a fixed or floating rate or the return of another stock or equity index. Equity swaps are also known as *equity-linked swaps* and *equity-indexed swaps*.

Equity swaps are not traded on an exchange but are privately negotiated. They are referred to as over-the-counter (OTC) contracts. One of the first-known equity swap agreements was offered by the Bankers Trust in 1989. Since then, the market for equity swaps and other equity-linked derivatives has grown rapidly. There are no exact figures on the size of the market. However, the Bank for International Settlements (BIS) provides market size estimates. According to BIS, the estimate of the worldwide total notional amounts outstanding of equity swaps and equity forwards was over \$300 trillion as of December 2007.

Equity swaps provide means to get exposure to the underlying stock or index without making a direct investment. Because equity swaps are OTC-contracts, they can be tailor-made to specific needs. The contracts have been used to circumvent barriers for direct investments in particular markets, bypass various taxes, and minimize transaction costs.

Defining Equity Swaps

Let $\{T_0, T_1, \dots, T_M\}$ be a sequence of dates. This is the *tenor structure* and we denote it by $\mathcal{T}$. For a given day-count convention, we specify a sequence of year fractions^a $\{\delta_1, \delta_2, \dots, \delta_M\}$ to $\mathcal{T}$. We denote the counterparties by A and B .

Definition 1 A generic equity swap

An equity swap with tenor structure $\mathcal{T}$ is a contract that starts at time T_0 and has payment dates $T_1, T_2, \dots, T_M$. At each payment date T_i for $i = 1, 2, \dots, M$, the two counterparties A and B exchange payments. At least one of the payments will be based

on the return of a stock or an equity index over the period $[T_{i-1}, T_i]$.

In general, the cash flows are specified in such a way that the initial value, at time T_0 , of the swap equals zero. Usually the equity swap pays out the total return of the underlying stock or equity index including dividends. However, there are also variants where the dividend is excluded.

A swap contract has a notional principal.^b It is a currency amount specified in the swap contract that determines the size of the payments expressed in currency units. While the notional principal of a bond, for instance, is paid out at maturity, the notional principal of a swap contract is, in general, never exchanged. Equity swaps can be classified into two categories depending on whether the notional principal is constant or varies over the lifetime of the swap. We focus on the former case, which is considered in the next section.

Contracts with Fixed Notional Principal

Let N denote the fixed notional principal. Let $\{Z(t)\}$ denote the price process of a stock or an equity index. Define the *period return* $R(T_i, T_{i+1})$ over the interval $[T_i, T_{i+1}]$ for asset Z by

$$R(T_i, T_{i+1}) = \frac{Z(T_{i+1})}{Z(T_i)} - 1 \quad (1)$$

Definition 2 A generic equity-for-fixed-rate swap

An equity-for-fixed-rate swap, with tenor structure $\mathcal{T}$, which is written on the equity Z will have a predetermined swap rate K and will give rise to the following payments between the counterparties A and B at each payment date T_i :

- A pays to B the amount: $NR(T_{i-1}, T_i)$.
- B pays to A the amount: $N\delta_i K$.

In general, the swap rate is chosen such that the initial value of the swap at time T_0 equals zero.

In its most simple form, this contract is referred to as a *plain vanilla equity swap*. The period return is then determined by a domestic asset or index and the nominal amount is expressed in units of the domestic currency. Examples can be found in [5] and [8].

Some equity swaps are structured so that instead of a fixed swap rate they pay a floating interest rate,

usually a LIBOR rate. Let $L(T_i, T_{i+1})$ denote the simple spot rate over the period $[T_i, T_{i+1}]$.

Definition 3 A generic equity-for-floating-rate swap

An equity-for-floating-rate swap, with tenor structure T , which is written on the equity Z will give rise to the following payments between the counterparties A and B at each payment date T_i :

- *A pays to B the amount: $NR(T_{i-1}, T_i)$.*
- *B pays to A the amount: $N\delta_i (L(T_{i-1}, T_i) + s)$.*

where s is a constant rate such that the initial value of the swap at time T_0 equals zero.

An equity-for-floating swap can be decomposed into an equity-for-fixed swap and a suitably chosen interest rate swap (see **LIBOR Rate** and [2]).

Let R_1 and R_2 denote the return of assets Z_1 and Z_2 , respectively.

Definition 4 A generic equity-for-equity swap

An equity-for-equity swap, with tenor structure T , which is written on the equities Z_1 and Z_2 , will give rise to the following payments between the counterparties A and B at each payment date T_i :

- *A pays to B the amount: $NR_1(T_{i-1}, T_i)$.*
- *B pays to A the amount: $N(R_2(T_{i-1}, T_i) + s\delta_i)$.*

where s is the constant rate such that the initial value of the swap at time T_0 equals zero.

The equity-for-equity swap is also referred to as a *two-way equity swap*. The simplest contract of this type is a domestic equity-for-equity swap where both returns are based on domestic indices or assets.

So far, we have only considered domestic equity indices and assets. However, all of the three equity swaps mentioned above have versions where one or both cash flows are based on a foreign equity return or interest rate. They are so called *cross-currency swaps*.

To illustrate a cross-currency equity swap, suppose that the United States is the domestic market. Let the notional principal be expressed in US dollars. Let Z_1 be a foreign equity index such as, for instance, the NIKKEI, while Z_2 is a domestic equity index such as the S&P 500. The period return R_1 is based on a foreign equity index, while the nominal amount is in domestic units. There is a currency mismatch in the cash flow that A pays (but none in the cash

flow that B pays). This type of contract is referred to as a *quanto swap* (see also **Quanto Options**). Quanto swaps are more complicated to price than other swaps. Quanto contracts have been considered in [3, 4] and [7].

From a pricing and hedging perspective, the simplest cross-currency swaps are the ones that are currency adjusted. Consider a cross-currency equity-for-equity swap with currency-adjusted returns. Let Z_1 be a foreign equity, while Z_2 is a domestic equity. Let $X(t)$ denote the exchange rate expressed as the number of domestic currency units per foreign currency unit. Then the currency-adjusted period return over the interval $[T_i, T_{i+1}]$ for the asset Z_1 is

$$R_1(T_i, T_{i+1}) = \frac{X(T_{i+1})Z_1(T_{i+1})}{X(T_i)Z_1(T_i)} - 1 \quad (2)$$

While the unit of $Z_1(t)$ is foreign currency, the unit of $Z_1(t)X(t)$ is domestic currency. Regarding the underlying index as the foreign asset times the exchange rate, R_1 can be treated as the return on a domestic index. A cross-currency equity-for-equity swap that is currency adjusted is, from a valuation point of view, equal to a domestic equity-for-equity swap.

Contracts with Variable Notional Principal

Some equity swaps are constructed with a variable notional principal. A variable notional principal changes over time according to changes in the referenced equity index.

Consider an equity-for-fixed-rate swap. It can essentially be regarded as a leveraged position in the underlying equity. If the notional principal is constant, the realized returns from the equity index are withdrawn in each period, resulting in a position that is rebalanced periodically. If the notional principal is variable, the realized returns in each period are reinvested.

Let N_i denote the variable notional principal, which determines the size of the payments at time T_i for $i = 1, 2, \dots, M$. Let $N_1 = 1$ and $N_i = Z(T_{i-1})/Z(T_0)$ for $i = 2, 3, \dots, M$. Thus, for instance, at the third payment date T_3

- *A pays to B the amount: $\frac{Z(T_2)}{Z(T_0)} R(T_2, T_3)$.*
- *B pays to A the amount: $\frac{Z(T_2)}{Z(T_0)} \delta_3 K$.*

Equity swaps with variable notional principals are treated in [2, 6] and [9].

More Equity Swaps & Strategies

There can be many variations of the equity swaps listed so far. For instance, there can be more than one tenor structure, that is, the payments made by A and B can have different periodicity. It is also possible to make forward agreements to enter into a swap contract in the future. Such contracts are known as *forward swaps* or *deferred swaps*. There are also equity swaps with option features like *capped equity swaps* and *barrier equity swaps*. Further examples are *blended index swaps* and *outperformance swaps* (see [2, 6] and [8]).

We conclude by providing an example of how equity swaps were used in the United States during the 1990s to circumvent taxes. The executive equity swap strategies were developed for large single stock shareholders, for instance, a founder of a company. The swap was constructed so that the shareholder made payments based on the return of the stock to the swap contractor. In exchange, the shareholder received either a fixed interest rate or the return of a large equity index such as S&P 500. By entering into such a contract, the stockholder could keep the stocks and the voting rights, but still reduce the risk of the total portfolio and avoid capital gains taxes. As a result, the tax regulation was changed. The new regulation states that taxpayers should recognize that transactions that are essentially equivalent to a sale should be treated as such and thus be taxed. For a more detailed description on this topic, see [1] and [8].

End Notes

^aFor instance, if the convention “Actual/365” is used, δ_1 is equal to the number of days between the dates T_0 and T_1 , divided by 365.

^bSometimes called *face value*.

Volatility Index Options

Volatility index options are options on a volatility index. Volatility index options enable one to take a pure volatility exposure without the need to take positions in the index itself and without the need to delta-hedge. These features make these options very interesting for pure volatility trades and bets. They also allow one to trade the spread between realized and implied volatility, or to hedge the volatility exposure of other positions or businesses, without being contaminated by the index price dependence like in the standard index options. This explains their popularity among traders and hedge funds.

Originally, volatility index options were traded over the counter (OTC), and a large part is still traded OTC, through volatility and variance swaps (see **Variance Swap**). In February 2006, the Chicago board option exchange (CBOE) realized the interest in the financial community for exchanged standardized volatility index options and started offering standardized options first on the VIX (which is the CBOE volatility index) and later on the Russel 2000 volatility index. In Europe, although the major exchanges have already developed volatility on the major indexes (and futures on these) like the VDAX, FTSE 100 volatility index, VSTOXX, VCAC, or VSML, they still do not offer any options on these indexes.

Volatility Index

The underlying volatility index is computed from option prices to capture information from the options market by some means. The overall idea of index volatility is to provide a good estimate of the so-called implied volatility extracted from the options market, as opposed to the historical volatility. More precisely, the aim is to estimate the risk-neutral market's expectation of the future volatility. In the specific case of the VIX, the formula is public and weights the various options as follows:

$$\sigma^2 = \sum_i \frac{2\Delta K_i}{T_i K_i^2} e^{RT} Q(K_i) - \frac{1}{T_i} \left(\frac{F}{K_0} - 1 \right)^2 \quad (1)$$

where σ is the $VIX/100$, or equivalently, $VIX = 100\sigma$, T_i the time to expiration of the i th option, F

the forward index level derived from option prices, K_0 the highest strike just below the forward index level, F , K_i the strike price of the i th option: a call if $K_i > K_0$, a put if $K_i < K_0$ and both call and put for $K_i = K_0$, ΔK_i the interval between strike prices, R the risk-free rate to expiration, and $Q(K_i)$ the midpoint of the bid-ask spread for each options with strike K_i .

The CBOE calculates and publishes minute-to-minute the VIX using real-time bid-ask market quotes of options on S & P500 index (SPX) with nearby and second nearby maturities and applying the multiplier of \$100. Overall, the VIX reflects market's view of the future short term volatility. A high value of the index indicates a more volatile market, while a low value indicates a less volatile environment. Often referred to as the *fear index*, it represents one measure of the market's expectation of volatility over the next 30-day period. In short term, bias can explain some key differences between the VIX and the overall market sentiment. This is particularly true at times when the most liquid options are in the range of 2–6 months to expiration. Therefore, VIX tries to quantify the market volatility, mainly focusing on short term, being unable to completely explain the market volatility, which is a complex concept.

It is worth noting that VIX is computed to be the square root of the par variance swap rate (see **Variance Swap**), and not the volatility swap rate (see **Volatility Swaps**). This is because variance swap can be perfectly, statically replicated through vanilla puts and calls, whereas volatility swap requires dynamic hedging [1]. We will discuss this point later in the section on pricing.

VIX options are European call and put options on the VIX index, with strikes ranging from 10 to 65 (with interval of 1 and 2.5 points for liquid and 5 points for less liquid points), while maturities are up to 6 months. Like many other listed options, VIX options are quoted with a multiplier of \$100. The expiration date is roughly speaking the third Wednesday of the expiry month. More details can be found on the CBOE website [3].

Pricing Models

In terms of pricing, roughly speaking there are two methods to price index volatility options:

- a model-dependent approach that assumes a model for the index volatility diffusion and provides a closed-form formula of call and put options;
- a model-free approach that computes the cost of the static hedge to replicate the volatility index option.

Historically, the model-dependent approach has been the first to emerge. Successively, among others, Whaley [11], Grunbichler and Longstaff [6], Howison *et al.* [7], and Elliott *et al.* [5], and lately Sepp [9, 10], presented the model-dependent approaches to price volatility index options. They all assume an underlying stochastic process for the index volatility (or the index volatility futures) and explicitly compute the price of the call and put options.

The first model-dependent approach presented by Whaley [11] assumed a log normal diffusion for the VIX cash index and the VIX futures leading to a standard Black–Scholes formula for the VIX call options as follows:

$$C(T, F, K) = D_T [F N(d_+) - K N(d_-)] \quad (2)$$

$$d_{\pm} = \frac{\ln \frac{F}{K} \pm \frac{1}{2} T \sigma^2}{\sqrt{T} \sigma} \quad (3)$$

where $C(T, F, K)$ stands for the value of the call option with expiry time T , strike K , and forward

price F , and where σ is the volatility of the futures price, D_T is the discount factor expiring at time T , and $N(x)$ is the cumulative normal distribution up to x . A straightforward drawback of the Whaley approach was the strong log normal underlying assumption. This motivated further research and led to many works. Grunbichler and Longstaff [6] proposed a mean-reverting square root process for the volatility process. Following the popularity of stochastic volatility, Howison [7] and Elliott [5] suggested to use stochastic volatility model for the index volatility to capture the risk of volatility for the index volatility. Moreover, because it is well known that index volatility is upward sloping, the stochastic volatility approach, which can cope with this important feature, was an appealing modeling choice. Figure 1, for instance, gives the VIX smile for 27 July 2009.

Lately, Sepp [9, 10] argued in favor of adding jumps to the stochastic volatility model to get a more realistic diffusion for the index volatility. This was supported by the econometric works that confirmed the evidence of jumps for the volatility index.

To sum up, the model-dependent approach aims at modeling the index volatility evolution as accurately as possible and providing a very consistent framework for pricing any type of option on index volatility. The strength is the flexibility in terms of pricing as there is no limitation for the types of options. The

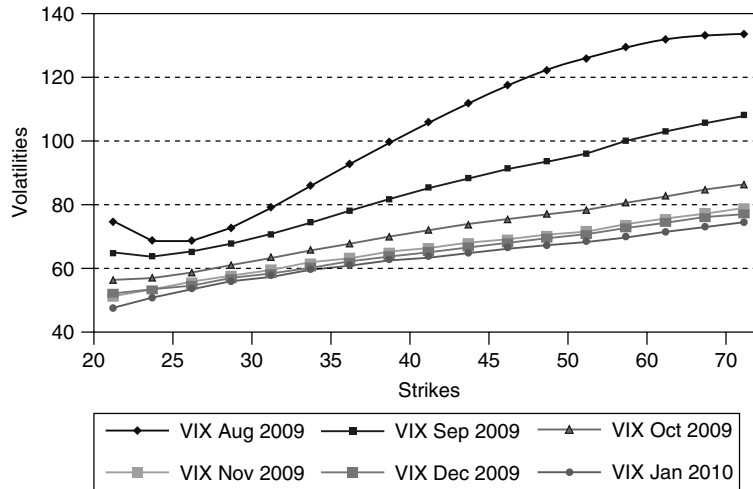

Figure 1 VIX Smile

weakness is the strong assumption of a specific model and distribution for the index volatility.

Another approach initiated by Neuberger [8], Demeter *et al.* [4], Carr and Lee [1], and Carr and Wu [2] is to exhibit a static hedge and compute in a model free way the price of this hedge using call and put options on the index itself. In a very insightful paper, Demeter *et al.* [4] showed that a static portfolio of call and puts options on the volatility index can replicate a variance swap. Lately, Carr and Lee [1] and Carr and Wu [2] extended the closed form formula to the case of both the variance and the volatility swap. The starting point is to assume a pure diffusion given as follows:

$$dS_t = \mu_t S_t dt + \sigma(t, \dots) S_t dW_t \quad (4)$$

where μ is the drift term and $\sigma(t, \dots)$ is a very general volatility function (that can be assumed to be a local volatility for the clarity of the explanation). A trivial application of the Itô lemma on $\log(S_t)$ provides the main intuition and leads to the fact that one can relate the volatility to a log contract as follows:

$$\frac{dS_t}{S_t} - d\log(S_t) = \frac{1}{2}\sigma^2(t, \dots) dt \quad (5)$$

Like any function of the underlying asset, the log contract can be replicated by a series of call and put options. This leads, in particular, to the Par swap rate of a variance swap as follows (referred in the literature as the replication variance swap price):

$$\begin{aligned} K_{\text{var}} = & \frac{2}{T} \left[rT - \left(\frac{S_0}{S_*} e^{rT} - 1 \right) - \log \left(\frac{S_*}{S_0} \right) \right. \\ & + e^{rT} \int_0^{S_*} \frac{1}{K^2} P(K) dK \\ & \left. + e^{rT} \int_{S_*}^{\infty} \frac{1}{K^2} C(K) dK \right] \quad (6) \end{aligned}$$

where $P(K)$ and $C(K)$, respectively, denote the current fair value of a put and call option of strike K , r is the risk free rate, T is the maturity of the variance swap, S_0 is the initial spot value of the underlying asset, and S_* is an arbitrary point to do the split between the liquid call and put options. It is often chosen to be the forward value.

Unlike the previous model-dependent approaches, the model-free approach replicates the variance and

the volatility swaps using market prices of volatility options as inputs. The resulting pricing consists in numerically computing the cost of the hedging strategy with the series of options as shown by the integrals of equation (6).

The obvious strength of this approach is to avoid any assumption on the underlying distribution of the index volatility. Primarily, the weaknesses are that the replication methods do not work for very specific index volatility options and that the discretization bias due to the lack of reliable liquid quotes for call and put options at any strikes can be of the same order of the magnitude as the misspecification of the index volatility distribution.

Realized Volatility Options

Let the underlying process Y be a positive semi-martingale, and let $X_t := \log(Y_t/Y_0)$.

Define realized variance to be $[X]$, where $[\cdot]$ denotes the quadratic variation (but see the section “Contract Specifications in Practice”).

Define a *realized variance option* on Y with variance strike Q and expiry T to pay

$$\begin{aligned} ([X]_T - Q)^+ & \text{ for a realized variance call} \\ (Q - [X]_T)^+ & \text{ for a realized variance put} \end{aligned}$$

and define a *realized volatility option* on Y with volatility strike $Q^{1/2}$ and expiry T to pay

$$\begin{aligned} ([X]_T^{1/2} - Q^{1/2})^+ & \text{ for a realized volatility call} \\ (Q^{1/2} - [X]_T^{1/2})^+ & \text{ for a realized volatility put} \end{aligned}$$

In some places, we restrict attention to puts. Call prices follow by put–call parity: for realized variance options, a long-call short-put combination pays $[X]_T - Q$, equal to a Q -strike variance swap, and for realized volatility options, a long-call short-put combination pays $[X]_T^{1/2} - Q^{1/2}$, equal to a $Q^{1/2}$ -strike volatility swap.

Unlike variance swaps (*see* **Variance Swap; Weighted Variance Swap**), which admit exact model-free (assuming only continuity of Y) hedging and pricing in terms of Europeans, variance, and volatility options have a range of values, consistent with the given prices of Europeans. With no further assumptions, there exist sub/superreplication strategies and lower/upper pricing bounds (in the section “Pricing Bounds by Model-free Use of Europeans”). Under an independence condition, there exist exact pricing formulas in terms of Europeans (in the section “Pricing by Use of Europeans, Under an Independence Condition”). Under specific models, there exist exact pricing formulas in terms of model parameters (in the section “Pricing by Modeling the Underlying Process”).

Unless otherwise noted, all prices are denominated in units of a T -maturity discount bond. The results apply to dollar-denominated prices, provided that

interest rates vary deterministically, because if Y' is a dollar-denominated share price and Y is that share’s bond-denominated price, then $\log Y - \log Y'$ has finite variation; hence, $[\log Y] = [\log Y']$.

Expectations $\mathbb{E}$ will be with respect to martingale measure $\mathbb{P}$.

Transform Analysis

Some of the methods surveyed here (in the sections “Pricing by Modeling the Underlying Process” and “Pricing via Transform”) will price variance/volatility options by integrating prices of payoffs of the form $e^{z[X]_T}$. Transform analysis relates the former to the latter, by the following pricing formulas, proved in [5].

Assume that the continuous payoff function $h : \mathbb{R} \rightarrow \mathbb{R}$ satisfies

$$\int_{-\infty}^{\infty} e^{-\alpha q} h(q) dq < \infty \quad (1)$$

for some $\alpha \in \mathbb{R}$. For all $z \in \alpha + \mathbb{R}i := \{z \in \mathbb{C} : \operatorname{Re} z = \alpha\}$, define the bilateral Laplace transform

$$H(z) := \int_{-\infty}^{\infty} e^{-zq} h(q) dq \quad (2)$$

If $|H|$ is integrable along $\alpha + \mathbb{R}i$ for some $\alpha \leq 0$, then by Bromwich and Fubini, the $h([X]_T)$ payoff has price

$$\mathbb{E}h([X]_T) = \frac{1}{2\pi i} \int_{\alpha - \infty i}^{\alpha + \infty i} H(z) \mathbb{E}e^{z[X]_T} dz \quad (3)$$

For a *variance put*, let $h(q) = (Q - q)^+$. Then for all $\alpha < 0$, formula (3) holds with

$$H(z) = \frac{e^{-Qz}}{z^2} \quad (4)$$

For a *volatility put*, let $h(q) = (\sqrt{Q} - \sqrt{q^+})^+$. Then for all $\alpha < 0$, formula (3) holds with

$$H(z) = -\frac{\sqrt{\pi} \operatorname{Erf}(\sqrt{zQ})}{2z^{3/2}} \quad (5)$$

To price variance and volatility calls by put–call parity, we have the variance swap value

$$\mathbb{E}[X]_T = \frac{\partial}{\partial z} \bigg|_{z=0} \mathbb{E}e^{z[X]_T} \quad (6)$$

and the volatility swap value

$$\mathbb{E}[X]_T^{1/2} = \frac{1}{2\sqrt{\pi}} \int_0^\infty \frac{1 - \mathbb{E}e^{-z[X]_T}}{z^{3/2}} dz \quad (7)$$

if $\mathbb{E}e^{z[X]_T}$ is analytic in a neighborhood of $z = 0$.

Pricing by Modeling the Underlying Process

Under Heston and under Lévy models, we give formulas for the transform $\mathbb{E}e^{z[X]_T}$, where $\text{Re } z \leq 0$. Hence, formula (3) prices the variance put and volatility put, using equations (4) and (5), respectively.

Example: Heston Dynamics

Under the Heston model for instantaneous variance (see **Heston Model**),

$$dV_t = (a - \kappa V_t) dt + \beta \sqrt{V_t} dW_t \quad (8)$$

and the transform of $[X]_T = \int_0^T V_t dt$ is

$$\mathbb{E}e^{z[X]_T} = e^{A(z) + B(z)V_0} \quad (9)$$

where

$$A(z) := \frac{a}{\beta^2} \left[(\kappa - \gamma)T - 2 \log \left(1 + \frac{\kappa - \gamma}{2\gamma} (1 - e^{-\gamma T}) \right) \right] \quad (10)$$

$$B(z) := \frac{2z(e^{\gamma T} - 1)}{2\gamma + (\gamma + \kappa)(e^{\gamma T} - 1)},$$

$$\gamma := \sqrt{\kappa^2 - 2\beta^2 z} \quad (11)$$

by [6]. Other affine models also have explicit formulas for $\mathbb{E}e^{z[X]_T}$.

Example: Lévy Dynamics

If X is a Lévy process (see **Lévy Processes**) with Gaussian variance σ^2 and Lévy measure ν , then $[X]$ has transform

$$\mathbb{E}e^{z[X]_T} = \exp \left(T \frac{\sigma^2 z^2}{2} + T \int_{\mathbb{R}} (e^{zx^2} - 1) \nu(dx) \right) \quad (12)$$

For variance option pricing under pure-jump processes with independent increments, but without assuming stationary increments, see [2].

Pricing by Use of Europeans, Under an Independence Condition

In this section, let Y be a share price that follows general stochastic volatility dynamics

$$dY_t = \sigma_t Y_t dW_t \quad (13)$$

where σ and the Brownian motion W are independent. Although all three subsections use this assumption, the schemes in the sections “Pricing via Transform” and “Pricing and Hedging via Uniform or L^2 Payoff Approximation” are immunized, to first order, against violations of the independence condition.

Pricing via Transform

The transform of $[X]_T = \int_0^T \sigma_t^2 dt$ satisfies [5]

$$\mathbb{E}e^{z[X]_T} = \mathbb{E} \left(\theta_+ (Y_T/Y_0)^{1/2 + \sqrt{(1/4) + 2z}} + \theta_- (Y_T/Y_0)^{1/2 - \sqrt{(1/4) + 2z}} \right) \quad (14)$$

provided that the expectations are finite. Here, $\theta_{\pm} := (1 \mp 1/\sqrt{1 + 8z})/2$. The right-hand side (RHS) of equation (14) is in principle observable from T -expiry Europeans, which allows variance/volatility put option pricing by the formulas (3–5). In this context, equation (6) can be replaced by the log-contract value $-2\mathbb{E}X_T$, and equation (7) can be replaced by the synthetic volatility swap value (see **Volatility Swaps**).

Moreover, source [5] shows that equation (14) still holds approximately in the presence of correlation between σ and W , in the sense that the RHS is constructed to have zero sensitivity to first-order correlation effects.

Pricing and Hedging via Uniform or L^2 Payoff Approximation

For continuous payoffs, $h : [0, \infty) \rightarrow \mathbb{R}$ with finite limit at ∞ , such as the variance put or volatility put,

consider an n th-order approximation to $h(q)$

$$A_n(q) := a_{n,n}e^{-cnq} + a_{n,n-1}e^{-c(n-1)q} + \dots + a_{n,0} \quad (15)$$

where $c > 0$ is an arbitrary constant.

To choose A by uniform approximation, $a_{n,k}$ may be determined as the coefficients of the n th Bernstein polynomial approximation to the function $x \mapsto h(-(1/c) \log x)$ on $[0, 1]$.

Then source [5] shows that

$$\begin{aligned} \mathbb{E}h([X]_T) &= \lim_{n \rightarrow \infty} \mathbb{E} \sum_{k=0}^n a_{n,k} \left(\theta_+(Y_T/Y_0)^{1/2 + \sqrt{1/4 - 2ck}} \right. \\ &\quad \left. + \theta_-(Y_T/Y_0)^{1/2 - \sqrt{1/4 - 2ck}} \right) \end{aligned} \quad (16)$$

where $\theta_{\pm} := (1 \mp 1/\sqrt{1 - 8ck})/2$. The RHS of equation (16) is, in principle, observable from T -expiry Europeans and is moreover designed to have zero sensitivity to first-order correlation effects.

Alternatively, to choose A by L^2 approximation, the $a_{n,k}$ may be determined by $L^2(\mu)$ projection of h onto $\text{span}\{1, e^{-cq}, \dots, e^{-cnq}\}$, where the “prior” μ is a finite measure on $[0, \infty)$. In practice, $a_{n,k}$ may be computed by weighted least squares regression of $h(q)$ on the regressors $\{q \mapsto e^{-ckq} : k = 0, \dots, n\}$, with weights given by μ . Then source [5] shows that equation (16) still holds, regardless of the choice of the prior μ , provided that $dP/d\mu$ exists in $L^2(\mu)$, where P denotes the $\mathbb{P}$ -distribution of $[X]_T$.

For *hedging* purposes, the summation in the RHS of equation (16) provides a European-style payoff that, in conjunction with share trading, replicates the volatility payoff $h([X]_T)$ to arbitrary accuracy.

Pricing via Variance Distribution Inference

Given the prices $\mathbf{c} \in \mathbb{R}^{N \times 1}$ of vanilla options at strikes $K_1, \dots, K_N$, a scheme in [8] discretizes into $\{v_1, \dots, v_J\}$ the possible values of $[X]_T$, and proposes to infer the discretized variance distribution $\mathbf{p} \in \mathbb{R}^{J \times 1}$ where $p_j := \mathbb{P}([X]_T = v_j)$, by solving approximately for $\mathbf{p}$ in

$$\mathbf{B}\mathbf{p} = \mathbf{c} \quad (17)$$

where $\mathbf{B} \in \mathbb{R}^{N \times J}$ is given by $B_{nj} := C^{BS}(K_n, v_j)$, the Black–Scholes formula for strike K_n and squared unannualized volatility v_j . The approximate solution is chosen to minimize $\|\mathbf{B}\mathbf{p} - \mathbf{c}\|^2$ plus a convex penalty term. The contact paying $h([X]_T)$ is then priced as $\sum p_j h(v_j)$.

Pricing by Use of Variance or Volatility Swaps

With sufficient liquidity, variance and/or volatility swap quotes can be taken as inputs. For example, an approximation in [8] prices variance options by fitting a lognormal variance distribution to variance and volatility swaps of the same expiry. An approximation in [4] prices and hedges variance and volatility options by fitting a displaced lognormal, to variance and volatility swaps.

The variance curve models in [1] apply a different approach to using variance swaps; they take as inputs the variance swap quotes at multiple expiries, and they model the dynamics of the term structure of forward variance. Applications include pricing and hedging of realized variance options.

Pricing Bounds by Model-free Use of Europeans

In this section, consider variance options on, more generally, any continuous share price Y .

Given European options of the same expiry T , there exist model-free sub/superreplication strategies, and hence lower/upper pricing bounds, for the variance options. Here *model-free* means that, aside from continuity and positivity, we make *no* assumptions on Y .

Subreplication and Lower Bounds

The following subreplication strategy is due to [7]; this exposition also draws from [3].

Let $\lambda : (0, \infty) \rightarrow \mathbb{R}$ be convex, let λ_y denote its left-hand derivative, and assume that its second derivative in the distributional sense has a density, denoted λ_{yy} , which satisfies for all $y \in \mathbb{R}_+$

$$\lambda_{yy}(y) \leq 2/y^2 \quad (18)$$

Define for $y > 0$ and $v > 0$

$$BS(y, v; \lambda) := \int_{-\infty}^{\infty} \lambda(ye^z) \frac{1}{\sqrt{2\pi}v} e^{-(z+v/2)^2/(2v)} dz \quad (19)$$

and define $BS(y, 0; \lambda) := \lambda(y)$, and let BS_y denote its y -derivative. Let $\tau_Q := \inf\{t \geq 0 : [X]_t \geq Q\}$. Then the following trading strategy subreplicates the variance call payoff: hold statically a claim that pays at time T

$$\lambda(Y_T) - BS(Y_0, Q; \lambda) \quad (20)$$

and trade shares dynamically, holding at each time $t \in (0, T)$

$$\begin{aligned} -BS_y(Y_t, Q - [X]_t; \lambda) & \quad \text{shares if } t \leq \tau_Q \\ -\lambda_y(Y_t) & \quad \text{shares if } t > \tau_Q \end{aligned} \quad (21)$$

and a bond position that finances the shares and accumulates the trading gains or losses. Therefore, the time-0 value of the contract paying (20) provides a lower bound on the variance call value.

The lower bound from equation (20) is optimized by λ consisting of $2/K^2 dK$ out-of-the-money vanilla payoffs at all K where $I_0(K, T)$, the squared unannualized Black–Scholes implied volatility, exceeds Q :

$$\lambda(y) = \int_{\{K: I_0(K, T) > Q\}} \frac{2}{K^2} \text{van}_K(y) dK \quad (22)$$

See [3] for generalization to forward-starting variance options.

Superreplication and Upper Bounds

The following superreplication strategy is due to [3]. Choose any $b_d \in (0, Y_0]$ and $b_u \in [Y_0, \infty)$. Let

$$\begin{aligned} BP(y, q) & \\ := \int_{-\infty - \alpha i}^{\infty - \alpha i} & \left[\sqrt{y/b_u} \sinh(\log(b_d/y) f(z)) \right. \\ & \left. - \sqrt{y/b_d} \sinh(\log(b_u/y) f(z)) \right] \\ & \left/ \left[2\pi z^2 e^{i(Q-q)z} \sinh(\log(b_u/b_d) f(z)) \right] \right. dz \end{aligned} \quad (23)$$

where $f(z) := \sqrt{1/4 - 2iz}$ and where $\alpha > 0$ is arbitrary. For $y > 0$ and $b_d \neq b_u$, define

$$\begin{aligned} L(y; b_d, b_u) & \\ := -2 \log(y/b_u) + 2 \frac{\log(b_u/b_d)}{b_u - b_d} (y - b_u) \end{aligned} \quad (24)$$

and define $L(y; Y_0, Y_0) := -2 \log(y/Y_0) + 2y/Y_0 - 2$. Let

$$L^*(y) := \begin{cases} L(y) & \text{if } y \notin (b_d, b_u) \\ -BP(y, 0) & \text{if } y \in (b_d, b_u) \end{cases} \quad (25)$$

Let BP_y and L_y denote the y -derivatives, and let $\tau_b := \inf\{t \geq 0 : Y_t \notin (b_d, b_u)\}$.

Then, the following strategy superreplicates the variance call payoff $([X]_T - Q)^+$. Hold statically a claim that pays at time T

$$L^*(Y_T) - L^*(Y_0) \quad (26)$$

and trade shares dynamically, holding at each time $t \in (0, T)$

$$\begin{aligned} BP_y(Y_t, [X]_t - [X]_0) & \quad \text{shares if } 0 \leq t \leq \tau_b \\ -L_y(Y_t) & \quad \text{shares if } t > \tau_b \end{aligned} \quad (27)$$

and a bond position that finances the shares and accumulates the trading gains or losses.

Therefore, the time-0 value of the contract paying (26) provides an upper bound on the variance call value. Given T -expiry European options data, the upper bound from equation (26) may be optimized over all choices of (b_d, b_u) .

Connection to the Skorokhod Problem

Whereas the sections “Subreplication and Lower Bounds” and “Superreplication and Upper Bounds” presented explicit hedging strategies, which imply pricing bounds, this section presents (a logarithmic version of) the result in [7], which showed that stopping-time analysis also implies pricing bounds.

Denote by ν the $\mathbb{P}$ -distribution of Y_T , which is revealed by the prices of T -expiry options on Y .

Suppose that $\tilde{Y}$ is a continuous $\mathcal{F}$ -martingale with $\tilde{Y}_T \sim \nu$, and $[\tilde{X}]_T$ has finite expectation, where $\tilde{X} := \log \tilde{Y}$. Then Dambis–Dubins–Schwartz implies that

$\tilde{Y}_t = G_{[\tilde{X}]_t}$, where G is a driftless unit-volatility geometric $\mathcal{G}$ -Brownian motion (on an enlarged probability space if needed) with $G_0 = Y_0$, and $[\tilde{X}]_t$ are $\mathcal{G}$ -stopping times, where $\mathcal{G}_s := \mathcal{F}_{\inf\{t: [\tilde{X}]_t > s\}}$. Thus $G_{[\tilde{X}]_T} \sim \nu$; and hence $[\tilde{X}]_T$ solves a *Skorokhod problem* (see **Skorokhod Embedding**): it is a finite-expectation stopping time that embeds the distribution ν in G . Conversely, if some finite-expectation τ embeds ν in a driftless unit-volatility geometric Brownian motion G , then $\tilde{Y}_t := G_{\tau \wedge (t/(T-t))}$ defines a continuous martingale with $\tilde{Y}_T \sim \nu$ and $[\log \tilde{Y}]_T = \tau$.

Therefore, distributions of stopping times solving the Skorokhod problem are identical to distributions of realized variance consistent with the given price distribution ν . Skorokhod solutions that have optimality properties, therefore, imply bounds on prices of variance/volatility options. In particular, *Root's* solution is known [9] to minimize the expectations of convex functions of the stopping time; the minimized expectation is, in that sense, a sharp lower bound on the price of a variance option (see also **Skorokhod Embedding**).

Contract Specifications in Practice

In practice, the realized variance in the payoff specification is defined by replacing quadratic variation $[X]_T$ with an annualized discretization that monitors Y , typically daily, for N periods, resulting in a specification

$$\text{Annualization} \times \sum_{n=1}^N \left(\log \frac{Y_n}{Y_{n-1}} \right)^2 \quad (28)$$

If the contract adjusts for dividends (as typical for single-stock dividends but not index dividends) then

the term inside the parentheses becomes $\log((Y_n + D_n)/Y_{n-1})$, where D_n denotes the discrete dividend payment, if any, of the n th period.

Put–Call Parity

Put–call parity means that one may switch between call and put positions by selling or buying the underlying forward: “long call, short put is long forward contract” or $\mathbf{c} - \mathbf{p} \equiv \mathbf{f}$. In other words, one may replicate a put contract by buying a call of identical characteristics (underlying asset, strike, maturity) and selling the underlying asset forward ($\mathbf{p} \equiv \mathbf{c} - \mathbf{f}$), and one may replicate a call by buying a put and the underlying forward ($\mathbf{c} \equiv \mathbf{p} + \mathbf{f}$). This is shown in the three payoff diagrams (Figures 1–3).

A logical proof of the third instance ($\mathbf{c} \equiv \mathbf{p} + \mathbf{f}$) is as follows: a rational investor will exercise a call option whenever the asset price S at maturity is above the strike K ; this is equivalent to promising to buy the asset at K and having the option to sell it at that level, which a rational investor will exercise whenever S falls below K .

Put–call parity is often referred to as *option synthetics* by practitioners and holds only for European options.^a It does not require any assumption other than the ability to buy or sell the asset forward, but it is worth noting that this may not always be the case: to sell forward, either a futures market must exist or one must be able to short-sell the asset.

Put–call parity must not be confused with “put–call symmetry” (see **Foreign Exchange Symmetries**) in foreign exchange, which states that a call struck at K on a given exchange rate S (e.g., dollars per 1 euro) is identical to a put struck at $1/K$ on the reverse rate $1/S$ (euros per 1 dollar), after the *ad hoc* numeraire conversions: $\mathbf{c}(S, K)/S \equiv K \mathbf{p}(1/S, 1/K)$.

Price Relationship

Assuming no arbitrage, the synthetic relationship immediately translates into the well-known price relationship: “call minus put equals forward” or $c_t - p_t = f_t$. Note that here f_t denotes the price of a forward contract struck at K , that is, the present value (p.v.) of the gap between the forward price F_t and the strike price K (see **Forwards and Futures**). Denoting the price of the zero-coupon bond maturing

at T by B_t and rearranging terms, we have

$$\begin{aligned} & \text{call} + \text{p.v. of strike price} \\ &= \text{put} + \text{p.v. of forward price} \end{aligned} \quad (1)$$

or

$$c_t + K \cdot B_t = p_t + F_t \cdot B_t \quad (2)$$

For all investment assets where short selling is feasible, the forward price can be further expressed as a function of the spot price S_t and the revenue or cost of carry until maturity T (see **Forwards and Futures**). For example, the forward price of a stock with continuous dividend rate q satisfies $F_t = S_t/B_t \cdot \exp(-q(T-t))$, and put–call parity simplifies to

$$c_t + K \cdot B_t = p_t + S_t \cdot e^{-q(T-t)} \quad (3)$$

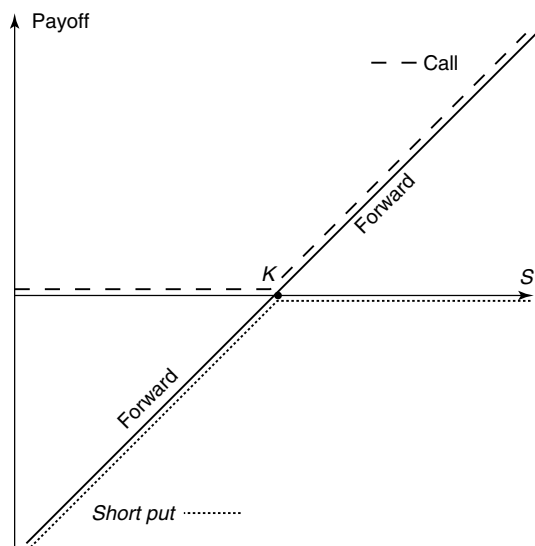

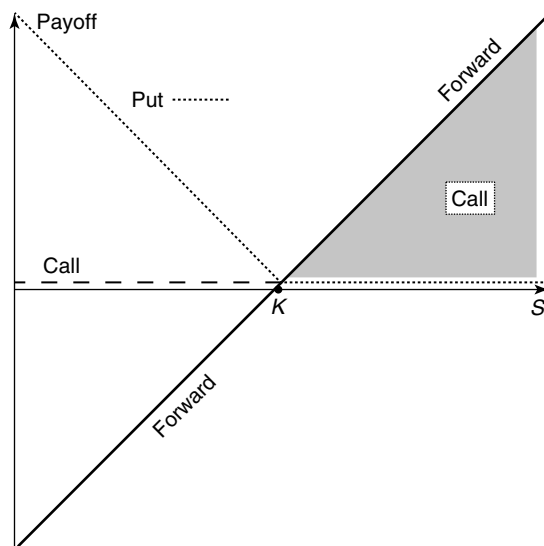

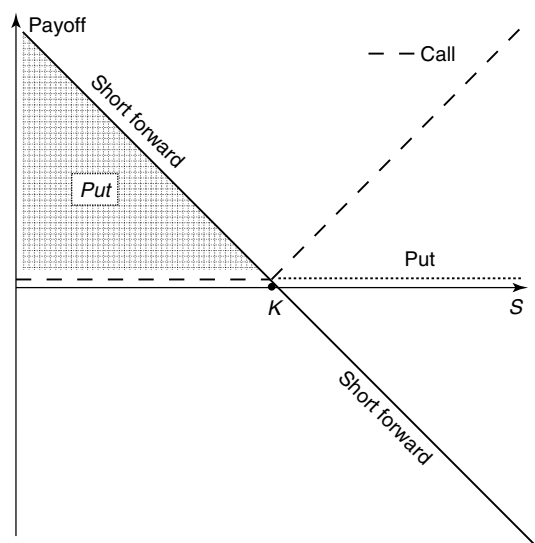

In practice, Kamara and Miller [5] give empirical evidence that while put–call parity has many small violations, almost half of the arbitrages would result in a loss when execution delays are accounted for.

Basic Implications

- For trading purposes, puts and calls are identical instruments (up to a directional position in the underlying asset).
- At-the-money-forward calls and puts must have the same value. (An at-the-money-forward option has its strike set at the forward price of the underlying asset.)
- In the absence of revenue or cost of carry, the deltas (see **Black–Scholes Formula; Delta Hedging**) of a call and put must add up to 1 (in absolute value).
- Puts and calls must have the same gamma and vega (see **Black–Scholes Formula; Gamma Hedging**).

In volatility modeling, put–call parity implies that calls and puts of identical characteristics must have the same **implied volatility**.

In exotic option pricing, Carr and Lee [1] put forward the idea of a generalized American option that may be indefinitely exercised until maturity to lock-in the intrinsic value and switch between call and put styles. The authors show that this option may be replicated by holding onto a European

Figure 1 $c - p \equiv f$ Figure 3 $c \equiv p + f$ Figure 2 $p \equiv c - f$

vanilla call and subsequently selling and buying the forward contract at every exercise. This strategy is a straightforward illustration of how put–call parity may be exploited to alternate between call and put positions by only trading in the forward contract.

History

Haug [3] traces put–call parity as far back as the seventeenth century, but its formulation was then “diffuse”. According to the author, an early formulation of put–call parity “as we know it” can be found in the work by Higgins [4], who wrote in 1902:

It can be shown that the adroit dealer in options can convert a ‘put’ into a ‘call’, a ‘call’ into a ‘put’ [...] by dealing against it in the stock.

Derman and Taleb [2] argue that the Black–Scholes–Merton formulas could have been established earlier than 1973 *via* put–call parity instead of the dynamic replication argument. Specifically, the authors cite similar formulas published in the 1960s, all of which “involved unknown risk premiums that would have been determined to be zero had [...] the put–call replication argument” been used.

Put–call parity can fail when there are restrictions on short selling, when the underlying asset is hard to borrow or illiquid, or in the case of corporate events such as leveraged buyouts.

End Notes

^aThe reason put–call parity fails with American options is best seen in the first instance ($c - p \equiv f$), whereby an

agent attempts to replicate a forward contract by buying a call and selling a put. If the put is American, it may be exercised against the agent before maturity, thus breaking the replication strategy.

Discretely Monitored Options

Traditional pricing models for path-dependent options rely on continuously monitoring the underlying, often resulting in closed-form or analytic formulas. References include [14, 19, 20, 21] for barrier options, [6, 12, 13] for look-back options, and [11, 18] for Asian or average options. However, in practice, monitoring is performed over discrete dates (e.g., monthly, weekly, or daily), while the underlying is still assumed to follow a continuous model. In contrast to continuous monitoring, discrete monitoring rarely, if ever, leads to similarly tractable solutions and using continuous monitoring as approximation for discrete monitoring often leads to significant mispricing (cf. [5, 15, 16].) As a consequence, various approaches have been followed to arrive at practically useful computational schemes.

For illustration, we focus on a down-and-out call option, where a standard call option with strike K is canceled if the underlying falls below a barrier prior to expiry T . We first assume the traditional Black–Scholes–Merton setup with the price $\{S_t\}$ of the underlying following a geometric Brownian motion

$$S_t = S_0 e^{B_t} \quad (1)$$

where $\{B_t\}$ is a Brownian motion with drift $r - \sigma^2/2$ and standard deviation σ . Here the parameters r and σ represent the prevailing risk-free rate and the return volatility of the underlying asset, respectively. Let $H > 0$ be a given constant (barrier) and assume $H < S_0$. With monitoring effected over a set of m dates $n\Delta t$ ($n = 1, \dots, m$) such that $\Delta t = T/m$, let $U_n = X_1 + X_2 + \dots + X_n$, where the X_i s are independent normal random variables with mean $\mu = (r - \sigma^2/2) \Delta t$ and standard deviation $\tilde{\sigma} = \sigma \sqrt{\Delta t}$. Then the call is knocked-out the first (random) time $\tau \in \{1, 2, \dots, m\}$ such that $H \geq S_\tau$ and the time-0 price of such a call is

$$V_m(H) = e^{-rT} E \left(S_0 e^{U_m} - K \right)^+ 1_{\{\tau > m\}} \quad (2)$$

where $\tau = \inf\{n : U_n \leq \log(H/S_0)\}$. The main source of the evaluation of the above expectation

is the computational complexity associated with an m -variate normal distribution for even moderate values of m . For example, Monte Carlo or tree-based algorithms may take several hours or even days for common values of m [4]. In their paper, Broadie *et al.* [3] (see also [17]), opt to circumvent this hurdle by linking $V_m(H)$ to the price of a continuously monitored option with a barrier shifted away from the original. More precisely, they show that

$$V_m(H) = V \left(H e^{\pm \beta \sigma \sqrt{\Delta t}} \right) + o(1/\sqrt{m}) \quad (3)$$

where $V(\tilde{H})$ is the price of a continuously monitored barrier option with threshold $\tilde{H}$ and $\beta \approx 0.5826$, with $+$ for an up option and $-$ for a down option.

Although this approach works very well, it appears to be inaccurate when the barrier is near the initial price of the underlying. Under such circumstances, one can opt to use the recursive method of Ait-Sahlia and Lai [1], which consists in reducing an m -dimensional integration problem to successively evaluating m one-dimensional integrals. Specifically, they show that

$$V_m(H) = \int_{\log(H/S_0)}^{\infty} (S_0 e^x - K)^+ f_m(x) dx \quad (4)$$

where, for $1 \leq n \leq m$, $f_n(x) dx = P\{\tau > n, U_n \in dx\}$ for $x > \log(H/S_0)$, with f_n defined recursively for each n according to the following:

$$\begin{aligned} f_1(x) &= \psi(x) \\ f_n(x) &= \int_{\log(H/S_0)}^{\infty} f_{n-1}(y) \psi(x - y) dy \\ &\text{for } 2 \leq n \leq m \end{aligned} \quad (5)$$

Here $\psi(x) = \tilde{\sigma}^{-1} \phi = ((x - \mu)/\tilde{\sigma})$, with ϕ being the density of a standard normal distribution, and $f_n(x) = 0$, for $x \leq \log(H/S_0)$ and $1 \leq n \leq m$. This approach is very accurate and efficient for generally moderate values of m , using as little as 20 integration points.

Both the continuity correction and recursive integration methods can also be similarly applied to discretely monitored look-back options (cf. [2] and [4].) Alternatives to the above abound as well. Fusai *et al.* [10] use a Wiener–Hopf machinery to also compute hedge parameters. In the

context of a GARCH model, Duan *et al.* [7] propose a Markov chain technique that can also handle American-style exercise. Partial differential equations are used in [9, 22, 23, 24] to price average and barrier options, including when volatility is stochastic and exercise is of American style. Finally, [8] contains an approach that ultimately relies on Hilbert and Fourier transform techniques to address the situation when the underlying follows a Lévy process.

FARID AITSAHLIA

Weighted Variance Swap

Let the underlying process Y be a semimartingale taking values in an interval I . Let $\varphi : I \rightarrow \mathbb{R}$ be a difference of convex functions, and let $X := \varphi(Y)$. A typical application takes Y to be a positive price process and $\varphi(y) = \log y$ for $y \in I = (0, \infty)$.

Then (the floating leg of) a forward-starting *weighted variance swap* or *generalized variance swap* on $\varphi(Y)$ (shortened to “on Y ” if the φ is understood), with *weight* process w_t , forward-start time θ , and expiry T , is defined to pay, at a fixed time $T_{\text{pay}} \geq T > \theta \geq 0$,

$$\int_{\theta}^T w_t d[X]_t \quad (1)$$

where $[\cdot]$ denotes quadratic variation. In the case that $\theta = 0$, the trade date, we have a spot-starting weighted variance swap. The basic cases of weights take the form $w_t = w(Y_t)$, for a measurable function $w : I \rightarrow [0, \infty)$, such as the following.

1. The weight $w(y) = 1$ defines a *variance swap* (see **Variance Swap**).
2. The weight $w(y) = \mathbb{1}_{y \in C}$, the indicator function of some interval C , defines a *corridor variance swap* (see **Corridor Variance Swap**) with corridor C . For example, a corridor of the form $C = (0, H)$ produces a *down* variance swap.
3. The weight $w(y) = y/Y_0$ defines a *gamma swap* (see **Gamma Swap**).

Model-free Replication and Valuation

Assuming a deterministic interest rate r_t , let Z_t be the time- t price of a bond that pays 1 at time T_{pay} . Assume that Y is the continuous price process of a share that pays continuously a deterministic proportional dividend q_t . Let

$$Z_t = \exp\left(-\int_t^{T_{\text{pay}}} r_u du\right) \quad \text{and} \quad Q_t := \exp\left(\int_0^t q_u du\right) \quad (2)$$

so the share price with reinvested dividends is $Y_t Q_t$. Then the payoff

$$\int_{\theta}^T w(Y_t) d[X]_t \quad (3)$$

admits a model-independent replication strategy, which holds European options statically and trades the underlying shares dynamically. Indeed, let $\lambda : I \rightarrow \mathbb{R}$ be a difference of convex functions, let λ_y denote its left-hand derivative, and assume that its second derivative in the distributional sense has a signed density, denoted λ_{yy} , which satisfies for all $y \in I$

$$\lambda_{yy}(y) = 2\varphi_y^2(y)w(y) \quad (4)$$

where φ_y denotes the left-hand derivative of φ . Then

$$\begin{aligned} \int_{\theta}^T w(Y_t) d[X]_t &= \lambda(Y_T) - \lambda(Y_{\theta}) - \int_{\theta}^T \lambda_y(Y_t) dY_t \\ &= \lambda(Y_T) - \lambda(Y_{\theta}) + \int_{\theta}^T (q_t - r_t) \lambda_y(Y_t) Y_t dt \\ &\quad - \int_{\theta}^T \lambda_y(Y_t) \frac{Z_t}{Q_t} d(Y_t Q_t / Z_t) \end{aligned} \quad (5)$$

where equation (5) is by a proposition in [2] that slightly extends [1], and equation (6) is by Ito's rule. So the following self-financing strategy replicates (and hence prices) the payoff (3). Hold statically a claim that pays at time T_{pay}

$$\lambda(Y_T) - \lambda(Y_{\theta}) + \int_{\theta}^T (q_{\tau} - r_{\tau}) \lambda_y(Y_{\tau}) Y_{\tau} d\tau \quad (7a)$$

and trade shares dynamically, holding at each time $t \in (\theta, T)$

$$-\lambda_y(Y_t) Z_t \quad \text{shares} \quad (7b)$$

and a bond position that finances the shares and accumulates the trading gains or losses. Hence, the payoff (3) has time-0 value equal to that of the replicating claim (7a), which is synthesizable from Europeans with expiries in $[\theta, T]$. Indeed, for a put/call separator κ (such as $\kappa = Y_0$), if $\lambda(\kappa) = \lambda_y(\kappa) = 0$, then

each λ claim decomposes into puts/calls at all strikes K , with quantities $2\varphi_y^2(K)w(K) dK$:

$$\lambda(y) = \int_I 2\varphi_y^2(K)w(K)\text{Van}(y, K) dK \quad (8)$$

where $\text{Van}(y, K) := (K - y)^+ \mathbb{1}_{K < \kappa} + (y - K)^+ \mathbb{1}_{K > \kappa}$ denotes the vanilla put or call payoff. For put/call decompositions of general European payoffs, see [1].

Futures-dependent Weights

In equation (3), the weight is a function of spot Y_t . The alternative payoff specification

$$\int_{\theta}^T w(Y_t Q_t / Z_t) d[X]_t \quad (9)$$

makes w_t a function of the *futures* price (a constant times $Y_t Q_t / Z_t$).

In the case $\varphi = \log$, we have $[X] = [\log Y] = [\log(YQ/Z)]$; hence

$$\begin{aligned} & \int_{\theta}^T w(Y_t Q_t / Z_t) d[X]_t \\ &= \lambda\left(\frac{Y_T Q_T}{Z_T}\right) - \lambda\left(\frac{Y_{\theta} Q_{\theta}}{Z_{\theta}}\right) \\ & \quad - \int_{\theta}^T \lambda_y(Y_t Q_t / Z_t) d(Y_t Q_t / Z_t) \end{aligned}$$

for λ satisfying equation (4). So the alternative payoff (9) admits replication as follows: hold statically a claim that pays at time T_{pay}

$$\lambda(Y_T Q_T / Z_T) - \lambda(Y_{\theta} Q_{\theta} / Z_{\theta}) \quad (10a)$$

and trade shares dynamically, holding at each time $t \in (\theta, T)$

$$- \lambda_y(Y_t Q_t / Z_t) Q_t \text{ shares} \quad (10b)$$

and a bond position that finances the shares and accumulates the trading gains or losses. Thus, the payoffs (9) and (10a) have equal values at time 0.

In special cases (such as $w = 1$ or $r = q = 0$), the spot-dependent (3) and futures-dependent (9) weight specifications are equivalent. In general, the spot-dependent weighting is harder to replicate, as it requires a continuum of expiries in equation (7a),

unlike equation (10a). The spot-dependent weighting is, however, the more common specification and is assumed in remainder of this article.

Examples

Returning to the previously specified examples of weights $w(Y_t)$, we express the replication payoff λ in a compact formula, and also expanded in terms of vanilla payoffs according to equation (8). We take $\varphi(y) = \log y$ unless otherwise stated.

- *Variance swap*: Equation (4) has solution

$$\begin{aligned} \lambda(y) &= -2 \log(y/\kappa) + 2y/\kappa - 2 \\ &= \int_0^{\infty} \frac{2}{K^2} \text{Van}(y, K) dK \end{aligned} \quad (11)$$

- *Arithmetic variance swap*: For $\varphi(y) = y$, equation (4) has solution

$$\lambda(y) = (y - \kappa)^2 = \int_0^{\infty} 2 \text{Van}(y, K) dK \quad (12)$$

- *Corridor variance swap*: Equation (4) has solution

$$\lambda(y) = \int_{K \in C} \frac{2}{K^2} \text{Van}(y, K) dK \quad (13)$$

- *Gamma swap*: Equation (4) has solution

$$\begin{aligned} \lambda(y) &= \frac{2}{Y_0} \left[y \log(y/\kappa) - y + \kappa \right] \\ &= \int_0^{\infty} \frac{2}{Y_0 K} \text{Van}(y, K) dK \end{aligned} \quad (14)$$

In all cases, the strategy (7) replicates the desired contract. In the case of a variance swap, the strategy (10) also replicates it, because $w(Y) = 1 = w(YQ/Z)$.

Discrete Dividends

Assume that at the fixed times t_m where $\theta = t_0 < t_1 < \dots < t_M = T$, the share price jumps to $Y_{t_m} = Y_{t_m-} - \delta_m(Y_{t_m-})$, where each discrete dividend is given by a function δ_m of prejump price. In this case, the dividend-adjusted weighted variance swap can be defined to pay at time T_{pay}

$$\sum_{m=1}^M \int_{t_{m-1}+}^{t_m-} w(Y_t) d[X]_t \quad (15)$$

If the function $y \mapsto y - \delta_m(y)$ has an inverse $f_m : I \rightarrow I$, and if Y is still continuous on each $[t_{m-1}, t_m)$, then each term in equation (15) can be constructed via equation (7), together with the relation $\lambda(Y_{t_m-}) = \lambda(f_m(Y_{t_m}))$. Specifically, the m th term admits replication by holding statically a claim that pays at time T_{pay}

$$\begin{aligned} & \lambda(f_m(Y_{t_m})) - \lambda(Y_{t_{m-1}}) \\ & + \int_{t_{m-1}}^{t_m} (q_\tau - r_\tau) \lambda_y(Y_\tau) Y_\tau \, d\tau \end{aligned} \quad (16)$$

and holding dynamically $-\lambda_y(Y_t)Z_t$ shares, at each time $t \in (t_{m-1}, t_m)$.

Contract Specifications in Practice

In practice, weighted variance swap transactions are forward settled; no payment occurs at time 0, and at time T_{pay} the party long the swap receives the total payment

$$\text{Notional} \times (\text{Floating} - \text{Fixed}) \quad (17)$$

where “fixed” (also known as the *strike*), expressed in units of annualized variance, is the price contracted at time 0 for time- T_{pay} delivery of “floating”, an annualized discretization of equation (15) that monitors Y , typically daily, for N periods. In the usual case of $\varphi = \log$, this results in a specification

Floating := Annualization

$$\times \sum_{n=1}^N w(Y_n) \left(\log \frac{Y_n + D_n}{Y_{n-1}} \right)^2 \quad (18)$$

where D_n denotes the discrete dividend payment, if any, of the n th period. Both here and in the theoretical form (15), no adjustment is made for any dividends deemed to be continuous (for example, index variance contracts typically do not adjust for index dividends; see [3]).

In some contracts—for example, single-stock (down-)variance—the risk to the variance seller that Y crashes is limited by imposing a cap on the payoff. Hence,

$$\text{Notional} \times \left(\min(\text{Floating}, \text{Cap} \times \text{Fixed}) - \text{Fixed} \right) \quad (19)$$

replaces equation (17), where “Cap” is an agreed constant, such as the square of 2.5.

Model Calibration

The fundamental theorem of asset pricing (*see **Fundamental Theorem of Asset Pricing***) shows that, in an arbitrage-free market, market prices can be represented as (conditional) expectations with respect to a martingale measure $\mathbb{Q}$: a probability measure $\mathbb{Q}$ on the set Ω of possible trajectories $(S_t)_{t \in [0, T]}$ of the underlying asset such that the asset price S_t/N_t discounted by the numeraire N_t is a martingale. The value $V_t(H_T)$ of a (discounted) terminal payoff H_T at T is then given by

$$V_t(H_T) = E^{\mathbb{Q}}[B(t, T)H_T | \mathcal{F}_t] \quad (1)$$

where $B(t, T) = N_t/N_T$ is the discount factor. For example, the value under the pricing rule $\mathbb{Q}$ of a call option with strike K and maturity T is given by $E^{\mathbb{Q}}[B(t, T)(S_T - K)^+ | \mathcal{F}_t]$. However, this result does not say how to construct the pricing measure $\mathbb{Q}$. Given that data sets of option prices have become increasingly available, a common approach for selecting a pricing model $\mathbb{Q}$ is to choose, given a set of liquidly traded derivatives with (discounted) terminal payoffs $(H^i)_{i \in I}$ and market prices $(C_i)_{i \in I}$, a pricing measure $\mathbb{Q}$ compatible with the observed market prices:

Problem 1 [Calibration Problem] *Given market prices $(C_i)_{i \in I}$ (say at date $t = 0$) for a set of options with discounted terminal payoffs $(H_i)_{i \in I}$, construct a probability measure $\mathbb{Q}$ on Ω such that*

- *the (discounted) asset price $(S_t)_{t \in [0, T]}$ is a martingale under $\mathbb{Q}$*

$$T \geq t \geq u \geq 0 \Rightarrow E^{\mathbb{Q}}[S_t | \mathcal{F}_u] = S_u \quad (2)$$

- *the pricing rule implied by $\mathbb{Q}$ is consistent with market prices*

$$\forall i \in I, \quad E^{\mathbb{Q}}[H_i] = C_i \quad (3)$$

where, for ease of notation, we have set discount factors to 1 (prices are discounted) and $E[\cdot]$ denotes the conditional expectation given initial information $\mathcal{F}_0$. Thus, a pricing rule $\mathbb{Q}$ is said to be calibrated to the *benchmark instruments* H_i if the value of these instruments, computed in the model, correspond to their market prices C_i .

Option prices being evaluated as expectations, this inverse problem can also be interpreted as a (generalized) moment problem for the law $\mathbb{Q}$ of risk-neutral process given a finite number of option prices, it is typically an *ill-posed* problem and can have many solutions. However, the number of observed options can be large ($\simeq 100 - 200$ for index options) and finding even a single solution is not obvious and requires efficient numerical algorithms.

In the Black–Scholes model (*see **Black–Scholes Formula***), calibration amounts to picking the volatility parameter to be equal to the implied volatility of a traded option. However, if more than one option is traded, the Black–Scholes model cannot be calibrated to market prices, since in most options markets implied volatility varies across strikes and maturities; this is the *volatility smile* phenomenon. Therefore, to solve the calibration problem, we need more flexible models, some examples of which are given here.

Example 1 [Diffusion Model (*see **Local Volatility Model***)] If an asset price is modeled as a diffusion process

$$dS_t = S_t[\mu dt + \sigma(t, S_t) dW_t] \quad (4)$$

parameterized by a local volatility function

$$\sigma : (t, S) \rightarrow \sigma(t, S) \quad (5)$$

then the values of call options can be computed by solving the Dupire equation (*see **Implied Volatility Surface***)

$$\begin{aligned} \frac{\partial C_0}{\partial T} + Kr \frac{\partial C_0}{\partial K} - \frac{K^2 \sigma^2(T, K)}{2} \frac{\partial^2 C_0}{\partial K^2} &= 0 \\ \forall K \geq 0, \quad C_0(T = 0, K) &= (S - K)^+ \end{aligned} \quad (6)$$

The corresponding inverse problem is to find a (smooth) volatility function $\sigma : [0, T] \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$ such that $C^\sigma(T_i, K_i) = C^*(T_i, K_i)$ where C^σ is the solution of equation (6) and $C^*(T_i, K_i)$ are the market prices of call options.

Example 2 In an exponential–Lévy model $S_t = \exp X_t$, where X_t is a Lévy process (*see **Exponential Lévy Models***) with diffusion coefficient $\sigma > 0$ and Lévy measure ν , call prices $C^{\sigma, \nu}(t_0, S_0; T_i, K_i)$ are easily computed using Fourier-based methods (*see*

Fourier Methods in Options Pricing). The calibration problem is to find σ, ν such that

$$\forall i \in I, C^{\sigma, \nu}(t_0, S_0; T_i, K_i) = C^*(T_i, K_i) \quad (7)$$

This is an example of a nonlinear inverse problem where the parameter lies in a space of measures.

Example 3 In the LIBOR market model, a set of N interest rates (LIBOR rates) is modeled as a diffusion process $L_t = (L_t^i)_{i=1..N}$ with constant covariance matrix $\Sigma = {}^t \sigma \cdot \sigma \in \text{Sym}^+(n \times n)$:

$$dL_t^i = \mu_t^i dt + L_t^i \sigma_i \cdot dW_t^j \quad (8)$$

This model can then be used to analytically price caps, floors, and swaptions (using a lognormal approximation), whose prices depend on the entries of the covariance matrix Σ . The calibration problem is to find a symmetric semidefinite positive matrix $\Sigma \in \text{Sym}^+(n \times n)$ such that the model prices C^Σ match market prices

$$\forall i \in I, C^\Sigma(T_i, K_i) = C^*(T_i, K_i) \quad (9)$$

This problem can be recast as a semi-definite programming problem [2].

Other examples include the construction of yield curves from bond prices (*see Bond Options*) calibration of term structure models (*see Term Structure Models*) to bond prices, recovering the distribution of volatility from option prices [28] calibration to American options in diffusion models [1] and recovery of portfolio default rates from market quotes of credit derivatives [16, 18].

These problems are typically ill-posed in the sense that, either solutions may not exist (model class is too narrow to reproduce observations) or solutions are not unique (if data is finite or sparse). In practice, existence of a solution is restored by formulating the problem as an optimization problem

$$\inf_{\theta \in E} F(C^\theta - C) \quad (10)$$

where E is the parameter space and F is a loss function applied to the discrepancy $C^\theta - C$ between market prices and model prices. An algorithm is then used to retrieve *one* solution and the main issue is the *stability* of this reconstructed solution as a function of inputs (market prices).

Inversion formulas

In the theoretical situation where prices of European options are available for all strikes and maturities, the calibration problem can sometimes be explicitly solved using an inversion formula.

For the diffusion model in Example 1, the Dupire formula [25] (*see Dupire Equation*):

$$\sigma(T, K) = \sqrt{\frac{\frac{\partial C_0}{\partial T} + Kr \frac{\partial C_0}{\partial K}}{\frac{K^2}{2} \frac{\partial^2 C_0}{\partial K^2}}} \quad (11)$$

allows to invert the volatility function from call option prices. Similar formulas can be obtained in credit derivative pricing models, for inverting portfolio default rates from collateralized debt obligation (CDO) tranche spreads [16] and pure jump models with state-dependent jump intensity (“local Levy” model) [12]. No such inversion formula is available in the case of American options (*see American Options*). The Dupire formula (11) has been widely used by practitioners for recovering the local volatility function from call/put option prices by interpolating in strike and maturity and applying equation (11). However, since equation (11) involves differentiating the inputs, it suffers from instability and sensitivity to small changes in inputs, as shown in Figure 1. This instability deters one from using inversion formulas such as equation (6) even in the rare cases where they exist.

Least-squares Formulation

Typically, if the model is misspecified, the observed option prices may not lie within the range of prices attainable by the model. Also, option prices are defined up to a bid–ask spread: a model may generate prices compatible with the market but may not exactly fit the mid-market prices for any given $\theta \in E$. For these reasons, one often reformulates calibration as a least-squares problem

$$\inf_{\theta \in E} J_0(\theta), \quad J_0(\theta) = \sum_{i=1}^I w_i |C_i(\theta) - C_i|^2 \quad (12)$$

where C_i are mid-market quotes and $w_i > 0$ are a set of weights, often chosen inversely proportional to the (squared) bid–ask spread of C_i .

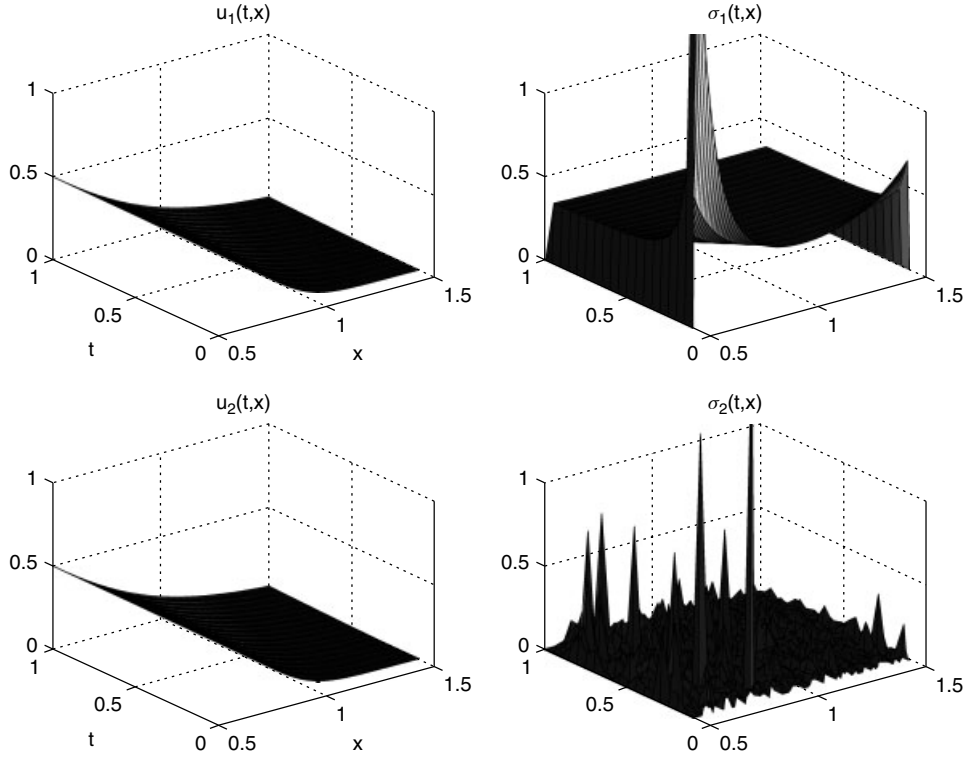

Figure 1 Extreme sensitivity of Dupire formula to noise in the data. Two examples of call price function (left) and their corresponding local volatilities (right). The prices differ through IID noise $\sim UNIF(0, 0.001)$, representing a bid–ask spread

In most models, the call prices are computed numerically *via* Fourier transform (see **Fourier Methods in Options Pricing**) or by solving a partial differential equation (PDE) (see **Partial Differential Equations**). However, in many situations (short or long maturity, small vol–vol, etc.) approximation formulae for implied volatilities $\Sigma(T_i, K_i)$ of call options are available [5, 10, 11, 30] in terms of model parameters (see **Implied Volatility in Stochastic Volatility Models; Implied Volatility: Volvol Expansion; Implied Volatility: Long Maturity Behavior; SABR Model**). In these situations, parameters are calibrated by a least-squares fit to the approximate formula:

$$\inf_{\theta \in E} \sum_{i=1}^I w_i |\Sigma(T_i, K_i; \theta) - \Sigma^*(T_i, K_i)|^2 \quad (13)$$

An example is the SABR model (see **SABR Model**), whose popularity is almost entirely due

to its ease of calibration using the Hagan formula [30].

In most cases, option prices $C_i(\theta)$ depend continuously on θ and E is a subset of a finite dimensional space (i.e., there are a finite number of bounded parameters), so the least-squares formulation always admits a solution. However, the solution of equation (12) need not be unique: J_0 may, in fact, have several *global* minima, when the observed option prices do not uniquely identify the model. Figures 2 and 3 show examples of the function J_0 for some popular parametric option pricing models, computed using a data set of DAX index options prices on May 11, 2001. The pricing error in the Heston stochastic volatility model (see **Heston Model**), shown in figure as a function of the “volatility of volatility” and the mean reversion rate, displays a line of local minima. The pricing error for the variance gamma model (see **Variance-gamma Model**) in Figure 3 displays a non-convex profile, with two distinct minima in the range

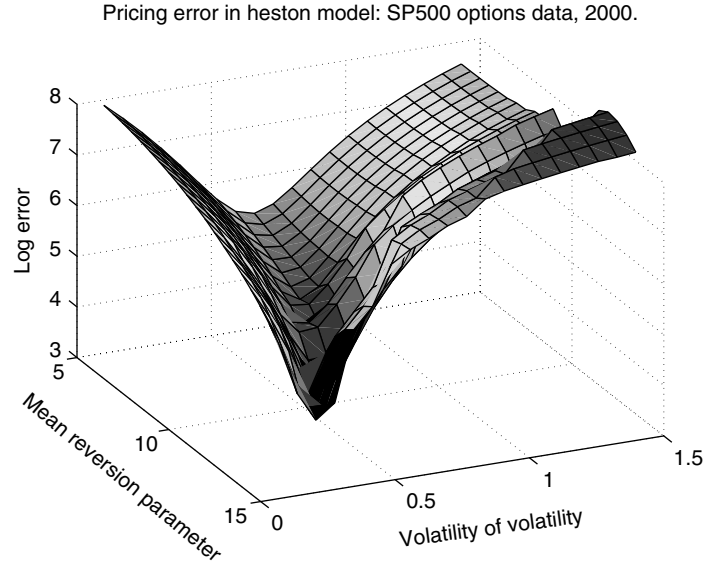

Figure 2 Error surface for the Heston stochastic volatility model, DAX options

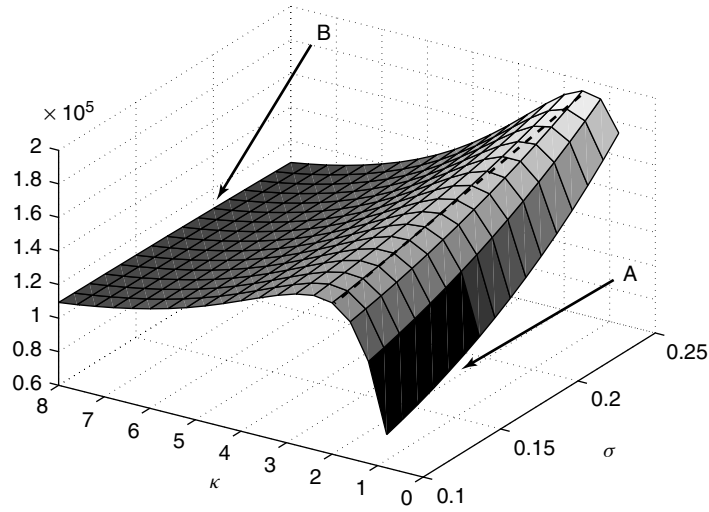

Figure 3 Error surface for variance gamma (pure jump) model, DAX options

of observed values. These examples show that, even if the number of observations (option prices) is much higher than the number of parameters, this does not imply identifiability of parameters.

Regularization methods can be used to overcome this problem [27]. A common method is to have a convex penalty term R , called the *regularization*

term, to the pricing error and solve the auxiliary problem:

$$\inf_{\theta \in E} J_{\alpha}(\theta) \quad (14)$$

where

$$J_{\alpha}(\theta) = J_0(\theta) + \alpha R(\theta) \quad (15)$$

The functional (16) consists of two parts: the regularization term $\alpha R(\theta)$ which is convex in its argument and the quadratic pricing error which measures the precision of calibration. The coefficient α , called *regularization parameter*, defines the relative importance of the two terms: it characterizes the trade-off between prior knowledge and the information contained in option prices. $J_\alpha(\cdot)$ is usually minimized by gradient-based methods, where the crux of the algorithm is an efficient computation of the gradient $\nabla_\theta J$.

When parameter is a function (such as the local volatility function), the regularization term is often chosen to be a smoothness (e.g., Sobolev) norm. This method, called *Tikhonov regularization* (see **Tikhonov Regularization**) has been applied to diffusion models [1, 2, 13, 23, 26] and to exponential-Lévy models [19].

Another popular choice of regularization term is the relative entropy (see **Entropy-based Estimation**) $R(\theta) = H(\mathbb{Q}^\theta | \mathbb{P})$ with respect to a prior probability measure $\mathbb{P}$. In continuous-time models, relative entropy can be used as regularization criterion only if the prior possesses a nonempty class of equivalent martingale measures, that is, it corresponds to an incomplete market model (see **Complete Markets**). From a calibration perspective, market incompleteness (i.e., the nonuniqueness of equivalent martingale measure) is therefore an *advantage*: it allows to conciliate compatibility with option prices and equivalence with respect to a reference probability measure. Examples are provided by jump processes (see **Jump Processes; Exponential Lévy Models**) or reduced-form credit risk models (see **Reduced Form Credit Risk Models**): one can modify the jump size distribution (Lévy measure) or the default intensity while preserving equivalence (see **Equivalence of Probability Measures**) of measures [18, 20]. For Lévy processes (see **Exponential Lévy Models**), the relative entropy term $H(\nu)$ is computable in terms of the Lévy measure ν [21]. The calibration problem then takes the following form:

Problem 2 *Given a prior Lévy process with law $\mathbb{Q}_0$ and characteristics (σ_0, ν_0) , find a Lévy measure ν which minimizes*

$$J_\alpha(\nu) = \alpha H(\nu) + \sum_{i=1}^N w_i (C_0^\nu(T_i, K_i) - C_0(T_i, K_i))^2 \quad (16)$$

This regularized formulation has the advantage that its solution exhibits continuous dependence on market prices and with respect to the choice of the prior model [21, 22].

Simpler regularization methods can be used in settings where prices are computed using analytical transform methods. Belomestny & Reiss [8] propose a spectral regularization method for calibrating exponential-Lévy models. Aspremont [3] formulates the calibration of LIBOR market models (Example 3) as semidefinite programming problems under constraints.

Different regularization terms select *different* solutions: Tikhonov regularization approximates the least-squares solution with smallest norm [27] while entropy-based regularization selects the minimum-entropy least-squares solution [22].

Entropy Minimization Under Calibration Constraints

An alternative approach to regularization is to select a pricing model $\mathbb{Q}$ by minimizing the relative entropy (see **Entropy-based Estimation**) of the probability measure $\mathbb{Q}$ with respect to a prior, under calibration constraints

$$\inf_{\mathbb{Q} \sim \mathbb{P}} H(\mathbb{Q} | \mathbb{P}) \quad \text{under} \quad C_i = E^{\mathbb{Q}}[H_i] \quad \text{for } i \in I \quad (17)$$

Relative entropy being strictly convex, any solution of equation (17) is unique and can be computed in a stable manner using Lagrange multiplier (dual) methods [24] (see **Convex Duality**).

Application of these ideas to a set of scenarios leads to the *weighted Monte Carlo algorithm* (see **Weighted Monte Carlo**) [6]: one first simulates N sample paths $\Omega_N = \{\omega_1, \dots, \omega_N\}$ from a *prior* model $\mathbb{P}$ and then solves the above problem (AV) using as prior the uniform distribution on Ω_N . The idea is to weight the paths in order to verify the calibration constraints. The weights $(\mathbb{Q}_N(\omega_i), i = 1..N)$ are constructed by minimizing relative entropy under calibration constraints

$$\inf_{\mathbb{Q}_N \in \mathcal{P}(\Omega_N)} \sum_{i=1}^N \mathbb{Q}_N(\omega_i) \ln \frac{\mathbb{Q}_N(\omega_i)}{\mathbb{P}_N(\omega_i)} \quad \text{under}$$

$$\sum_{i=1}^N \mathbb{Q}_N(\omega_i) G_j(\omega_i) = C_j \quad (18)$$

This constrained optimization problem is solved by duality [6, 24]: the dual has an explicit solution, in the form of a Gibbs–Boltzmann measure [4, 6] (see **Entropy-based Estimation**). A (discounted) payoff X is then priced using the same set of simulated paths *via*

$$\begin{aligned} E^{\mathbb{Q}_N}[X] &= \sum_{i=1}^N \mathbb{Q}_N(\omega_i) X(\omega_i) \\ &= \frac{1}{N} \sum_{i=1}^N \frac{\mathbb{Q}_N(\omega_i)}{\mathbb{P}_N(\omega_i)} X(\omega_i) \end{aligned} \quad (19)$$

The benchmark payoffs (calibration instruments) play the role of *biased* control variates, leading to variance reduction [29]:

$$E^{\mathbb{Q}_N}[X] = E^{\mathbb{Q}_N} \left[X - \sum_{i=1}^I \alpha_i H_i \right] + \sum_{i=1}^I \alpha_i C_i \quad (20)$$

This method yields as a by-product, a static hedge portfolio α_i^* , which minimizes the variance in equation (20) [3, 6, 17].

A drawback is that the martingale property is lost in this process since it would correspond to an infinite number of constraints. As a result, derivative prices computed with the weighted Monte Carlo algorithm may fail to verify arbitrage relations across maturities (e.g. calendar spread relations), especially when applied to forward-starting contracts.

These arbitrage constraints can be restored by representing $\mathbb{Q}$ as a random mixture of martingales the law of random mixture being chosen *via* relative entropy minimization under calibration constraints [17]. This results in an arbitrage-free version of the weighted Monte Carlo approach, which is applied to recovering covariance matrices implied by index options in [15].

Stochastic Control Methods

In certain continuous-time models, the relative entropy minimization approach can be mapped, *via* a duality argument, into a stochastic control problem, which can then be solved using dynamic

programming techniques. Consider a Markovian model where the state variable S_t (asset price, interest rate,...) follows a stochastic differential equation

$$\begin{aligned} dX_t &= \mu_\theta(t) dt + \sigma_\theta(t, S_t) dW_t \\ &\quad + \int \gamma_\theta(t, X_{t-}) \mu(dt dz) \end{aligned} \quad (21)$$

where W is a Wiener process and μ a compensated Poisson random measure with intensity $\nu_\theta(dz) \lambda_\theta(t) dt$. The coefficients of the model are parameterized by some parameter $\theta \in E$; in a non-parametric setting, θ is just the coefficient itself and E is a functional space. Denote the law of the solution by $\mathbb{Q}^\theta$. Consider now the case where the calibration criterion $J(\cdot)$ can be expressed as an expected value $J(\theta) = E^\theta[\int_0^T \phi(X_t) dt]$ with a strictly convex function $\phi(\cdot)$. A classical approach to solve the calibration problem

$$\inf_{\theta \in E} J(\theta), \quad \text{under} \quad E^\theta[H_i] = C_i \quad (22)$$

is to introduce the *Lagrangian* functional

$$\begin{aligned} \mathcal{L}(\theta, \lambda) &= J(\theta) - \sum_{i \in I} \lambda_i (E^\theta[H_i] - C_i) \\ &= E^\theta \left[\int_0^T \phi(X_t) dt - \sum_{i \in I} \lambda_i (H_i - C_i) \right] \end{aligned} \quad (23)$$

where λ_i is the Lagrange multiplier associated to the calibration constraint for payoff H_i . The *dual* problem associated to the constrained minimization problem (22) is given by

$$\begin{aligned} \inf_{\theta \in E} \mathcal{L}(\theta, \lambda) &= \inf_{\theta \in E} E^\theta \int_0^T \phi(X_t) dt \\ &\quad - \underbrace{\sum_{i \in I} \lambda_i (H_i - C_i)}_{\Phi} \end{aligned} \quad (24)$$

It can be viewed as a *stochastic control problem* (see **Stochastic Control**) with running cost $\phi(t, X_t)$ and *terminal cost* Φ .

This original formulation of the calibration problem was first presented by Avellaneda *et al.* [7] in the

context of diffusion model with unknown volatility

$$dS_t = S_t \sigma(t, S_t) dW_t \quad (25)$$

The calibration criterion in [7] was chosen to be

$$J(\sigma) = E^\sigma \left[\int_0^T dt \eta(\sigma^2(t, X_t^\sigma)) \right] \quad (26)$$

where η is a strictly convex function. Duality between (22) and (24) is not obvious in this case since the Lagrangian is not convex with respect to its argument [31]. The stochastic control approach can also be applied in the context of model calibration by relative entropy minimization for classes of models where absolute continuity is preserved under a change of parameters, such as models with jumps. Cont and Minca [18] use this approach for retrieving the default rate in a portfolio from CDO tranche spreads indexed on the portfolio.

Stochastic Algorithms

Objective functions used in calibration (with the exception of entropy-based methods) are typically nonconvex, even after regularization, leading to multiple minima and lack of convergence in gradient-based methods. Stochastic algorithms known as evolutionary algorithms, which contain simulated annealing as a special case, have been widely used for global nonconvex optimization and are natural candidate for solving such problems [9].

Suppose, for instance, we want to minimize the pricing error

$$J_0(\theta) = \sum_{i=1}^I w_i |C_i^\theta - C_i|, \quad \theta \in E \quad (27)$$

where C_i^θ are model prices and C_i are observed (transaction or mid-market) prices for the benchmark options. Now define the *a priori* error level δ as

$$\delta = \sum_{i=1}^I w_i |C_i^{\text{bid}} - C_i^{\text{ask}}| \quad (28)$$

Given the uncertainty on option values due to bid–ask spreads, one cannot meaningfully distinguish a “perfect” fit $J_0(\theta) = 0$ from any other fit with $J_0(\theta) \leq \delta$. Therefore, all parameter values in the level set $G_\delta = \{\theta \in E, J_0(\theta) \leq \delta\}$ correspond to

models that are compatible with the market data $(C_i^{\text{bid}}, C_i^{\text{ask}})_{i=1..I}$. An evolutionary algorithm simulates an inhomogeneous Markov chain $(X_n)_{n \geq 1}$ in E^N which undergoes mutation–selection cycles [9] designed such that as the number of iterations n grows, the components $(\theta_1^N, \dots, \theta_n^N)$ of X_n converge to the G_δ , yielding a population of points (θ_k) which converges to a sample of model parameters compatible with the market data $(C_i^{\text{bid}}, C_i^{\text{ask}})_{i=1..I}$ in the sense that $J_0(\theta_k) \leq \delta$. We thus obtain a population of N model parameters calibrated to market data, which can be different especially if the initial problem has multiple solutions.

Figure 4 shows a sample of local volatility functions obtained using this approach [9]. These examples illustrate that precise reconstruction of local volatility from call option prices is at best illusory; the parameter uncertainty is too important to be ignored, especially for short maturities where it does not affect the prices very much; short-term volatility hovers anywhere between 15% and 30%. These observations cast a doubt on the volatility content of very short-term options in terms of volatility and questions whether one can solely rely on short maturity asymptotics (see **SABR Model**) in model calibration.

Parameter Uncertainty

Model calibration is usually the first step in a procedure whose ultimate purpose is the pricing and hedging of (exotic) options. Once the model parameter θ is calibrated to market prices, it is used to compute a model-dependent quantity $f(\theta)$ —price of an exotic option or a hedge ratio—using a numerical procedure. Given the ill-posedness of the calibration problem and the resulting uncertainty on the solution θ , one question is the impact of this uncertainty on such model-dependent quantities. This aspect is often neglected in practice and many users of pricing models view the calibrated parameter as fixed, equating calibration with a curve-fitting exercise.

Particle methods yield, as a by-product, a way to analyze model uncertainty. While calibration algorithms based on deterministic optimization yield a *point estimate* for model parameters, particle methods yield a *population* $\mathcal{Q} = \{\mathbb{Q}_{\theta_1}, \dots, \mathbb{Q}_{\theta_k}\}$ of pricing models, all of which price the benchmark options with equivalent precision $E^{\mathbb{Q}}(H_i) \in [C_i^{\text{bid}}, C_i^{\text{ask}}]$. The

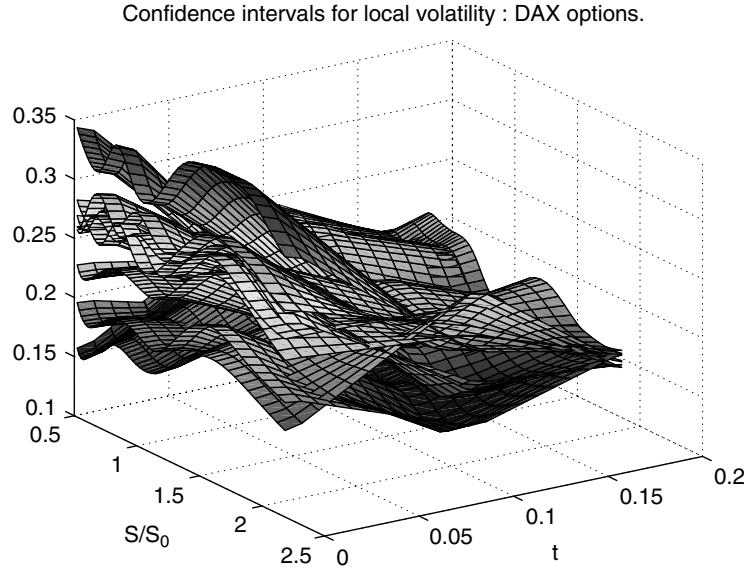

Figure 4 A sample of local volatility surfaces calibrated to DAX options

heterogeneity of this population reflects the uncertainty in model parameters, which are left undetermined by the benchmark options. This idea can be exploited to produce a quantitative measure of model uncertainty compatible with observed market prices of benchmark instruments [14], by considering the interval of prices

$$\left[\inf_{Q \in \mathcal{Q}} E^Q[X], \sup_{Q \in \mathcal{Q}} E^Q[X] \right] \quad (29)$$

for a payoff X in the various calibrated models. Another approach is to calibrate several different models to the same data and compare the value of the exotic option across models [14, 32]. Model uncertainty in derivative pricing is further discussed in [14].

Relation with Pricing and Hedging

Calibrating a model to market prices simply ensures that model prices of benchmark instruments reflect current “mark-to-market” values. It also ensures that the cost of a static hedge (see **Static Hedging**) using these benchmark instruments is correctly reflected in model prices: if a payoff H can be statically hedged

with a portfolio containing α_i units of benchmark instrument H_i ,

$$H = \alpha_0 + \sum_{i \in I} \alpha_i H_i \quad (30)$$

the cost $\alpha_0 + \sum \alpha_i C_i$ of setting up the hedge is automatically equal to the model price $E^Q[H]$.

Calibration does not entail that prices, hedge ratios, or risk parameters generated by the model are “correct” in any sense. This requires a correct model specification with realistic dynamics for risk factors. Indeed, many different models may calibrate the same prices of, say, a set of call options but lead to very different prices of hedge ratios for exotics [14, 32]. For example, any equity volatility smile can be reproduced by a one-factor diffusion model (see Example 1) *via* an appropriate specification of the local volatility surface, but there is ample evidence that volatility itself should be modeled as a risk factor (see **Stochastic Volatility Models**) and a one-factor diffusion may lead to an underestimation of volatility risk and unrealistic dynamics [30].

However, a model that is *not calibrated* to market prices of liquidly traded derivatives is typically not easy to use. For example, even if a payoff can be statically hedged with traded derivatives using an initial capital V_0 , the model price will not be

equal to V_0 . Thus, model prices will, in general, be inconsistent with hedging costs if the model is not calibrated. Thus, calibration seems a necessary but not sufficient condition for choosing a model for pricing and hedging.

Dupire Equation

The Dupire equation is a partial differential equation (PDE) that links the contemporaneous prices of European call options of all strikes and maturities to the instantaneous volatility of the price process, assumed to be a function of price and time only. The main application of the equation is to compute (i.e., invert) local volatilities from market option prices to build a local volatility model, which many major banks currently use for option pricing.

If we assume that the price process S follows the stochastic differential equation,

$$\frac{dS_t}{S_t} = \mu_t dt + \sigma(S_t, t) dW_t \quad (1)$$

Then if $C(S, t, K, T)$ denotes the price at time t for an underlying price of S of the European call of strike K and maturity T that pays $(S_T - K)^+$ at time T , C satisfies, for a fixed (S, t) .

For a fixed (S, t) , the Dupire equation,

$$\frac{\partial C}{\partial T} = \frac{\sigma^2(K, T)}{2} K^2 \frac{\partial^2 C}{\partial K^2} - (r - q)K \frac{\partial C}{\partial K} - qC \quad (2)$$

where r is the interest rate, q is the dividend yield (or foreign interest rate in the case of a currency), and the boundary conditions are given by $C(S, t, K, T) = (S - K)^+$.

This can be established by a variety of methods, including double integration of the Fokker–Plank equation, Tanaka formula, and replication strategy. It is commonly named the *forward equation*, as it indicates how current call prices are affected by an increase in maturity. This can be contrasted with the classical backward Black–Scholes PDE that applies to a European call of fixed strike and maturity:

$$\frac{\partial C}{\partial t} = -\frac{\sigma^2(S, t)}{2} S^2 \frac{\partial^2 C}{\partial S^2} - (r - q)S \frac{\partial C}{\partial S} + rC \quad (3)$$

Interpretation

The backward Black–Scholes equation applies to a given call option and relates its time derivative to its convexity. It is a heat equation that defines the price at a given time as the discounted expectation of the

call price an instant later and the Jensen convexity bias θ depends on.

According to the forward Dupire equation, the cost of extending the maturity of a call depends on the probability of being at the strike at maturity and on the level of volatility there. It can be seen as relating the price of a calendar spread to the price of a butterfly spread.

Uses

The equation

$$\frac{\partial C}{\partial T} = \frac{\sigma^2(K, T)}{2} K^2 \frac{\partial^2 C}{\partial K^2} - (r - q)K \frac{\partial C}{\partial K} - qC \quad (4)$$

can be used in the following two ways:

1. If the local volatility $\sigma(S, t)$ is known, the PDE can be used to compute the price today of all call options in a single sweep, starting from the boundary condition $C(S, t, K, T) = (S - K)^+$. In contrast, the Black–Scholes backward equation requires one PDE for each strike and maturity.

In the case of calibrating a parametric form of $\sigma(S, t)$ to a set of market option prices, one needs to compute the model price of all these options and the forward equation can accelerate the computation to a factor 100.

2. If the call prices are known today, one can compute their derivatives and extract the local volatility by the following formula:

$$\sigma(K, T) = \sqrt{\frac{\frac{\partial C}{\partial T} + (r - q)K \frac{\partial C}{\partial K} + qC}{K^2 \frac{\partial^2 C}{\partial K^2}}} \quad (5)$$

This equation is also known as the *stripping formula*.

Starting from a finite set of listed option prices, a good interpolation in strike and maturities provides a continuum of option prices and we can apply the stripping formula to get the local volatilities. Here is an example on the NASDAQ, where interpolation/extrapolation is performed by first fitting a stochastic volatility Heston model to the listed option

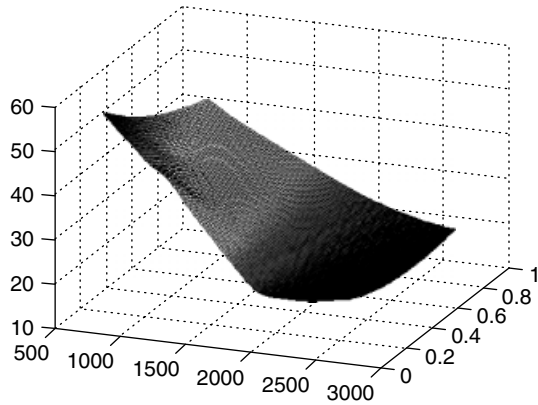

Figure 1 Implied volatility surface of the NASDAQ

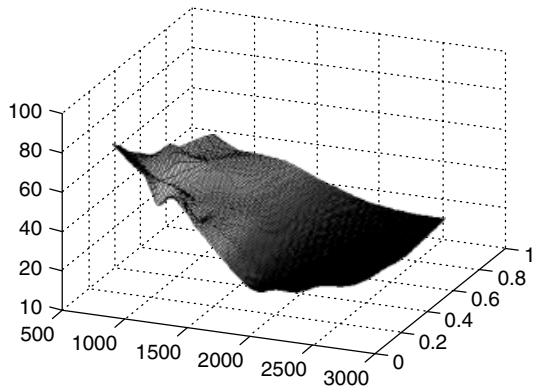

Figure 2 Local volatility surface of the NASDAQ

prices and then applying a nonparametric interpolation to the residuals.

Figure 1 displays the implied volatility surface of NASDAQ, and the associated local volatility surface is shown in Figure 2.

Once the local volatilities are obtained, one can price nonvanilla instruments with this calibrated local volatility model (Figure 3).

Properly accounting for the market skew can have a massive impact on the price of exotics. For instance, an up-and-out call option has a positive gamma close to the strike and a negative gamma close to the barrier. A typical equity negative skew corresponds to high local volatilities close to the strike, which adds value to the option due to the positive gamma and low local volatilities close to the barrier, which is also beneficial to the option holder as the gamma is negative there.

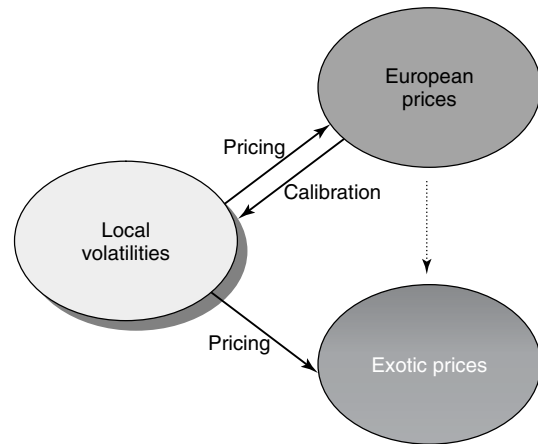

Figure 3 Local volatilities give a way to price exotic options from European options

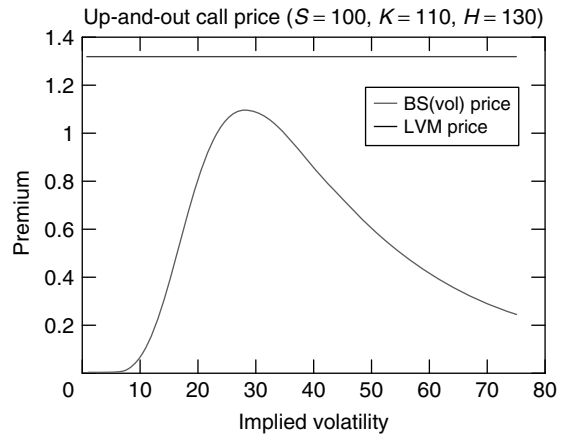

Figure 4 Comparison of an up-and-out call option in the local volatility model and in Black–Scholes model with various volatilities

The combined effect is that the up-and-out call local volatility price may exceed the price of any Black–Scholes model, irrespective of the volatility input used (Figure 4).

Local Volatilities as Forward Volatilities

The most common interpretation of local volatility is that it is the instantaneous volatility as a certain function of spot price and time that fits market prices. It gives the simplest model calibrated to the market but assumes a deterministic behavior of instantaneous

volatility, a fact crudely belied by the market. As such, the local volatility model is an important step away from the Black–Scholes model, which assumes constant volatility, though it may not necessarily provide the most realistic dynamics for the price.

The second interpretation, as forward volatilities, is far more patent. More precisely, the square of the local volatility, the local variance, is the instantaneous forward variance conditional to the spot price being equal to the strike at maturity:

$$\sigma^2(K, T) = E[\sigma_t^2 | S_T = K] \quad (6)$$

This means that in a frictionless market where all strikes and maturities are available, it is possible to combine options into a portfolio that will lock these forward values. In other words, the local variance is not only a function calibrated to the market that allows to retrieve market prices but it is also the fair value of the fixed leg of a swap with a floating leg equal to the instantaneous variance at time T , with the exchange taking place only if the price at maturity is K . It can be seen as an infinitesimal forward corridor variance swap.

By way of consequence, if one disagrees with the forward variance, one can put on a trade (in essence calendar spread against butterfly spread) aligned with this view. Conversely, if one has no view but finds someone who disagrees with the forward view and accepts to trade at a different level, one can lock the difference.

Another important consequence of this relationship is that a stochastic volatility model (with no jumps) will be calibrated to the market if and only if the conditional expectation of the instantaneous variance is the local variance computed from the market prices. In essence, it means that a calibrated stochastic volatility model is a noisy version of the local volatility model, which is centered on it. In this sense, the local volatility model plays a central role.

Beyond the fit to the current market prices, these results have dynamic consequences. For example, they imply that in the absence of jumps, the at-the-money (ATM) implied volatility converges to the instantaneous volatility when the maturity shrinks to 0. The same relation indicates that for any stochastic volatility model calibrated to the market, the average level of the short-term ATM implied variance at any

time in the future, conditioned on a price level, has to equal the local variance, which is dictated by the current market prices of calls and puts. Fitting to today's market strongly constrains future dynamics and, for instance, the backbone, defined as the behavior of the at-the-money volatility as a function of the underlying price, cannot be independently specified.

Once we get a perfect fit of option prices using equation (5), we can perturb the volatility surface, recalibrate, and conduct a sensitivity analysis. This provides a decomposition of the volatility risk of any structured product (or portfolio of) across strikes and maturities, because seeing the price as a function of the whole volatility surface provides through perturbation analysis the sensitivity to all volatilities.

Extensions

There are numerous extensions of the forward PDE, with stochastic rates and dividends, stochastic volatility, jumps, to the Greeks (sensitivities) and to other products than European options, such as barrier options, compound options, Asian options, and basket options. However, until now, there is no satisfactory counterpart for American options.

BRUNO DUPIRE

Implied Volatility Surface

The widespread practice of quoting option prices in terms of their Black–Scholes implied volatilities (IVs) in no way implies that market participants believe underlying returns to be lognormal. On the contrary, the variation of IVs across option strike and term to maturity, which is widely referred to as the *volatility surface*, can be substantial. In this article, we highlight some empirical observations that are most relevant for the construction and validation of realistic models of the volatility surface for equity indices.

The Shape of the Volatility Surface

Ever since the 1987 stock market crash, volatility surfaces for global indices have been characterized by the *volatility skew*: For a given expiration date, IVs increase as strike price decreases for strikes below the current stock price (spot) or current forward price. This tendency can be seen clearly in the S&P500 volatility surface shown in Figure 1. For short-dated expirations, the cross section of IVs as a function of strike is roughly V-shaped, but has a rounded vertex and is slightly tilted. Generally, this V-shape softens and becomes flatter for longer dated expirations, but the vertex itself may rise or fall depending on whether the term structure (TS) of (ATM) At-the-money volatility is upward or downward sloping.

Conventional explanations for the volatility skew include the following:

- *The leverage effect*: Stocks tend to be more volatile at lower prices than at higher prices.
- Volatility moves and spot moves are anticorrelated.
- Big jumps in spot tend to be downward rather than upward.
- *The risk of default*: There is a nonzero probability for the price of a stock to collapse if the issuer defaults.
- *Supply and demand*: Investors are net long of stock and so tend to be net buyers of downside puts and sellers of upside calls.

The volatility skew probably reflects all of these factors.

Conventional stochastic volatility (SV) models imply a relationship between the assumed dynamics of the instantaneous volatility and the volatility skew (see Chapter 8 of [8]). Empirically, volatility is well known to be roughly lognormally distributed [1, 4] and in this case, the derivative of IV with respect to log-strike in an SV model is approximately independent of volatility [8]. This motivates a simple measure of skew: For a given term to expiration, the “95–105” skew is simply the difference between the IVs at strikes of 95% and 105% of the forward price. Figure 2 shows the historical variation of this measure as a function of term to expiration as calculated from end-of-day SPX volatility surfaces generated from listed options prices between January 2, 2001 to February 6, 2009. To fairly compare across different dates and over all volatility levels, all volatilities for a given date are scaled uniformly to ensure that the one-year at-the-money-forward (ATMF) volatility equals its historical median value over this period (18.80%). The skews for all listed expirations are binned by their term to expiration; the median value for each five-day bin is plotted along with fits to both $1/\sqrt{T}$ and the best-fitting power-law dependence on T .

The important conclusion to draw here is that the TS of skew is approximately consistent with square-root (or at least power-law) decay. Moreover, this rough relationship continues to hold for longer expirations that are typically traded (OTC) Over-the-counter.

Significantly, this empirically observed TS of the volatility skew is inconsistent with the $1/T$ dependence for longer expirations typical of popular one-factor SV models (see Chapter 7 of [8] for example): Jumps affect only short-term volatility skews, so adding jumps does not resolve this disagreement between theory and observation. Introducing more volatility factors with different timescales [3] does help but does not entirely eliminate the problem. Market models of IV (*see Implied Volatility: Market Models*) obviously fit the TS of skew by construction, but such models are, in general, time inhomogeneous and, in any case, have not so far proven to be tractable. In summary, fitting the TS of skew remains an important and elusive benchmark by which to gauge models of the volatility surface.

Volatility Surface Dynamics

Volatility surfaces cannot have arbitrary shape; they are constrained by no-arbitrage conditions (such as the convexity of price with respect to strike). In practice, these restrictions are not onerous and generally are met provided there are no large gradients anywhere on the surface. This observation, together with the fact that index options in most markets trade actively over a wide range of strikes and expiration dates, might lead one to expect the dynamics of the volatility surface to be quite complicated. On the contrary, several principal component analysis (PCA) studies have found that an overwhelming fraction of the total daily variation in volatility surfaces is explained by just a few factors, typically three.

Table 1 makes clear that a level mode, one where the entire volatility surface shifts upward or downward in tandem, accounts for the vast majority of variation; this result holds across different markets, historical periods, sampling frequencies, and statistical methodologies. Although the details vary, generally this mode is not quite flat; short-term volatilities tend to move more than longer ones, as evidenced by the slightly upward tilt in Figure 3(a).

In most of the studies, a TS mode is the next most important mode: Here, short-term volatilities move in the opposite direction from longer term ones, with little variation across strikes. In the Merrill Lynch data, which are sampled at 30, 91, 182, 273, 365, and 547 days to expiration, the pivot point is close to the 91-day term (see Figure 3(b)). In all studies where TS is the second most important mode, the third mode is always a skew mode: one where strikes below the spot (or forward) move in the opposite direction

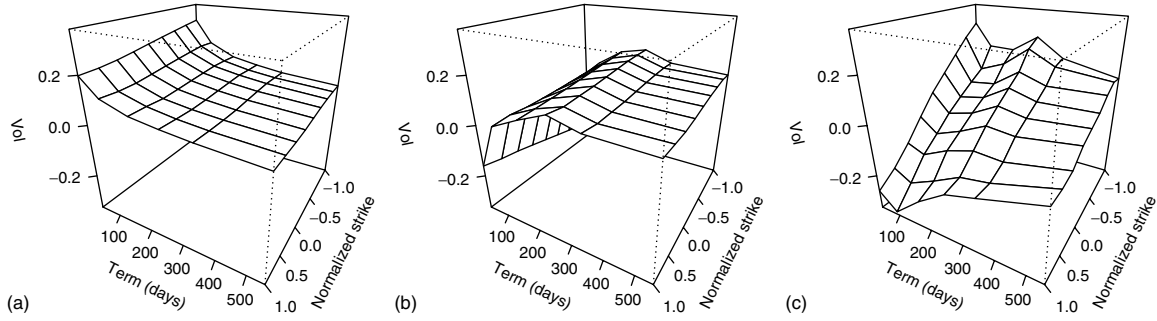

Figure 3 PCA modes for Merrill Lynch S&P500 volatility surfaces: (a) level; (b) term structure; and (c) skew

from those above and where the overall magnitude is attenuated as term increases (Figure 3c).

It is also worth noting that the two studies [5, 9] that looked at two different markets during comparable periods found very similar patterns of variation; the modes and their relative importance were very similar, suggesting strong global correlation across index volatility markets.

In the study by Cont and da Fonseca [5], a TS mode does not figure in the top three modes; instead a skew mode and another strike-related mode related to the curvature emerge as number two and three. This likely reflects the atypically low variation in TS over the historical sample period and is not due to any methodological differences with the other studies. As in the other studies, the patterns of variation were very similar across markets (S&P500 and FTSE100).

Changes in Spot and Volatility are Negatively Correlated

Perhaps the sturdiest empirical observation of all is simply that changes in spot and changes in volatility (by pretty much any measure) are negatively and strongly correlated. From the results that we have surveyed here, this can be inferred from the high R^2 obtained in the regressions of daily ATMF volatility changes shown in Table 1, as well as directly from the correlations between spot return and PCA modes shown in Table 2. It is striking that the correlation between the level mode and spot return is consistently high across studies, ranging from -0.66 to -0.87 . Correlation between the spot return and the other modes is significantly weaker and less stable.

This high correlation between spot returns and changes in volatility persists even in the most extreme

Table 2 Historical estimates of β_T

T	β_T standard error	R^2
30	1.55 (0.02)	0.774
91	1.50 (0.02)	0.825
182	1.48 (0.02)	0.818
365	1.49 (0.02)	0.791

market conditions. For example, during the turbulent period following the collapse of Lehman Brothers in September 2008, which was characterized by both high volatility and high volatility of volatility, spot-volatility correlation remained at historically high levels: -0.92 for daily changes between September 15, 2008 and end December 31, 2008. On the other hand, the skew mode, which is essentially uncorrelated with spot return in the full historical period (see Table 1), did exhibit stronger correlation in this period (-0.55), while the TS mode did not. These observations underscore the robustness of the level-spot correlation as well as the time-varying nature of correlations between spot returns and the other modes of fluctuation of the volatility surface.

Other studies have also commented on the robustness of the spot-volatility correlation. For example, using a maximum-likelihood technique, Aït-Sahalia and Kimmel [1] carefully estimated the parameters of The Heston, CEV, and GARCH models from S&P500 and VIX data between January 2, 1990 and September 30, 2003; the correlation between spot and volatility changes varied little between these models and various estimation techniques, and all estimates were around -0.76 for the period studied.

A related question that was studied by Bouchaud *et al.* [4] is whether spot changes drive *realized*

volatility changes or *vice versa*. By computing the correlations of leading and lagging returns and squared-returns, they find that for both stocks and stock indices, price changes lead to volatility changes. In particular, there is no volatility feedback effect, whereby changes in volatility affect future stock prices. Moreover, unlike the decay of the IV correlation function itself, which is power-law with an exponent of around 0.3 for SPX, the decay of the spot-volatility correlation function is exponential with a short half-life of a few days. Supposing the general level of IV (the variation of which accounts for most of the variation of the volatility surface) to be highly correlated with realized volatility, these results also apply to the dynamics of the IV surface. Under diffusion assumptions, the relationship between implied and realized volatility is even more direct: Instantaneous volatility is given by the IV of the ATM option with zero time to expiration.

Skew Relates Statics to Dynamics

Volatility changes are related to changes in spot: as mentioned earlier, volatility and spot tend to move in opposite directions, and large moves in volatility tend to follow large moves in the spot.

It is reasonable to expect skew to play a role in relating the magnitudes of these changes. For example, if all the variation in ATM volatility were explained simply by movement along a surface that is unchanged as a function of strike when spot changes, then we would expect

$$\Delta\sigma_{\text{ATMF}}(T) = \beta_T \frac{d\sigma}{d(\log K)} \frac{\Delta S}{S} \quad (1)$$

with $\beta_T = 1$ for all terms to expiration (T).

The empirical estimates of β_T shown in Table 2 are based on the daily changes in S&P500 ATM volatility from January 2, 2001 to February 6, 2009 (volatilities tied to fixed expiration dates are interpolated to arrive at volatilities for a fixed number of days to expiration.) Two important conclusions may be drawn: (i) β is not 1.0, rather it is closer to 1.5 and (ii) remarkably β_T does not change appreciably by expiration. In other words, although the volatility skew systematically underestimates the daily change in volatility, it does so by roughly the same factor for all maturities. It is also worth noting that the hypothesis $\beta_T = 1$ would be rejected even if the

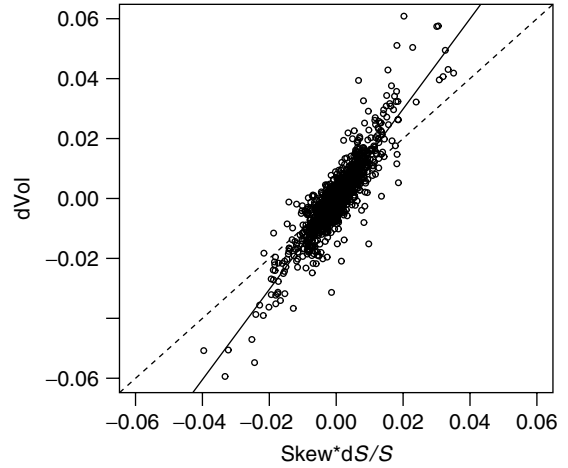

Figure 4 Regression of 91-day volatility changes *versus* spot returns. A zero-intercept least squares fit to model (1) leads to $\beta_{91} = 1.50$ (solid lines). The $\beta = 1$ (“sticky-strike”) prediction (dashed line) clearly does not fit

regression were restricted to spot returns of smaller magnitude, as suggested visually by the scatterplots of Figure 4.

Although empirical relationships between changes in ATM volatility and changes in spot are clearly relevant to volatility trading and risk management, the magnitude of β_T itself has direct implications for volatility modeling as well. In both local and SV models, $\beta_T \rightarrow 2$ in the short-expiration limit. Under SV, β_T is typically a decreasing function of T , whereas under the local volatility assumption where the local volatility surface is fixed with respect to a given level of the underlying, β_T is typically an increasing function of T .

Market participants often adopt a phenomenological approach and characterize surface dynamics as following one of these rules: “sticky strike,” “sticky delta,” or “local volatility”; each rule has an associated value of β_T . Under the sticky-strike assumption, $\beta_T = 1$ and the volatility surface is fixed by strike; under the sticky-delta assumption, $\beta_T = 0$ and the volatility surface is a fixed function of K/S ; and under the local volatility assumption, as mentioned earlier, $\beta_T = 2$ for short expirations.

Neither “sticky-strike” nor “sticky-delta” rules imply reasonable dynamics [2]: In a sticky-delta model, the log of the spot has independent increments and the only arbitrage-free sticky-strike model is Black–Scholes (where there is no smile).

Although the estimates of β_T in Table 2 are all around 1.5, consistent with SV, this does not exclude the possibility that there may be periods where the β_T may substantially depart from these average values. Derman [7] identified seven distinct regimes for S&P500 daily volatility changes between September 1997 and November 1998, finding evidence for all three of the alternatives listed above. A subsequent study [6] looked at S&P500 monthly data between June 1998 and April 2002 (47 points) and found that for that period, the data were much more consistent with the sticky-delta rule than with the sticky-strike rule.

Moment Explosions

Let $(S_t, V_t)_{t \geq 0}$ be a Markov process, representing a (not necessarily purely continuous) stochastic volatility model. $(S_t)_{t \geq 0}$ is the (discounted) price of a traded asset, such as a stock, and $(V_t)_{t \geq 0}$ represents a latent factor, such as stochastic volatility, stochastic variance, or the stochastic arrival rate of jumps. A **moment explosion** takes place, if the moment $\mathbb{E}[S_t^u]$ of some given order $u \in \mathbb{R}$ becomes infinite (“explodes”) after some finite time $T_*(u)$. This time is called the *time of moment explosion* and formally defined by

$$T_*(u) = \sup \{t \geq 0 : \mathbb{E}[S_t^u] < \infty\} \quad (1)$$

We say that no moment explosion takes place for some given order u , if $T_*(u) = \infty$.

Moment explosions can be considered both under the physical and the pricing measure, with most applications belonging to the latter. If $(S_t)_{t \geq 0}$ is a martingale, then Jensen’s inequality implies that moment explosions can only occur for moments of order $u \in \mathbb{R} \setminus [0, 1]$.

Conceptually, the notion of a moment explosion has to be distinguished from an explosion of the process itself, which refers to the situation that the process $(S_t)_{t \geq 0}$, not one of its moments, becomes infinite with some positive probability.

Applications

In *equity* and *foreign exchange* models, where $(S_t)_{t \geq 0}$ represents a stock price or an exchange rate, moment explosions are closely related to the shape of the implied volatility surface, and can be used to obtain approximations for the implied volatility of deep in-the-money and out-of-the-money options (see **Implied Volatility: Large Strike Asymptotics**, and the references therein). According to [5, 14], the asymptotic shape of the implied volatility surface for some fixed maturity T is determined by the smallest and largest moment of S_T that is still finite. These critical moments $u_-(T)$ and $u_+(T)$ are the piecewise inverse functions^a of the moment explosion time. Often the explosion time is easier to calculate, so a feasible approach is to first calculate explosion times, and then to invert to obtain the critical moments. Let

us note that finite critical moments of the underlying S_T correspond, in essence, to exponential tails of $\log(S_T)$. There is evidence that refined knowledge of how moment explosion occurs (or the asymptotic behavior of $u \mapsto \mathbb{E}[S_T^u]$ in the case of nonexplosion) can lead to refined results about implied volatility, see [6, 11] for some examples of stochastic alpha beta rho (SABR) type.

In *fixed-income* markets $(S_t)_{t \geq 0}$ might represent a forward LIBOR rate or swap rate. Andersen and Piterbarg [2] give examples of derivatives with super-linear payoff, whose pricing involves calculation of the second moment of S_T . It is clear that an explosion of the second moment will lead to infinite prices of such derivatives.

For *numerical procedures*, such as discretization schemes for stochastic differential equations (SDEs), error estimates that depend on higher order moments of the approximated process may break down if moment explosions occur [1]. Moment explosions may also lead to *infinite expected utility* in utility maximization problems [12].

Moment Explosions in the Black–Scholes and Exponential Lévy Models

In the Black–Scholes model, moment explosions never occur, since moments of all orders exist for all times. In an exponential Lévy model (see **Exponential Lévy Models**), S_t is given by $S_t = S_0 \exp(X_t)$, where X_t is a Lévy process. It holds that $\mathbb{E}[S_t^u] = e^{t\kappa(u)}$, where $\kappa(u)$ is the cumulant-generating function (cgf) of X_1 . Thus in an exponential Lévy model, the time of moment explosion is given by

$$T_*(u) = \begin{cases} +\infty & \kappa(u) < \infty \\ 0 & \kappa(u) = \infty \end{cases} \quad (2)$$

Let us remark that, from Theorem 25.3 in [16], $\kappa(u) < \infty$ iff $\int e^{ux} 1_{|x|>1} \nu(dx) < \infty$ where $\nu(dx)$ denotes the Lévy measure of X .

Moment Explosions in the Heston Model

The situation becomes more interesting in a stochastic volatility model, like the Heston model (see **Heston**

Model):

$$\begin{aligned} dS_t &= S_t \sqrt{V_t} dW_t^1, \quad S_0 = s \\ dV_t &= -\lambda(V_t - \theta) dt + \eta \sqrt{V_t} dW_t^2, \\ V_0 &= v, \quad \langle dW_t^1, dW_t^2 \rangle = \rho dt \end{aligned} \quad (3)$$

We now discuss how to compute the moments of S_t (equivalently, the moment-generating function of $X_t = \log S_t/S_0$). The joint process $(X_t, V_t)_{t \geq 0}$ is a (time-homogenous) diffusion, started at $(0, v)$, with generator

$$\begin{aligned} \mathcal{L} &= \frac{v}{2} \left(\frac{\partial^2}{\partial x^2} - \frac{\partial}{\partial x} \right) + \frac{v}{2} \eta^2 \frac{\partial^2}{\partial v^2} \\ &\quad + \lambda(\theta - v) \frac{\partial}{\partial v} + \rho \eta v \frac{\partial^2}{\partial x \partial v} \end{aligned} \quad (4)$$

Note that $(X_t, V_t)_{t \geq 0}$ has affine structure in the sense that the coefficients of $\mathcal{L}$ are affine linear in the state variables.^b

Now

$$\begin{aligned} \mathbb{E} [e^{uX_t} | X_t = x, V_t = v] \\ = e^{ux} \mathbb{E} [e^{uX_t} | X_t = 0, V_t = v] \end{aligned} \quad (5)$$

$$T_*^{\text{Heston}}(u) = \begin{cases} +\infty & \text{if } \Delta(u) \geq 0, \chi(u) < 0 \\ \frac{1}{\sqrt{\Delta(u)}} \log \left(\frac{\chi(u) + \sqrt{\Delta(u)}}{\chi(u) - \sqrt{\Delta(u)}} \right) & \text{if } \Delta(u) \geq 0, \chi(u) > 0 \\ \frac{2}{\sqrt{-\Delta(u)}} \left(\arctan \frac{\sqrt{-\Delta(u)}}{\chi(u)} + \pi \mathbf{1}_{\{\chi(u) < 0\}} \right) & \text{if } \Delta(u) < 0 \end{cases} \quad (10)$$

satisfies, as a function of (t, x, v) , the backward equation $\partial_t + \mathcal{L} = 0$ with terminal data e^{ux} and after replacing $T - t$ with t we can rewrite this as an initial value problem. Indeed, setting $f = f(t, v; u) := \mathbb{E} [e^{uX_t} | X_0 = 0, V_0 = v]$, and noting that

$$\begin{aligned} \left(\frac{\partial^2}{\partial x^2} - \frac{\partial}{\partial x} \right) (e^{ux} f) &= e^{ux} (u^2 - u) f \text{ and} \\ \frac{\partial^2}{\partial x \partial v} (e^{ux} f) &= e^{ux} u \frac{\partial}{\partial v} f \end{aligned} \quad (6)$$

we see that f satisfies a parabolic partial differential equation (PDE).

$$\begin{aligned} \partial_t f &= \mathcal{A}f := \left(\frac{v}{2} \eta^2 \frac{\partial^2}{\partial v^2} + [\lambda(\theta - v) + \rho \eta u v] \frac{\partial}{\partial v} \right. \\ &\quad \left. + \frac{v}{2} (u^2 - u) \right) f \end{aligned} \quad (7)$$

with initial condition $f(0, \cdot; u) = 1$, in which (again) all coefficients depend in an affine-linear way on v . The exponentially affine ansatz $f(t, v; u) = \exp(\phi(t, u) + v\psi(t, u))$ then immediately reduces this PDE to a system of ordinary differential equations (ODEs) for $\phi(t, u)$ and $\psi(t, u)$:

$$\frac{\partial}{\partial t} \phi(t, u) = F(u, \psi(t, u)), \quad \phi(0, u) = 0 \quad (8)$$

$$\frac{\partial}{\partial t} \psi(t, u) = R(u, \psi(t, u)), \quad \psi(0, u) = 0 \quad (9)$$

where $F(u, w) = \lambda \theta w$ and $R(u, w) = \frac{w^2}{2} \eta^2 + (\rho \eta u - \lambda)w + \frac{1}{2}(u^2 - u)$. Equation (9) is a Riccati differential equation, whose solution blows up at finite time, corresponding to the moment explosion of S_t . Explicit calculations ([2], for instance) yield^c

where $\chi(u) = \rho \eta u - \lambda$ and $\Delta(u) = \chi(u)^2 - \eta^2(u^2 - u)$. A simple analysis of this condition (cf. [2]) then allows to express the no-explosion condition in terms of the correlation parameter ρ . With focus on positive moments of the underlying, $u \geq 1$, we have

$$T_*^{\text{Heston}}(u) = +\infty \iff \rho \leq -\sqrt{\frac{u-1}{u}} + \frac{\lambda}{\eta u} \quad (11)$$

Similar results for a class of nonaffine stochastic volatility models is discussed below.

Moment Explosions in Time-changed Exponential Lévy Models

Stochastic volatility can also be introduced in the sense of running time at a stochastic “business” clock. For instance, when $\rho = 0$ the (log-price) in the Heston model is a Brownian motion with drift, $W_t - t/2$, run at a Cox–Ingersoll–Ross^d (CIR) clock $\tau(t, \omega) = \tau_t$ where

$$dV_t = -\lambda(V_t - \theta) dt + \eta\sqrt{V_t} dW_t, \quad V_0 = v \quad (12)$$

$$d\tau_t = V dt, \quad \tau_0 = 0 \quad (13)$$

Since (V, τ) has an affine structure, there is a tractable moment-generating/characteristic function in the form

$$\begin{aligned} \mathbb{E}(\exp(u\tau_T)) &= \mathbb{E}\left(\exp\left(u \int_0^T V(t, \omega) dt\right)\right) \\ &= \exp(A(u, T) + vB(u, T)) \end{aligned} \quad (14)$$

where^e

$$\begin{aligned} A(u, t) &= \lambda^2 \theta t / \eta^2 - \frac{2\lambda\theta}{\eta^2} \log \\ &\quad \times \left[\sinh(\gamma t/2) \cdot \left(\coth(\gamma t/2) + \frac{\lambda}{\gamma} \right) \right] \end{aligned} \quad (15)$$

$$\begin{aligned} B(u, t) &= 2u/(\lambda + \gamma \coth(\gamma t/2)), \quad \gamma = \sqrt{\lambda^2 - 2\eta^2 u} \end{aligned} \quad (16)$$

We can replace $W_t - t/2$ above by a general Lévy process $L = L_t$ and run it again at some independent clock $\tau = \tau(t, \omega)$, assuming only knowledge of the cgf $\kappa_T(u) = \log \mathbb{E}(\exp(u\tau_T))$. If we also set $\kappa_L(u) = \log \mathbb{E}[\exp(uL_1)]$, a simple conditioning argument shows that the moment-generating function of L_τ is given by

$$\begin{aligned} M(u) &= \mathbb{E}[\mathbb{E}(e^{uL_\tau} | \tau)] = \mathbb{E}[e^{\kappa_L(u)\tau}] \\ &= \exp[\kappa_\tau(\kappa_L(u))] \end{aligned} \quad (17)$$

From here on, moment explosions of L_τ can be investigated analytically, provided κ_τ, κ_L are known in sufficiently explicit form. For some computations in this context, also with regard to the asymptotic behavior of the implied volatility smile, see [5].

Moment Explosions in Non-affine Diffusion Models

Both [2] and [15] study existence of u th moments, $u \geq 1$, for (not necessarily affine) diffusion models of the type

$$dS_t = V_t^\delta S_t^\beta dW_t^1, \quad S_0 = s \quad (18)$$

$$\begin{aligned} dV_t &= \eta V_t^\gamma dW_t^2 + b(V_t) dt, \\ V_0 &= v, \quad \langle dW_t^1, dW_t^2 \rangle = \rho dt \end{aligned} \quad (19)$$

where $\delta, \gamma > 0, \beta \in [0, 1]$ and the function $b(v)$ are subject to suitable conditions that ensure a unique solution. For instance, the SABR model falls into this class. Lions and Musiela [15] first show that if $\beta < 1$, no moment explosions occur. For $\beta = 1$, the same reasoning as in the Heston model shows that $f(t, v; u) = \mathbb{E}[(S_t/s)^u]$ satisfies the PDE^f

$$\begin{aligned} \frac{\partial}{\partial t} f &= \mathcal{A}f := \frac{v^{2\gamma}}{2} \eta^2 \frac{\partial^2 f}{\partial v^2} + [b(v) + \eta \rho u v^{\delta+\gamma}] \frac{\partial f}{\partial v} \\ &\quad + \frac{v^{2\delta}}{2} (u^2 - u) f \end{aligned} \quad (20)$$

with initial condition $f(0, \cdot; u) \equiv 1$. Note that the Heston model is recovered as the special case $\beta = 1, \delta = \gamma = 1/2, b(v) = -\lambda(v - \theta)$. Using the (exponentially-affine in v^q) ansatz $f(t, v; u) = \exp(\phi(t, u) + v^q \psi(t, u))$, with suitably chosen q, ϕ , and ψ , Lions and Musiela [15] construct supersolutions of equation (20), leading to lower bounds for $T_*(u)$, and then subsolutions, leading to matching upper bounds.^g We report the following results from [15]:

1. $\beta < 1$: no moment explosion occurs, that is, $\mathbb{E}(S_t^u) < \infty$ for all $u \geq 1, t \geq 0$;
2. $\beta = 1, \gamma + \delta < 1$: as in 1. no moment explosion occurs;
3. $\beta = 1, \gamma + \delta = 1$: If $\gamma = \delta = \frac{1}{2}$, then this choice of parameters yields a Heston-type model, where

the mean-reversion term $-\lambda(V_t - \theta)dt$ has been replaced by the more general $b(V_t)dt$. With λ replaced by $\lim_{v \rightarrow \infty} -b(v)/v$ the formula (10) remains valid. If $\gamma \neq \delta$, then the model can be transformed into a Heston-like model by the change of variables $\tilde{V}_t := V_t^{2\delta}$. The time of moment explosion $T_*(u)$ can be related to the expression in equation (10), by

$$T_*(u) = \frac{1}{2\delta} T_*^{\text{Heston}}(u) \quad (21)$$

4. $\beta = 1, \gamma + \delta > 1$: Let $b_\infty = \lim_{v \rightarrow \infty} b(v)/v^{\delta+\gamma}$, and $\rho^*(u) = -\sqrt{(u-1)/u} - b_\infty/(\eta u)$, then

$$T_*(u) = \begin{cases} +\infty & \rho < \rho^*(u) \\ 0 & \rho > \rho^*(u) \end{cases} \quad (22)$$

The borderline case $\rho = \rho^*(u)$ is delicate and we refer to [15, page 13]. Observe that, the condition on $\rho < \rho^*(u)$ is consistent with the Heston model (11), upon setting $\gamma = \delta = 1/2, b_\infty = -\lambda$, whereas the behavior of $\rho > \rho^*(u)$ is different in the sense that there is no immediate moment explosion in the Heston model.

Moment Explosions in Affine Models with Jumps

Recall that in the Heston model

$$\begin{aligned} \mathbb{E}[e^{uX_t} | X_0 = x, V_0 = v] \\ = e^{ux} \exp(\phi(t, u) + v\psi(t, u)) \end{aligned} \quad (23)$$

and it was this form of exponentially affine dependence on x, v that allowed an analytical treatment *via* Riccati equations. Assuming validity only of equation (23), for all $u \in \mathbb{C}$ for which the expectation exists, and that $(X_t, V_t)_{t \geq 0}$ is a (stochastically continuous, time-homogenous) Markov process on $\mathbb{R} \times \mathbb{R}_{\geq 0}$ puts us in the framework of affine processes [8], which, in fact, includes the bulk of analytically tractable stochastic volatility models with and without jumps.

The infinitesimal generator $\mathcal{L}$ of the process $(X_t, V_t)_{t \geq 0}$ now includes integral terms corresponding to the jump effects and thus is a partial integro-differential operator. Nevertheless, the exponentially

affine ansatz $f(t, v; u) = \exp(\phi(t, u) + v\psi(t, u))$ still reduces the Kolmogorov equation to ordinary differential equations of the type equation (8). The functions $F(u, w)$ and $R(u, w)$ are no longer quadratic polynomials, but of Lévy–Khintchine form (*see Infinite Divisibility*). The time of moment explosion can be determined by calculating the blow-up time for the solutions of these *generalized* Riccati equations. This approach can be applied to a Heston model with an additional jump term:

$$\begin{aligned} dX_t &= \left(c(V_t) - \frac{V_t}{2} \right) dt + \sqrt{V_t} dW_t^1 + dJ_t(V_t), \\ X_0 &= 0 \end{aligned} \quad (24)$$

$$\begin{aligned} dV_t &= -\lambda(V_t - \theta) dt + \eta\sqrt{V_t} dW_t^2, \\ V_0 &= v, \quad \langle dW_t^1, dW_t^2 \rangle = \rho dt \end{aligned} \quad (25)$$

The process $J_t(V_t)$ is a pure-jump process based on a fixed Lévy measure $\nu(dx)$. More precisely, writing μ for the uncompensated and $\tilde{\mu}$ for the compensated Poisson random measure, independent of (W_t^1, W_t^2) , with intensity $\nu(dx) \otimes dt$, we assume that

$$\begin{aligned} dJ_t(V_t) &= \begin{cases} \int_{|x| < 1} x \tilde{\mu}(dx, dt) & \dots \text{ case (a)} \\ + \int_{|x| \geq 1} x \mu(dx, dt) & \\ \int_{|x| < 1} V_t x \tilde{\mu}(dx, dt) & \dots \text{ case (b)} \\ + \int_{|x| \geq 1} V_t x \mu(dx, dt) & \end{cases} \end{aligned} \quad (26)$$

In case (a), the process J_t is a genuine (pure-jump) Lévy process; in case (b) jumps are amplified linearly with the variance level, as proposed by Bates [4]. We focus first on case (a). Assuming $\mathbb{E}[e^{J_t}] < \infty$, or equivalently $\int e^x 1_{|x| \geq 1} \nu(dx) < \infty$, so that $e^{\tilde{J}_t} := e^{J_t + ct}$ is a martingale for suitable drift, $c = -\log \mathbb{E}[e^{J_1}]$, we have^h

$$\begin{aligned} \mathbb{E}[e^{uX_t}] &= \mathbb{E}[e^{uX_t^{\text{Heston}}}] \mathbb{E}[e^{u\tilde{J}_t}] \\ &= \mathbb{E}[e^{uX_t^{\text{Heston}}}] e^{t\tilde{\kappa}(u)} \end{aligned} \quad (27)$$

Here, $\tilde{\kappa}(u) = \int (e^{ux} - 1 - u(e^x - 1)) \nu(dx)$ is well defined with values in $(-\infty, \infty]$ and finiteness of $\tilde{\kappa}(u) < \infty$ is tantamount to $\int e^{ux} 1_{|x| \geq 1} \nu(dx) < \infty$. Hence in case (a), we can link the time of moment explosion $T_*(u)$ to $T_*^{\text{Heston}}(u)$, given by equation (10), and have

$$T_*(u) = \begin{cases} T_*^{\text{Heston}}(u) & \tilde{\kappa}(u) < \infty \\ 0 & \tilde{\kappa}(u) = \infty \end{cases} \quad (28)$$

In the case (b), the jump process $J_t(V_t)$ depends on V_t and the above argument cannot be used. A direct analysis of the (generalized) Riccati equations [13] shows that in the case $\tilde{\kappa}(u) < \infty$ the time of moment explosion is given by formula (10), only now $\Delta(u) = \chi(u)^2 - \eta^2(2\tilde{\kappa}(u) + u^2 - u)$, and immediate moment explosion happens in the case $\tilde{\kappa}(u) = \infty$.

Also the model introduced by Barndorff-Nielsen and Shephard [3] (see **Barndorff-Nielsen and Shephard (BNS) Models**), which features simultaneous jumps in price and variance, falls into the class of affine models. It is given by

$$dX_t = \left(c - \frac{V_t}{2}\right) dt + \sqrt{V_t} dW_t + \rho dJ_{\lambda t}, \quad X_0 = 0 \quad (29)$$

$$dV_t = -\lambda V_t dt + dJ_{\lambda t}, \quad V_0 = v, \quad (30)$$

where $\lambda > 0$, $\rho < 0$ and $(J_t)_{t \geq 0}$ is a pure-jump Lévy process with positive jumps only, and with Lévy measure $\nu(dx)$. The drift parameter c is determined by the martingale condition for $(S_t)_{t \geq 0}$. The time of moment explosion can be calculated [13] and is given by

$$T_*(u) = -\frac{1}{\lambda} \log \max \left(0, 1 - \frac{2\lambda \max(0, \kappa_+ - \rho u)}{u(u-1)} \right) \quad (31)$$

where $\kappa_+ := \sup \{u > 0 : \kappa(u) < \infty\}$ and $\kappa(u) = \int_0^\infty (e^{ux} - 1) \nu(dx) \in [0, \infty]$.

Moment Explosions in Affine Diffusion Models of Dai–Singleton Type

For affine diffusion models with an arbitrary number of stochastic factors, the analysis of moment explosions through the Riccati equations has been studied by Glasserman and Kim [10]. Without structural restrictions, this approach will lead to multiple coupled Riccati differential equations, whose blow-up behavior is tedious to analyze in full generality. However, for concrete specifications, this approach can still lead to explicit results. Glasserman and Kim [10] consider affine models (see **Affine Models**), of Dai–Singleton type [7], which are given by a diffusion process

$$dY_t = -A^\top (\Theta - Y_t) dt + \sqrt{\text{diag}(b + B^\top Y_t)} dW_t \quad (32)$$

evolving on the state space $\mathbb{R}_{\geq 0}^m \times \mathbb{R}^{n-m}$. The state vector Y is partitioned correspondingly, into components (Y^v, Y^d) , called *volatility factors* and *dependent factors*. The vector $b \in \mathbb{R}^n$ and matrices $A, B \in \mathbb{R}^{n \times n}$ are subject to the following structural constraints:

- (C1) $A = \begin{pmatrix} A^v & A^c \\ 0 & A^d \end{pmatrix}$, with real and strictly negative eigenvalues.
- (C2) The off-diagonal entries of A^v are nonnegative.
- (C3) The vector $\Theta = (\Theta^v, \Theta^d)$ has $\Theta^d = 0$, $\Theta^v \geq 0$, and $(-A^\top \Theta)^v \gg 0$.ⁱ
- (C4) $B = \begin{pmatrix} I & B^c \\ 0 & 0 \end{pmatrix}$, and $b = (b^v, b^d)$ with $b^v = 0$ and $b^d = (1, \dots, 1)$.

Note that condition C1 assumes strict mean reversion in all components, which is a typical assumption for interest rate models. Most equity pricing models, however, will not satisfy this condition in the strict sense: The Heston model, for example, is of the form (32), but has an eigenvalue of 0 in the matrix A , and thus does not satisfy C1. Nevertheless, relaxing this condition is in general not a problem, see for example [9]. Glasserman and Kim [10] show that the moments

of Y_t are represented by the *transform formula*

$$\begin{aligned} \mathbb{E}[\exp(2u \cdot Y_t)] &= \exp \left(-2 \int_0^t \Theta^\top A x(s) ds \right. \\ &\quad \left. + 2 \int_0^t |x^d(s)|^2 ds + 2x(t) \cdot Y_0 \right) \end{aligned} \quad (33)$$

where $x(t)$ is a solution to the coupled system of Riccati equations, given by

$$\begin{aligned} \begin{pmatrix} \dot{x}_1(t) \\ \vdots \\ \dot{x}_n(t) \end{pmatrix} &= \begin{pmatrix} A^v & A^c \\ 0 & A^d \end{pmatrix} \cdot \begin{pmatrix} x_1(t) \\ \vdots \\ x_n(t) \end{pmatrix} \\ &+ \begin{pmatrix} I & B^c \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} x_1^2(t) \\ \vdots \\ x_n^2(t) \end{pmatrix} \end{aligned} \quad (34)$$

with initial condition $x(0) = u$. Equation (33) holds in the sense that if either side is well defined and finite, the other one is also finite, and equality holds. Thus, moment explosions can again be linked to the blow-up time of the ODE (34). [10] considers two concrete specifications of the above model, with one volatility factor and one dependent factor in each case. Owing to conditions C1–C4, the model parameters are of the form $A = \begin{pmatrix} p & q \\ 0 & r \end{pmatrix}$, $B = \begin{pmatrix} 1 & s \\ 0 & 0 \end{pmatrix}$, and $\Theta = (\theta_1, 0)$, with $p < 0$, $q \geq 0$, $r < 0$, $s \geq 0$, and $\theta_1 \geq 0$.

- $q = s = 0$: This specification decouples the system (34) fully, which can then easily be solved explicitly. In this case, the moment explosion time is given by

$$T_*(u_1, u_2) = \begin{cases} +\infty, & u_1 \leq -p \\ \frac{1}{p} \log \left(1 + \frac{p}{u_1} \right), & u_1 > -p \end{cases} \quad (35)$$

Note that the moment explosion time does not depend on u_2 .

- $s > 0$, $q = 0$, $r = p < 0$: In this case, the system (34) decouples only partially; The equation for the second component becomes $\dot{x}_2 =$

px_2 , with the solution $x_2(t) = u_2 e^{pt}$. Substituting into the equation for the first component yields $\dot{x}_1(t) = px_1 + x_1^2 + su_2^2 e^{2pt}$, a nonautonomous Riccati equation. After the transformation $\xi(t) = e^{-pt}x(t)$ it can be solved explicitly, and the moment explosion time is determined as

$$\begin{aligned} T_*(u_1, u_2) &= \frac{1}{p} \log \max \left\{ 0, \right. \\ &\quad \left. \frac{p}{|u_2|\sqrt{s}} \operatorname{arccot} \left(\frac{u_1}{|u_2|\sqrt{s}} + 1 \right) \right\} \end{aligned} \quad (36)$$

End Notes

- ^aOn the intervals $(-\infty, 0)$ and $(1, \infty)$, respectively.
^bIn fact, it does not even depend on x , which implies the homogeneity properties in equation (5).
^cOnly $u \notin [0, 1]$ needs to be discussed; in this case, $\chi(u) = 0 \implies \Delta(u) < 0$.
^dWhen $u=1$, equation (14) is precisely the Cox–Ingersoll–Ross bond pricing formula.
^eFor $u < u^*$ since equation (14) explodes as $u \uparrow u^*$, where $u^* > 0$ is determined by $I(u^*) \equiv \lambda + \gamma(u) \coth(\gamma(u)t/2) = 0$.
^fCare is necessary since f can be $+\infty$; see [15] for a proper discussion *via* localization.
^gA supersolution $\bar{f}$ of equation (20) satisfies $\mathcal{A}\bar{f} - \frac{\partial \bar{f}}{\partial t} \leq 0$, a subsolution $\underline{f}$ satisfies $\mathcal{A}\underline{f} - \frac{\partial \underline{f}}{\partial t} \geq 0$.
^h X_t^{Heston} denotes the usual log-price process in the classical Heston model, that is, with $J \equiv 0$.
ⁱFollowing the notation of [7], “ $\gg$ ” denotes strict inequality, simultaneously in all components of the vectors.

Implied Volatility in Stochastic Volatility Models

Given the geometric Brownian motion (hence constant volatility) dynamics of an underlying share price, the Black–Scholes formula finds the no-arbitrage prices of call or put options. Given, on the other hand, the price of a call or put, the Black–Scholes implied volatility is by definition the unique volatility parameter such that the Black–Scholes formula recovers the given option price.

If the share price truly follows geometric Brownian motion, then the Black–Scholes implied volatility matches the constant realized volatility of the shares. Empirically, however, stock prices do not exhibit constant volatility, which explains the description in [23] of implied volatility as “the wrong number to put in the wrong formula to obtain the right price”. Nonetheless, the Black–Scholes implied volatility remains, at the very least, a language/scale/metric by which option prices may be quoted and compared across strikes, expiries, underliers, and observation times, as noted in [17].

Moreover, even under stochastic volatility dynamics, Black–Scholes implied volatility is not only a language but indeed carries meaningful information about realized volatility. This article surveys those relationships between implied and realized stochastic volatility, in particular, the following:

- Expected realized variance equals the weighted average of implied variance across strikes, with “implied normal” weights.
- Implied volatility of an option is the *break-even realized volatility* for “business-time delta hedging” of that option.
- Implied volatility at-the-money *approximates expected realized volatility*, under an independence condition.

Aside from Black–Scholes implied volatility, alternative notions of options-implied volatility have robust relationships to realized volatility. We define and discuss two notions of model-free implied volatility (MFIV):

- “VIX-style” MFIV equals the square root of expected variance.
- “Synthetic volatility swap (SVS) style” MFIV equals expected volatility under an independence condition, and approximates expected volatility under perturbations of that condition.

Unless otherwise noted, the only assumptions on the underlying price process are positivity and continuity.

Specifically, on a filtered probability space $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}, \mathbb{P})$, let S be a positive continuous martingale. Regard S as the share price of an underlying tradable asset, and $\mathbb{P}$ as risk-neutral measure, with respect to a bond having price 1 at all times. Extensions to arbitrary deterministic interest rates are straightforward. Let $\mathbb{E}_t$ denote $\mathcal{F}_t$ -conditional expectation, with respect to $\mathbb{P}$. Let

$$X_t := \log(S_t/S_0) \quad (1)$$

denote the log returns process, and let $\langle X \rangle_t$ denote its *quadratic variation* process, which may be regarded as the unannualized running total of the squared realized returns of S continuously monitored on $[0, t]$.

Fixing a time horizon $T > 0$, define *realized variance* to be

$$\langle X \rangle_T$$

and define *realized volatility* to be the square root $\sqrt{\langle X \rangle_T}$ of realized variance. For example, if S has dynamics

$$dS_t = \sigma_t S_t dW_t \quad (2)$$

with respect to Brownian motion W , then $\langle X \rangle_T = \int_0^T \sigma_t^2 dt$.

Black–Scholes Implied Volatility

Fix a time horizon $T > 0$. Define the Black–Scholes [3] function, for S, K , and σ positive, by

$$C^{\text{bs}}(\sigma, S, K) := SN\left(\frac{\log(S/K)}{\sigma} + \frac{\sigma}{2}\right) - KN\left(\frac{\log(S/K)}{\sigma} - \frac{\sigma}{2}\right) \quad (3)$$

where N is the standard normal cdf. Define $C^{\text{bs}}(0, S, K) := (S - K)^+$.

For each $K > 0$, define the time-0 dimensionless Black–Scholes *implied volatility* $IV_0(K)$ to be the unique solution of

$$C^{\text{bs}}(IV_0(K), S_0, K) = \mathbb{E}_0(S_T - K)^+ =: C(K) \quad (4)$$

Dividing $IV_0(K)$ by $\sqrt{T}$ produces the usual annualized implied volatility.

Often, it is more convenient to regard the Black–Scholes formula as a function of dimensionless variance instead of dimensionless volatility, so define

$$C^{\text{BS}}(V, S, K) := C^{\text{bs}}(\sqrt{V}, S, K) \quad (5)$$

Moreover, it may be convenient to regard the Black–Scholes implied volatility as a function of log strike instead of strike, so define

$$IV_0(k) := IV_0(S_0 e^k) \quad (6)$$

We survey how the realized volatility $\sqrt{\langle X \rangle_T}$ (or realized variance $\langle X \rangle_T$) relates to the time-0 implied volatility (or its square, the *implied variance*).

Expected Realized Variance Equals Weighted Average Implied Variance Across Strikes

Black–Scholes implied variance at one strike does not determine the risk-neutral expectation of realized variance, but the weighted average of implied variance at all strikes does so. This result facilitates, for instance, analysis [14] of how the implied volatility skew’s slope and convexity relate to expected variance.

The “implied normal” weights are given by the standard normal distribution, applied to the log strike standardized by “implied standard deviations”. Specifically, assuming $IV_0(k) > 0$, define the standardized log strike by

$$z(k) := -d_2(k) := \frac{k}{IV_0(k)} + \frac{IV_0(k)}{2} \quad (7)$$

The result

$$\mathbb{E}_0 \langle X \rangle_T = \int_{-\infty}^{\infty} IV_0^2(k) dN(z(k)) \quad (8)$$

follows from relating each side to the value of a log contract.

Expected Realized Variance Equals Log Contract Value. Realized variance admits replication

by holding a log contract and dynamically trading shares, *via* the strategy developed in [7, 10, 21], and [9]. Specifically,

$$\begin{aligned} dX_t &= d \log S_t = \frac{1}{S_t} dS_t - \frac{1}{2S_t^2} d\langle S \rangle_t \\ &= \frac{1}{S_t} dS_t - \frac{1}{2} d\langle X \rangle_t \end{aligned} \quad (9)$$

hence,

$$\langle X \rangle_T = -2 \log(S_T/S_0) + \int_0^T \frac{2}{S_t} dS_t \quad (10)$$

Therefore, the log contract payoff $-2 \log(S_T/S_0)$, plus the profit/loss from a dynamic position long $2/S_t$ shares, replicates $\langle X \rangle_T$. A corollary is that

$$\mathbb{E}_0 \langle X \rangle_T = \mathbb{E}_0(-2X_T) \quad (11)$$

if they are finite.

Log Contract Value Equals Weighted Average Implied Variance. In turn, the expectation of $-2X_T$ equals weighted average implied variance. Proofs appear in [19] and [22]. The following is due to [22]. Let $P(K) := \mathbb{E}_0(K - S_T)^+$. Assuming differentiability of IV_0 ,

$$\mathbb{E}_0(-2X_T) = \int_0^{S_0} \frac{2}{K^2} P(K) dK + \int_{S_0}^{\infty} \frac{2}{K^2} C(K) dK \quad (12)$$

$$= \int_0^{S_0} \frac{2}{K} P'(K) dK + \int_{S_0}^{\infty} \frac{2}{K} C'(K) dK \quad (13)$$

$$\begin{aligned} &= 2 \int_{-\infty}^0 \left(N'(d_2) + N(-d_2) IV_0' \right) dk \\ &\quad + 2 \int_0^{\infty} \left(N'(d_2) IV_0' - N(d_2) \right) dk \end{aligned} \quad (14)$$

$$= 2 \int_{-\infty}^{\infty} k N'(d_2) d_2' dk + 2 \int_{-\infty}^{\infty} N'(d_2) IV_0' dk \quad (15)$$

$$= 2 \int_{-\infty}^{\infty} k N'(d_2) d_2' + N'(d_2) d_2 d_2' IV_0 dk \quad (16)$$

$$= \int_{-\infty}^{\infty} IV_0^2(k) N'(z(k)) z'(k) dk \quad (17)$$

where $'$ denotes derivative (unambiguously, as C , P , d_2 , IV_0 , N are defined as single-variable functions).

For brevity, we suppress the argument (k) of d_2 and IV_0 and their derivatives.

To justify the integration by parts in equations (15, 16), it suffices to assume the existence of $\varepsilon > 0$ such that $\mathbb{E}S_T^{1+\varepsilon} < \infty$ and $\mathbb{E}S_T^{-\varepsilon} < \infty$. Then the *moment formula* [18] implies that for some $\beta < 2$ and all $|k|$ sufficiently large, we have $IV_0^2(k) < \beta|k|$; hence

$$\begin{aligned} kN(d_2)|_{-\infty}^0 - kN(-d_2)|_0^\infty &= 0 \\ \text{and } N'(d_2)IV_0|_{-\infty}^\infty &= 0 \end{aligned} \quad (18)$$

Combining equations (11) and (17) gives the conclusion in equation (8).

Implied Volatility Equals Break-even Realized Volatility

Suppose that we buy at time 0 a T -expiry K -strike call or put; to be definite, let us say a call. We pay a premium of $C_0 := C^{\text{BS}}(IV_0^2(K), S_0, K)$.

Dynamically, delta hedging this option using shares, we have, in principle, a position that is delta neutral and “long vega”. Indeed, the implied volatility is the option’s *break-even realized volatility* in the following sense: There exists a model-independent share trading strategy N_t , such that

$$\begin{aligned} P\&L := -C_0 + \int_0^T N_t dS_t + (S_T - K)^+ \\ &< 0 \text{ in the event } \sqrt{\langle X \rangle_T} < IV_0(K) \end{aligned} \quad (19)$$

and $P\&L \geq 0$ in the event $\sqrt{\langle X \rangle_T} \geq IV_0(K)$.

In other words, total profit/loss (from the time-0 option purchase, the trading in shares, and the time- T option payout) is negative if and only if volatility realizes to less than the initial implied volatility.

Implied Volatility is Break-even Realized Volatility for Business-time Delta Hedging. Define the *business-time* delta hedging strategy by letting

$$\tau := \inf\{t : \langle X \rangle_t = IV_0^2(K)\} \quad (20)$$

and holding N_t shares at each time $t \in [0, T]$, where

$$\begin{aligned} N_t &:= -\frac{\partial C^{\text{BS}}}{\partial S}(IV_0^2(K) - \langle X \rangle_t, S_t, K) \\ &t \in [0, \tau \wedge T] \end{aligned} \quad (21)$$

$$N_t := -\mathbb{I}(S_t > K), \quad t \in (\tau \wedge T, T] \quad (22)$$

The break-even property follows from applying Ito’s rule to the process

$$C_t := C^{\text{BS}}(IV_0^2(K) - \langle X \rangle_t, S_t, K), \quad t \in [0, \tau \wedge T] \quad (23)$$

to obtain

$$\begin{aligned} dC_t &= -\frac{\partial C^{\text{BS}}}{\partial V} d\langle X \rangle_t + \frac{\partial C^{\text{BS}}}{\partial S} dS_t \\ &\quad + \frac{1}{2} \frac{\partial^2 C^{\text{BS}}}{\partial S^2} d\langle S \rangle_t \\ &= \left(\frac{1}{2} S_t^2 \frac{\partial^2 C^{\text{BS}}}{\partial S^2} - \frac{\partial C^{\text{BS}}}{\partial V} \right) d\langle X \rangle_t \\ &\quad + \frac{\partial C^{\text{BS}}}{\partial S} dS_t = \frac{\partial C^{\text{BS}}}{\partial S} dS_t \end{aligned} \quad (24)$$

where the partials of C^{BS} are evaluated at $(IV_0^2(K) - \langle X \rangle_t, S_t, K)$. Therefore,

$$-C_{\tau \wedge T} = -C_0 - \int_0^{\tau \wedge T} \frac{\partial C^{\text{BS}}}{\partial S} dS_t \quad (25)$$

as shown in [2, 11, 20].

In the event $\langle X \rangle_T < IV_0^2(K)$, hence $T < \tau$, we have

$$\begin{aligned} P\&L &= (S_T - K)^+ - C_T \\ &= (S_T - K)^+ - C^{\text{BS}}(IV_0^2(K) - \langle X \rangle_T, S_T, K) \\ &< 0 \end{aligned} \quad (26)$$

and in the event $\langle X \rangle_T \geq IV_0^2(K)$, hence $\tau \leq T$, we have

$$\begin{aligned} P\&L &= (S_T - K)^+ - C_\tau - \int_\tau^T \mathbb{I}(S_t > K) dS_t \\ &= (S_T - K)^+ - (S_\tau - K)^+ \\ &\quad - \mathbb{I}(S_\tau > K)(S_T - S_\tau) \geq 0 \end{aligned} \quad (27)$$

as claimed. This break-even result is a special case of a proposition in [6].

Implied Volatility is Not Break-even Realized Volatility for Standard Delta Hedging. The break-even property of the previous section does not extend

to standard “calendar time” delta hedging, defined by share holdings

$$-\frac{\partial C^{\text{BS}}}{\partial S}((T-t)\bar{IV}_0^2, S_t, K), \quad t \in [0, T] \quad (28)$$

where $\bar{IV}_0^2 := IV_0^2(K)/T$ denotes the time-0 annualized implied variance.

This strategy guarantees neither a profit in the event that $\langle X \rangle_T > IV_0^2(K)$ nor a loss in the opposite event. To see this, under the dynamics (2), let

$$Y_t = C^{\text{BS}}((T-t)\bar{IV}_0^2, S_t, K) \quad (29)$$

and apply Ito’s rule to obtain

$$\begin{aligned} dY_t &= -\frac{\partial C^{\text{BS}}}{\partial V}\bar{IV}_0^2 dt + \frac{\partial C^{\text{BS}}}{\partial S} dS_t \\ &\quad + \frac{1}{2} \frac{\partial^2 C^{\text{BS}}}{\partial S^2} d\langle S \rangle_t \\ &= -\frac{1}{2} \bar{IV}_0^2 S_t^2 \frac{\partial^2 C^{\text{BS}}}{\partial S^2} dt + \frac{\partial C^{\text{BS}}}{\partial S} dS_t \\ &\quad + \frac{1}{2} \sigma_t^2 S_t^2 \frac{\partial^2 C^{\text{BS}}}{\partial S^2} dt \end{aligned} \quad (30)$$

where the partial derivatives of C^{BS} are evaluated at $((T-t)\bar{IV}_0^2, S_t, K)$. Hence,

$$\begin{aligned} P\&L = Y_T - Y_0 - \int_0^T \frac{\partial C^{\text{BS}}}{\partial S} dS_t \\ &= \int_0^T \frac{1}{2} (\sigma_t^2 - \bar{IV}_0^2) S_t^2 \frac{\partial^2 C^{\text{BS}}}{\partial S^2} dt \end{aligned} \quad (31)$$

which is half the time-integrated *cash-gamma-weighted* difference of instantaneous variance σ_t^2 and implied variance $\bar{IV}_0^2$, as shown in [7] and [12]. So if, along some trajectory, $\sigma_t > \bar{IV}_0$ at points where gamma is low, but $\sigma_t < \bar{IV}_0$ at points where gamma is high, then it can occur that realized variance $\int_0^T \sigma_t^2 dt$ exceeds implied variance IV_0^2 , yet this long-vega strategy incurs a *loss*.

In conclusion, implied volatility is the option’s break-even realized volatility for business-time delta hedging, but not for calendar-time delta hedging.

Implied Volatility ATM Approximates Expected Realized Volatility, Under an Independence Condition

In this section, we specialize to dynamics (2) such that σ and W are *independent*.

Let $K_{\text{atm}} := S_0$ be the at-the-money (ATM) strike. Then

$$\mathbb{E}(S_T - K_{\text{atm}})^+ = \mathbb{E}C^{\text{bs}}(\sqrt{\langle X \rangle_T}, S_0, K_{\text{atm}}) \quad (32)$$

$$\leq C^{\text{bs}}(\mathbb{E}\sqrt{\langle X \rangle_T}, S_0, K_{\text{atm}}) \quad (33)$$

by the conditioning argument of [15], independence, and the concavity of

$$v \mapsto C^{\text{bs}}(v, S_0, K_{\text{atm}}) \quad (34)$$

It follows that

$$IV_0(K_{\text{atm}}) \leq \mathbb{E}\sqrt{\langle X \rangle_T} \quad (35)$$

The function (34), while concave, is nearly linear for small v ; indeed, its second derivative vanishes at $v = 0$, as observed in [4]. Therefore, the inequalities (33) and (35) are nearly equalities, as shown in [13]. In that sense,

$$IV_0(K_{\text{atm}}) \approx \mathbb{E}\sqrt{\langle X \rangle_T} \quad (36)$$

assuming the independence of σ and W .

Model-free Implied Volatility (MFIV)

Inverting Black–Scholes is not the only way to extract an implied volatility from option prices. While the ATM Black–Scholes implied volatility approximates expected volatility under the independence assumption, alternative definitions of MFIV use call/put data at all strikes, in order to reflect the expected variance or volatility under more general conditions.

VIX-style MFIV Equals the Square Root of Expected Realized Variance

Motivated by equation (11), define the VIX-style model-free implied volatility by

$$\begin{aligned} VIXIV_0 &:= \sqrt{\mathbb{E}_0[-2X_T]} \\ &:= \sqrt{\mathbb{E}_0[-2\log(S_T/S_0) + 2(S_T/S_0) - 2]} \end{aligned} \quad (37)$$

$VIXIV_0$ is an observable function of option prices, specifically the square root of the time-0 value of the portfolio

$$\begin{aligned} 2/K^2 dK & \text{ calls at strikes } K > S_0 \\ 2/K^2 dK & \text{ puts at strikes } K < S_0 \end{aligned} \quad (38)$$

Indeed in 2003, the Chicago board options exchange (CBOE) [8] adopted an implementation of equation (38) to define the VIX volatility index (but due to the availability of only finitely many strikes in practice, the CBOE VIX is not precisely identical to $VIXIV_0$; see [16]).

By equation (11), the square of VIX-style MFIV equals expected realized variance:

$$VIXIV_0 = \sqrt{\mathbb{E}_0 \langle X \rangle_T} \quad (39)$$

However, by Jensen's inequality, for random $\langle X \rangle_T$,

$$VIXIV_0 > \mathbb{E}_0 \sqrt{\langle X \rangle_T} \quad (40)$$

thus, VIX-style MFIV differs from expected realized volatility, due to convexity.

SVS-style MFIV Equals Expected Realized Volatility

For nonconstant $\langle X \rangle_T$, the VIX-style MFIV never equals $\mathbb{E}_0 \sqrt{\langle X \rangle_T}$; in contrast, the SVS-style MFIV will equal $\mathbb{E}_0 \sqrt{\langle X \rangle_T}$ exactly under an independence condition, and approximately under perturbations of that condition. Define SVS-style model-free implied volatility (where SVS stands for “synthetic volatility swap”) by

$$\begin{aligned} SVSIV_0 &:= \mathbb{E}_0 \sqrt{\frac{\pi}{2}} e^{X_T/2} \\ &\times \left| X_T I_0(X_T/2) - X_T I_1(X_T/2) \right| \end{aligned} \quad (41)$$

where $X_T := \log(S_T/S_0)$ and I_ν is the modified Bessel function of order ν .

$SVSIV_0$ is observable from option prices, as the time-0 value of the portfolio

$$\begin{aligned} & \sqrt{\pi/2}/S_0 \\ & \text{straddles at strike } K = S_0, \\ & \sqrt{\frac{\pi}{8K^3 S_0}} \left[I_1(\log \sqrt{K/S_0}) - I_0(\log \sqrt{K/S_0}) \right] dK \\ & \text{calls at strikes } K > S_0, \\ & \sqrt{\frac{\pi}{8K^3 S_0}} \left[I_0(\log \sqrt{K/S_0}) - I_1(\log \sqrt{K/S_0}) \right] dK \\ & \text{puts at strikes } K < S_0 \end{aligned} \quad (42)$$

Under the dynamics (2) with σ and W independent, the exact equality

$$SVSIV_0 = \mathbb{E}_0 \sqrt{\langle X \rangle_T} \quad (43)$$

is proved in [5]. Moreover, it still holds approximately, under perturbations of the independence assumption. To be precise, consider a family of processes $S^{[\rho]}$, indexed by parameters $\rho \in [-1, 1]$, and defined by

$$\begin{aligned} dS_t^{[\rho]} &= \sqrt{1 - \rho^2} \sigma_t S_t^{[\rho]} dW_{1t} + \rho \sigma_t S_t^{[\rho]} dW_{2t} \\ S_0^{[\rho]} &= S_0 \end{aligned} \quad (44)$$

where W_1 and W_2 are $\mathcal{F}_t$ -Brownian motions, and σ and W_2 are adapted to some filtration $\mathcal{H}_t \subseteq \mathcal{F}_t$, where $\mathcal{H}_T$ and $\mathcal{F}_T^{W_1}$ are independent. This includes all the standard stochastic volatility models of the form $d\sigma_t = \alpha(\sigma_t) dt + \beta(\sigma_t) dW_{2t}$.

Changing the ρ parameter does not affect the σ dynamics, and hence cannot affect $\mathbb{E}_0 \sqrt{\langle X \rangle_T}$. However, changing ρ does change the S dynamics, and hence may change option prices, $IV_0(K_{\text{atm}})$, and $SVSIV_0$. Thus, the relationships (36, 43) below

$$IV_0(K_{\text{atm}}) \approx \mathbb{E}_0 \sqrt{\langle X \rangle_T}, \quad SVSIV_0 = \mathbb{E}_0 \sqrt{\langle X \rangle_T} \quad (45)$$

that are valid for the uncorrelated case $S = S^{[0]}$, may not hold for $S = S^{[\rho]}$ where $\rho \neq 0$. Unlike $IV_0(K_{\text{atm}})$, the $SVSIV_0$ has the robustness property of being immunized against perturbations of ρ around $\rho = 0$, meaning that

$$\left. \frac{\partial}{\partial \rho} \right|_{\rho=0} SVSIV_0 = 0 \quad (46)$$

can be verified. This suggests that SVS-style implied volatility $SVSIV_0$ should outperform Black–Scholes implied volatility IV_0 , as an approximation to the expected realized volatility, at least for ρ not too large.

This is confirmed in [5] for Heston dynamics with parameters from [1], and $T = 0.5$. Across essentially all correlation assumptions, the SVS notion of implied volatility exhibited the smallest bias, relative to the true expected annualized volatility. For example, in the case $\rho = -0.64$, the VIX-style implied volatility had bias +98 bp, the Black–Scholes implied volatility had bias −30 bp, and the SVS-style implied volatility had the smallest bias, −6 bp.

Local Volatility Model

The most important input for pricing equity derivatives comes from vanilla call and put options on an equity index or a single stock. The market convention for these options follows the classic Black–Scholes–Merton (BSM) model [3, 15]: the price of each option can be represented by a single number called the *implied volatility*, which is the unknown volatility parameter required in the BSM model to reproduce the price. The implied volatilities for different maturities and strikes are often significantly different, and they collectively form the *implied volatility surface* of the underlying. A fundamental modeling problem is to explain the implied volatility surface accurately using logical assumptions. Many interesting applications follow directly from the solution to this problem. The impact from different parts of the implied volatility surface on a product can be assessed, leading to a deeper understanding of the product, its risks, and the associated hedging strategy. Moreover, different derivatives products, including those not available from the market, may be priced and analyzed under assumptions consistent with the vanilla options.

This article discusses the local volatility surface approach for analyzing equity implied volatility surfaces and examines a common framework in which different modeling assumptions can be incorporated. Local volatility models were first developed by Dupire [11], Derman and Kani [9], and Rubinstein [19] in the last decade and have since become one of the most popular approaches in equity derivatives quantitative research [1, 2, 7, 8, 10, 13, 16, 18]. We present the model from a practitioner’s perspective, discussing calibration techniques with extension to dividends and interest rate modeling, with emphasis on the ease of application to real-world problems.

Basic Model

The basic local volatility model is an extension of BSM to the case where the diffusion volatility becomes a deterministic function of time and the spot price. In the absence of dividends, the stock dynamics can be represented by the following stochastic differential equation:

$$\frac{dS_t}{S_t} = g_t dt + \sigma(t, S_t) dW_t \quad (1)$$

where S_t is the stock price at time t , $g_t = r_t - b_t$ is the known growth rate of the stock (r_t is the interest rate and b_t is the effective stock borrowing cost) at t , $\sigma(t, S)$ is the local volatility function for given time t and stock price S , and W_t is a Brownian motion representing the uncertainty in the stock price. Dynamics (1) can also be viewed as the effective representation of a general stochastic volatility model where $\sigma^2(t, S)$ is the expectation of the instantaneous diffusion coefficient conditioning on $S_t = S$ [13, 17]. If we use $C(t, S; T, K) = \mathbf{E}[\max(S_T - K, 0) | S_t = S]$ to represent the undiscounted price for a European call option with maturity T and strike K when the stock price at time $t \leq T$ is S , then equation (1) leads to the well-known Dupire equation for C :

$$\frac{\partial C}{\partial T} = \frac{\sigma^2(T, K)K^2}{2} \frac{\partial^2 C}{\partial K^2} + g_T \left(C - K \frac{\partial C}{\partial K} \right) \quad (2)$$

Equation (2) gives the relationship between the call option price C and the local volatility function $\sigma(t, S)$. In theory, if arbitrary-free prices of $C(T, K)$ were known for arbitrary T and K , $\sigma(t, S)$ could be recovered by inverting equation (2) with differentials of C . In practice, the market option prices are only directly available on a few maturities and strikes. Schemes for interpolating and extrapolating implied volatilities are often adopted in practice to arrive at a smooth function $C(T, K)$. Such schemes, however, typically lack explicit controls on the various derivatives terms in equation (2), and the local volatility directly inverted from equation (2) can exhibit strange shapes and sometimes attain nonphysical values for reasonable implied volatility input.

Instead of assuming the implied volatilities perfectly known for all maturities and strikes and inverting equation (2), one can model the local volatility function $\sigma(t, S)$ directly as a parametric function. Solving the forward partial differential equation (2) numerically with the initial conditions

$$C(t, S, T = t, K) = \max(S - K, 0) \quad (3)$$

yields call option prices for all maturity T s and strike K s, from which the implied volatility surface can be derived. The parameters of the local volatility function can then be determined by matching the implied volatility surface generated from the model

to that from the market. With a careful design of the local volatility function, this so-called *calibration* process can be implemented very efficiently for practical use. This methodology has the advantage that the knowledge of a perfect implied volatility surface is not required and the model is arbitrage free by construction. In addition, a great amount of analytical flexibility is available, which allows tailor-made designs of different models for specific purposes.

Volatility Surface Design and Calibration

The key to the success of a volatility model lies in an understanding of how the implied volatility surface is used in practice. Empirically, option traders often refer to the implied volatility surface and its shape deformation with intuitive descriptions such as *level*, *slope*, and *curvature*, effectively approximating the shape as simple quadratic functions. In addition, for strikes away from the at-the-money (ATM) region, sometimes the ability to modify the out-of-the-money (OTM) surface independent from the central shape is desired, which traders intuitively speak of as changing the *put wing* or the *call wing*. Thus there exist several degrees of freedom on the volatility surface that a good model should be able to accommodate, and we can design the local volatility function so that each mode is captured by a distinct parameter.

To facilitate comparison across different modeling techniques, we standardize the model specification in terms of the BSM implied volatilities on a small number of strikes per maturity, typically three or five. For example, volatilities on three strikes in the ATM region can be used to provide a precise definition of the traders' level, slope, and curvature parameters. Similarly, fixing volatilities at one downside strike and one upside strike in the OTM region allows the model to agree on a five-parameter specification of level, slope, curvature, put wing, and call wing. These calibration strikes on each maturity are chosen to cover the range of practical interest, usually one to two standard deviations of diffusion at the stock's typical volatility. In the absence of fine structures such as sharp jumps in the underlying, we expect that one standard deviation in the strike range provides a natural length scale over which the stock price distribution varies smoothly. Thus the

implied volatility should have a very smooth shape over the range thus defined, and matching the implied volatilities at the calibration strikes should produce a very good match for all the implied volatilities between them.

The preceding discussions give a straightforward strategy for building the local volatility model—we specify a small number of strikes, and tune the local volatility function with the same number of parameters as the number of strikes for each maturity in a bootstrapping process. The local volatility parameters are then solved through a root-finding routine so that the implied volatilities at the specified strikes on each maturity are reproduced. As each local volatility parameter is designed to capture a distinct aspect of the surface shape, the root-finding system is well behaved and converges quickly to the solution in practice. More importantly, such a process allows a much smaller numerical noise compared to a typical optimization process, giving rise to much more stable calibration results. This is essential in ensuring robust Greeks and scenario outputs from the model.

Discrete Dividend Models

Dividend modeling is an important problem in equity derivatives. It can be shown [15] that with nonzero dividends, the original BSM model only works when the payment amount is proportional to the stock price immediately before the ex-dividend date (ex-date), through incorporating the dividend yields in g_t of equation (1). However, many market participants tend to view future dividends as absolute cash amounts, and this is especially true after trading in index dividend swaps becomes liquid. Existing literature [4, 5, 12, 14] suggests even in the case of a constant volatility, cash dividend equity models (also known as *discrete dividend models*) are much less tractable than proportional dividend ones. Recently, Overhaus *et al.* [16] proposed a theory to ship future cash dividends from the stock price to arrive at a *pure* stock process, on which one can apply the Dupire equation. This theory calls for the changes in future dividends to have a global impact, especially for maturities *before* their ex-dates, a feature that certain traders find somewhat counterintuitive.

Nontrivial dividend specifications can be naturally introduced in the framework here. We note that between ex-dates, equations (1) and (2) continue to

hold without modification. Across an ex-date T_i , a simple model for the stock price is

$$S_{T_i^+} = (1 - Y_i) S_{T_i^-} - D_i \quad (4)$$

where Y_i and D_i are respectively the dividend yield and cash dividend amount for the ex-date T_i . This is the mixed-dividend model, which includes proportional and cash dividend models as special cases. Y_i and D_i can be determined from a *nominal* dividend schedule specifying the ex-dates and the dividend payment amount, as well as a mixing schedule specifying the portion of dividends that should remain as cash, the rest being converted into proportional yield. Typically, cash dividends can be specified for the first few years to reflect the certainty on expected dividends, gradually switching to all proportional in the long term. Theoretically, equation (4) has the disadvantage of allowing negative ex-dividend stock prices. In practice, if the mixing ratio is switched to all proportional after a few years, this does not pose a serious problem. According to dividend model (4), the forward equation across the ex-date becomes

$$C(T_i^+, K) = (1 - Y_i) C\left(T_i^-, \frac{K + D_i}{1 - Y_i}\right) \quad (5)$$

and can be implemented in the same way as standard jump conditions. With equation (5) incorporated, the calibration strategy in the section Volatility Surface Design and Calibration can be applied in exactly the same way. We note that it is straightforward to extend the local volatility model here to handle more interesting dividend models, in which the dividend amount can be made a function of the spot immediately before the ex-date. As long as such a function becomes small enough when the stock price goes to zero, the issue of negative ex-dividend stock prices can be theoretically eliminated.

Stochastic Interest Rate Models

Local volatility models can be extended to cases where stochastic interest rate needs to be considered [16]. The interest rate can be modeled through classic short-rate models, and the equity process is then specified as a diffusion with stochastic growth rate. Following Brigo and Mercurio [6], we have

$$\frac{dS_t}{S_t} = (r_t - b_t) dt + \sigma(t, S_t) dW_t \quad (6a)$$

$$r_t = u_t + y_t \quad (6b)$$

$$dy_t = \alpha(\phi - y_t) dt + \sigma_t y_t^\beta dB_t \quad (6c)$$

$$dW_t dB_t = \rho dt \quad (6d)$$

where u_t is a function of time describing the deterministic part of the interest rate, y_t is a diffusion process modeling the stochastic part of the interest rate, and B_t is a Brownian motion describing the interest rate uncertainty, correlated with W_t with coefficient ρ . In equation (6c), α , β , ϕ , and σ_t are parameters describing the short-rate process. For example, when $\phi = 0$ and $\beta = 0$, equation (6c) is equivalent to the Hull–White model. With nonzero ϕ and $\beta = \frac{1}{2}$, the shifted Cox–Ingersoll–Ross (CIR++) model is obtained. Both models admit closed form pricing formula for zero-coupon bonds, interest rate caps, and swaptions, which can be used for calibration to interest rate derivatives market observables. For a given short-rate model and its parameters, the local volatility function $\sigma(t, S)$ needs to be recovered from equity derivatives market information. This can be achieved by considering the transition density for the joint evolution of the stock price S_t and short rate r_t under stochastic discount factor, that is,

$$\begin{aligned} p(t, S, y; T, K, Y) \\ = \mathbf{E} \left[\exp \left(- \int_t^T r_\tau d\tau \right) \right. \\ \left. \times \delta(S_T - K) \delta(y_T - Y) \middle| S_t = S, y_t = y \right] \quad (7) \end{aligned}$$

The Fokker–Planck equation for such a quantity can be written down as

$$\begin{aligned} \frac{\partial p}{\partial T} = & \frac{\partial^2 (K^2 \sigma^2(T, K) p)}{2 \partial K^2} + \frac{\sigma_T^2}{2} \frac{\partial^2 (Y^{2\beta} p)}{2 \partial Y^2} \\ & + \rho \sigma_T \frac{\partial^2 (K \sigma(T, K) Y^\beta p)}{\partial K \partial Y} \\ & - (u_T + Y - b_T) \frac{\partial (K p)}{\partial K} \\ & - \alpha \phi \frac{\partial p}{\partial Y} + \alpha \frac{\partial (Y p)}{\partial Y} - (u_T + Y) p \quad (8) \end{aligned}$$

By solving equation (8) subject to vanishing boundary conditions on K and Y as well as delta-function initial condition at $T = t$, one can recover the European option prices as

$$C(t, S_t; T, K) = \int_0^\infty dS \max(S - K, 0) \times \int_{-\infty}^\infty p(t, S_t, y_0; T, S, Y) dY \quad (9)$$

and hence derive the implied volatility surface from the hybrid model (6). The strategy discussed in the

section Volatility Surface Design and Calibration can once again be invoked. In practice, since the two-factor model takes significantly more time in calculation than the basic model, it is very effective to use the basic model solution as a starting point for the hybrid calibration.

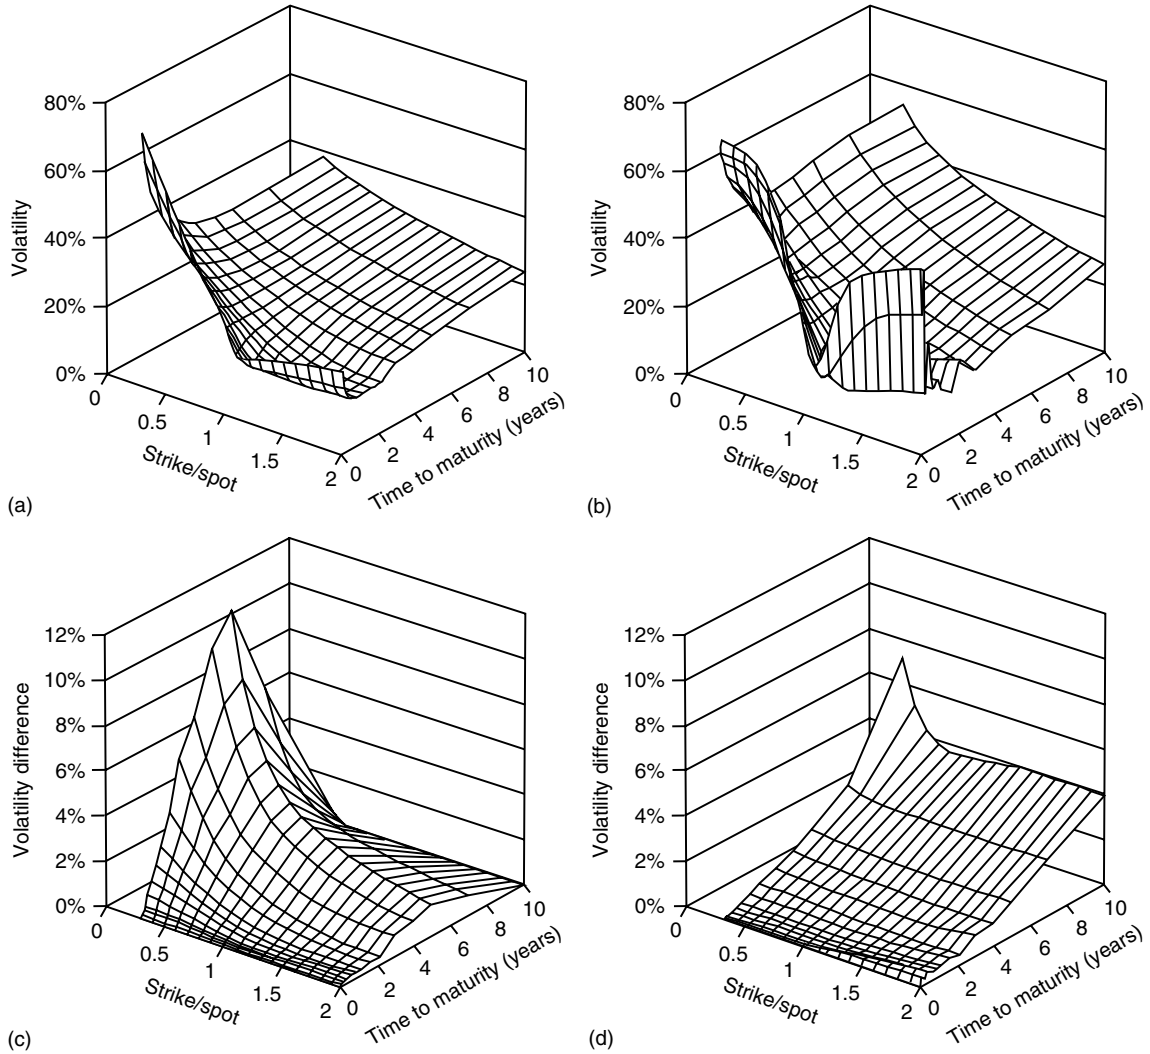

Figure 1 The implied and local volatility surface on the S&P 500 Index in November 2007. (a) The implied volatility as a function of time to maturity and strike price (expressed as a percentage of spot price). (b) The local volatility surface calibrated under the basic model. (c) Changes in the local volatility surface when cash dividends are assumed for the first five years, gradually transitioning to proportional dividends in 10 years. (d) Changes in the local volatility surface where the interest rate is assumed to follow the Hull-White model calibrated to ATM caps with correlation $\rho = 30\%$. In both (c) and (d) the new local volatility is smaller than in (b)

Examples

We use data from the S&P 500 index market as examples to illustrate the preceding discussions. Figure 1(a) and (b) shows a typical implied volatility surface and the calibrated local volatility surface under the basic model, that is, with proportional dividend and deterministic interest rate assumptions. The implied volatility surface is given by option traders. Normally it is retrieved from data in both the listed and OTC options market, interpolated, and extrapolated with trader-specified functions. The local volatility surface is built by simply calibrating to five strikes on each marked maturity, with the Libor-Swap curve and the full index dividend schedule. Excellent

calibration quality can be obtained: the option price differences computed using the input implied volatility surface and the calibrated local volatility surface are less than one basis point of the spot price for most liquid strikes and below 10 basis points across all strikes and maturities. This accuracy is sufficient for most practical purposes.

Figure 1(c) and (d) displays the changes in the local volatility surface when we include effects of cash dividends or stochastic interest rate into the model. We have assumed the Hull–White model for the interest rate in these calculations. The dividend and interest rate specifications are seen to have a significant impact on the local volatility surface and hence can be important in derivatives pricing. Cash

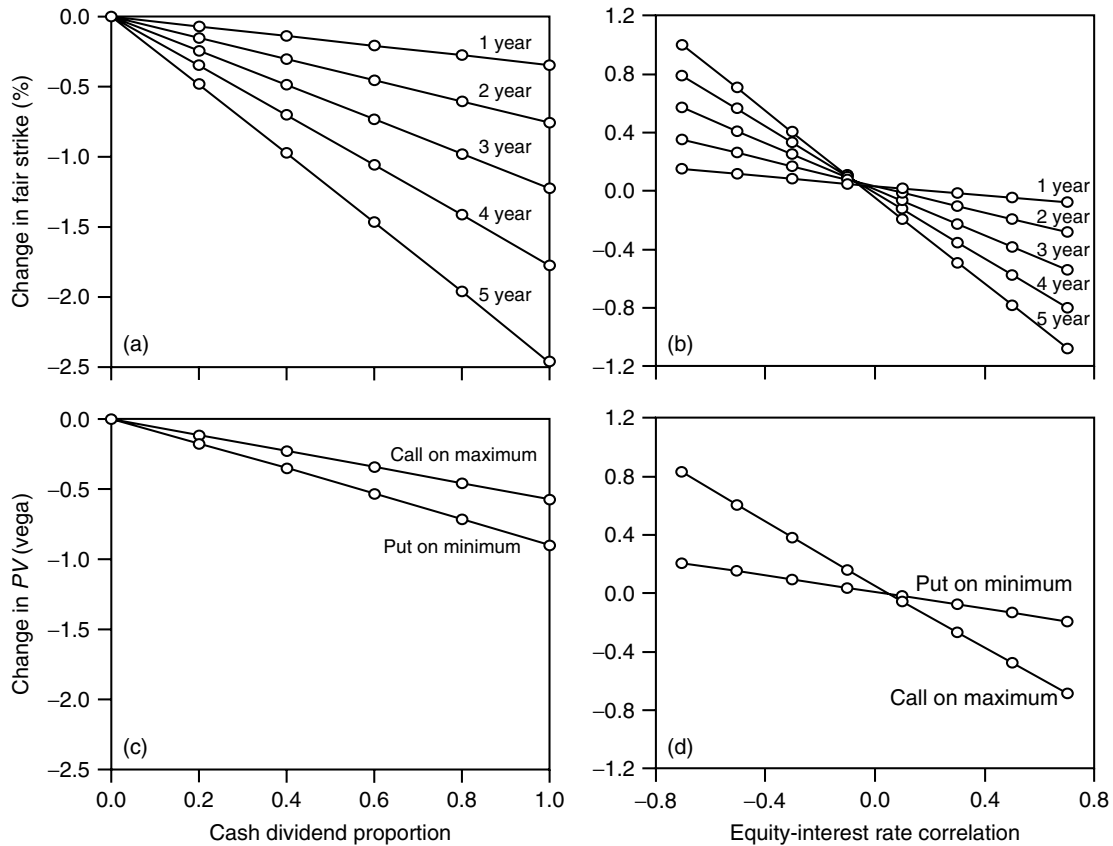

Figure 2 Impact of discrete dividends and stochastic interest rate on derivative pricing. (a) Changes to the fair strike of the variance swaps with different dividend assumptions. (b) Changes to the fair strike of the variance swaps under stochastic interest rate with different correlation. The labels indicate the maturity of the variance swaps. (c) Changes to the *PV* of the lookback options with different dividend assumption. (d) Changes to the *PV* of the lookback options under stochastic interest rate with different correlation. The numbers in (c) and (d) are in units of vega of Table 2

dividends introduce additional deterministic, nonproportional jump structures in the equity dynamics, and to maintain the same implied volatility surface the local volatility needs to become smaller. This effect depends on the dividend size relative to future spot prices, and thus become more pronounced for smaller strikes and longer maturities, producing a skewed shape in the difference. On the other hand, stochastic interest rate introduces volatility in discount bond prices and with positive correlation also reduces the equity local volatility. This effect does not depend on spot levels explicitly and is instead related to the volatility ratio between the interest rate and the equity and their correlation. Since the interest rate usually has a small volatility compared to the equity, to the leading order the effect of stochastic rates can sometimes be approximated by a parallel shift on the local volatility surface.

We can apply these local volatility models to price exotic derivatives not directly available from the vanilla market. One example is variance swaps, which are popular OTC products offered to capitalize on the discrepancy between implied and realized volatility. Another example is lookback options, which provide payoffs on the maximum/minimum index prices over a set of observation dates and can be appealing hedges to insurance companies who have sold policies with similar exposure. Tables 1 and 2 display the pricing results for these structures using the basic model.

Figure 2 shows the pricing impact on these structures when the effects of cash dividends and stochastic interest rates are considered. As the payout for the variance swap is directly linked to the equity's average local volatility, the pricing is strongly affected by the assumption of cash dividends and stochastic

Table 1 Pricing of variance swaps with the basic model

Maturity (years)	Fair strike (%)
1	27.59
2	28.18
3	28.42
4	29.14
5	30.00

The payoff for strike K at maturity is $\frac{252}{N} \sum_{i=0}^{N-1} (\ln \frac{S_{i+1}}{S_i})^2 - K^2$, where S_i is the index closing price on the i th business day from the current date ($i = N$ corresponds to the maturity). The fair strike is the value K such that the contract costs nothing to enter

Table 2 Pricing of five-year lookback options with the basic model

Option type	Payout formula	PV (%)	Vega (%)
Call on maximum	$\max_{i=0}^5 \left(\frac{S_i}{S_0} \right) - \frac{S_5}{S_0}$	25.29	1.17
Put on minimum	$1 - \min_{i=0}^5 \left(\frac{S_i}{S_0} \right)$	22.35	0.85

S_i ($i = 0, 1, \dots, 5$) is the index price at annual observation dates on year i from the current date. The PV is the calculated present value according to the payout formula at maturity. The Vega is the change in PV when a parallel shift of 1% is applied to the implied volatility surface

interest rate. For lookback options, one needs to look at the joint distribution among equity prices across different observation dates. Cash dividends generally reduce the local volatility and hence decrease the correlation between the equity prices at different dates, leading to lower lookback prices. With stochastic interest rate, the effect of modified equity diffusion volatility can either reinforce (e.g., call on maximum) or partly cancel (e.g., put on minimum) the effect of stochastic discounting.

The numerical impact of different modeling assumptions can be comparable to a full percentage difference in volatility. Hence, it may be important to take these into account when accurate and competitive pricing of exotic equity derivatives is required. An extensive and detailed discussion of the impact of stochastic interest rate on popular hybrid products can be found in [16].

Dividend Modeling

A dividend is a portion of a company's earnings paid to its shareholders. In the process of dividend payment, the following stages are distinguished: (i) declaration date, when the dividend size and the ex-dividend date are announced; (ii) ex-dividend date, when the share starts trading net of dividend; (iii) record date, when holders eligible to dividend payment are identified; and (iv) payment date, when delivery is made. At the ex-dividend date, the stock price drops by an amount proportional to the size of the dividend; the proportionality factor depends on the tax regulations. There are a lot of issues, research streams, and approaches in dividend modeling; here the issue is considered mainly in the context of option pricing theory.

The usual way to price derivatives on dividend-paying stocks is to take a model for non-dividend-paying stocks and extend it to take the dividends into account. The dividends then are commonly modeled as (i) continuously paid dividend yield, (ii) proportional dividends (known fractions of the stock price) paid at known discrete times, or (iii) fixed dividends (known amounts), paid at known discrete times. It is also possible to model the dividend amounts and the dividend dates stochastically (though there is evidence that this has a negligible impact on vanilla options [10]). In fact, there is an alternative approach where the stochastic dividends are the primary quantities and the stock followed by option price are derived from these, which was pioneered in [9]. As usual, one has to choose the complexity of the model depending on dividend exposure of the derivative to be priced.

In practice, one comes across the notion of implied dividends: the value of the dividends (independent of how they are modeled) can be inverted from the synthetic forward or future contract; the fact that one can get quite different (from analyst predictions) numbers reflects various uncertainties. Among them are the sundry tax regulations in different countries for various market players, timing, and value of the dividends, just to name a few.

The impact of dividends can be illustrated, starting simply by adding a continuous dividend yield to the drift. For the sake of the simplicity of notations, it is

written in lognormal terms:

$$dS_t = (r - q)S_t dt + \sigma S_t dW_t \quad (1)$$

This approach is especially popular when modeling options on indexes, where dividend payments are numerous and spread through time. Another choice, of proportional amounts $d_i = f_i S_{t_i}$ paid at ex-dividend dates $t_1 < t_2 < \dots$ for single shares, can be justified by the fact that dividends tend to increase when a company is doing well, which is correlated with a high share price:

$$dS_t = (r - Q_t)S_t dt + \sigma S_t dW_t \quad \text{with} \\ Q_t = \sum_i \delta(t - t_i) f_i \quad (2)$$

In both these cases, the stock price at each time still has a lognormal distribution, so the prices of European options are given by straightforward modifications of the Black-Scholes (BS) pricing formula. This is no longer true, however, for discrete cash dividends:

$$dS_t = (rS_t - D_t) dt + \sigma S_t dW_t \quad \text{with} \\ D_t = \sum_i \delta(t - t_i) d_i \quad (3)$$

The stock price S_t jumps down with the amount of dividend d_i paid at time t_i and between the dividends it follows a geometric Brownian motion. In this setting, the stock price can become negative, but this is usually so unlikely that, in practice, it is not a problem. Still, one might want to use a more robust dividend policy in the model, such as capping the dividend at the stock price. Obviously, different dividend policies result in different option prices [7].

Impact on Option Pricing

To compute an option price under equation (3) the standard collection of numerical methods can be employed: finite difference (FD) method with jump conditions across ex-dividend date [11], Monte Carlo simulations, or nonrecombining trees [8]. There is no real closed-form solution with multiple dividends for European option under equation (3); however, several approximations are available. All of them are

based on bootstrapping, that is, repeatedly computing the convolution of the option value at one dividend date with the density kernel from that date to the previous dividend date and applying the jump condition at the dividend dates, starting from the payoff at maturity. One can use a piecewise linear or a more sophisticated approximation of the option value at each convolution step and enjoy having a finite sum of closed-form solutions. On the basis of the fact that diffusion preserves monotonicity and convexity, it can be shown that the result converges to the true value (unpublished work of Amaro de Matos *et al.*). Another choice of parameterization was made in [7]: at each step of the integration the option value is approximated by BS-like function where strike and volatility are adjusted to obtain the best fit. Such methods can be used for any underlying process where one can compute the density kernel (Green function, propagator) for the convolution, though it will probably be not much faster or more accurate than employing the standard finite difference method, especially in the case of multiple dividends. For the handling of American options, one can find an extensive list of references in [4] and the relation between early exercise and dividends is explained in **American Options; Finite Difference Methods for Early Exercise Options** or [8].

A Common Approach

As already pointed out in the discrete cash dividend model (3), the price of a European option has no closed-form solution and trees do not recombine. In order to remedy this, traders often split the stock price into a risky net-dividend part and a deterministic dividend part:

$$\begin{aligned} d\tilde{S}_t &= r\tilde{S}_t dt + \tilde{\sigma}\tilde{S}_t dt \\ S_t &= \tilde{S}_t + \tilde{D}_t \end{aligned} \quad (4)$$

$$\begin{aligned} \tilde{D}_t &= \tilde{D}_t^{\text{fut}} - \tilde{D}_t^{\text{past}} \\ \tilde{D}_t^{\text{fut}} &= \sum_{t < t_i \leq T} \alpha_i d_i e^{-r(t_i-t)} \\ \tilde{D}_t^{\text{past}} &= \sum_{0 < t_i \leq t} (1 - \alpha_i) d_i e^{-r(t_i-t)} \end{aligned} \quad (5)$$

Note that the dependence on the option maturity T in the notation $\tilde{D}_t^{\text{fut}}$ is suppressed. The most common

choices used by practitioners [3, 5] are

$$\alpha_i = 1 \quad \text{so} \quad \tilde{D}_t = \sum_{t < t_i \leq T} d_i e^{-r(t_i-t)} \quad (6)$$

$$\alpha_i = 0 \quad \text{so} \quad \tilde{D}_t = \sum_{0 < t_i \leq t} d_i e^{-r(t_i-t)} \quad (7)$$

$$\alpha_i = 1 - \frac{t_i}{T} \quad (8)$$

In this approach, the tree for $\tilde{S}_t$ is recombining (*see Binomial Tree* or [8]), and the price of a European option is again given by a BS type formula, where the spot and the strike are adjusted as $S_0 \rightarrow S_0 - \tilde{D}_0^{\text{fut}}$ and $K \rightarrow K + \tilde{D}_T^{\text{past}}$. Needless to say, however, the volatility for each of these processes will be different. Namely, choice (6) underestimates and choice (7) overestimates the volatility compared to the “true” model (3); the weighted choice (8) aims to minimize this effect.

Arbitrage Opportunities

In reference [1], it was shown that arbitrage opportunities exist in the most standard approach (6) if the volatility surface is continuously interpolated around ex-dividend dates. They apply a rough volatility adjustment to prevent the arbitrage opportunities. The following example demonstrates that the continuous interpolation of volatility around ex-dividend dates can lead to significant mispricing. Figure 1 shows

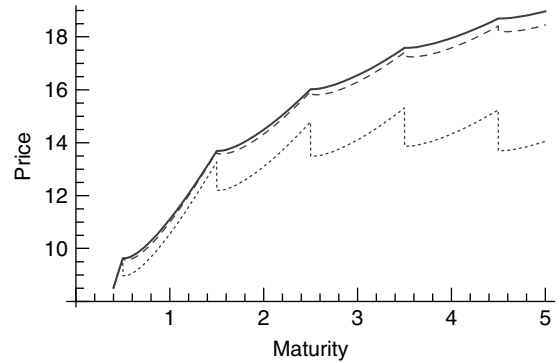

Figure 1 Price of an American call as a function of the time to maturity T for the following models: (3) (solid line), (6) (dotted line), and (6) with the volatility adjustment (10) (dashed line). The parameters are $S_0 = 100$, $K = 100$, $r = 0.05$, $\sigma = 0.3$, $d_i = 8$, and $t_i = i - \frac{1}{2}$

the price of an American call as a function of the time to maturity T for different models. Given a flat volatility, the prices under equation (6) jump down after an ex-dividend date, which is not realistic, because a risk-free profit can be locked in by selling an option maturing just before the ex-dividend date and by buying a similar option maturing just after the ex-dividend date. Although the mispricing under equation (6) is most evident for American options, it is equally present in the valuation of European options. Note that equation (4) produces continuous prices around dividend payments and the price differences between the two models increase dramatically with maturity (see [1, 5] for similar results). Another primitive pitfall with equation (6) is to use constant extrapolation of the implied volatility to longer maturities. For example, if the present value of dividends of a long-term contract is half of the current stock price, then with simple flat term structure extrapolation one will underestimate the volatility by a factor of at least one and a half [2].

Volatility Adjustments

To understand the difference in terms of volatility for the specified models, consider the local volatility model. Substitution of equation (4) into equation (3) yields the result that $\tilde{S}$ follows the process with local volatility

$$\tilde{\sigma}(\tilde{S}, t) = \left(1 + \frac{\tilde{D}_t}{\tilde{S}}\right) \sigma \quad (9)$$

It is handy to translate this result into implied terms [6]. Following the line of reasoning presented in [2], a slightly generalized result for the implied volatility can be derived:

$$\tilde{\sigma}^2 \approx \sigma^2 + \sigma \sqrt{\frac{\pi}{2T}} A \quad (10)$$

where

$$\begin{aligned} A = & 4e^{\frac{b_1^2}{2}-s} \sum_i \tilde{d}_i \left(\omega_i [\mathcal{N}(b_1) - \mathcal{N}(b_1 - \xi_i)] \right. \\ & \left. + \tilde{\omega}_i [\mathcal{N}(b_2) - \mathcal{N}(b_1 - \xi_i)] \right) \\ & + e^{\frac{c_1^2}{2}-2s} \sum_{i,j} \tilde{d}_i \tilde{d}_j \left(\omega_i \omega_j [\mathcal{N}(c_1) - \mathcal{N}(c_1 - \psi_{ij})] \right. \\ & \left. - \tilde{\omega}_i \tilde{\omega}_j [\mathcal{N}(c_2) - \mathcal{N}(c_1 - \psi_{ij})] \right. \\ & \left. + \Omega_{ij} [\mathcal{N}(c_1 - \Psi_{ij}) - \mathcal{N}(c_1 - \psi_{ij})] \right) \quad (11) \end{aligned}$$

with $s = \ln(S_0 - \tilde{D}_0^{\text{fut}})$, $k = \ln(K + \tilde{D}_T^{\text{past}}) - rT$, $x_t = (s + (k - s)\frac{t}{T}) + rt$, $y_t = \frac{t(T-t)}{T}$, $\tilde{\omega}_i = 1 - \omega_i$, $\tilde{d}_i = d_i e^{-r t_i}$, $a = \frac{s-k}{\sigma\sqrt{T}}$, $b_{1/2} = a \pm \frac{\sigma\sqrt{T}}{2}$, $c_{1/2} = a \pm \sigma\sqrt{T}$, $\xi_i = \sigma \frac{t_i}{\sqrt{T}}$, $\psi_{ij} = 2 \min(\xi_i, \xi_j)$, $\Psi_{ij} = 2 \max(\xi_i, \xi_j)$, $\Omega_{ij} = \omega_i \tilde{\omega}_j 1_{t_i > t_j} + \omega_j \tilde{\omega}_i 1_{t_j > t_i}$.

This gives a very simple and quick way of switching between models for trading practice as well as for understanding the essence of the feature. Moreover, it can be used independently of the option type. To give an idea of the quantitative value of presented methods, some numerical results with and without volatility adjustment are summarized in Table 1. All results are compared to the numerical solution calculated with the FD method. Bootstrapping with the piecewise linear interpolation converges to FD with sufficiently many points; HHL approximation of [7] differs a bit, probably due to the fact that the BS-like formula cannot exactly fit the shape of the integrand. Clearly, even in approximate form, equation (10) gives a fair correction in all cases, performing especially well for the weighted model (8).

When pricing equity derivatives, one should be aware that these instruments can be sensitive to

Table 1 European call prices with parameter set of Figure 1 for different strikes. HHL refers to the approximation of [7]; FD to finite difference and BS to closed-form solution

Strike	FD for (3)	HHL for (3)	BS for (6)	BS for (6) with (10)	BS for (8)	BS for (8) with (10)
50	33.509	33.641	29.908	33.312	33.547	33.497
80	22.482	22.559	17.846	22.414	22.304	22.473
100	17.393	17.428	12.772	17.404	17.102	17.388
120	13.573	13.575	9.250	13.644	13.209	13.573
150	9.511	9.479	5.836	9.635	9.099	9.515

dividends. Examples are exotic options on stocks and derivatives involving realized volatility, such as variance swaps (see **Variance Swap**), volatility swaps (see **Volatility Swaps**), correlation swaps (see **Correlation Swap**), and gamma swaps (see **Gamma Swap**). This sensitivity determines the required sophistication in dividend modeling. Adding dividends to a stock price process may seem trivial at first glance, but one has to be careful in setting the model parameters. The resulting model can then be solved by the usual methods. For the plain vanilla option with dividends, a number of numerical approximations have been developed.

Implied Volatility: Volvol Expansion

In order to calibrate stochastic volatility models, it is convenient to have an accurate analytical formula or approximation for call options. However, deriving such a formula is not always an easy task. In the Heston model, the most popular technique involves numerical integration, which is necessarily time consuming. The main idea is to apply a perturbation method to the volvol parameter, calculating the first and second order of the difference between a stochastic volatility model and a Black–Scholes model. In general case, we can reduce the integration of the exact formula to some simpler integration.

Consider the following two-factor stochastic volatility model:

$$dS = (r - d)Sdt + \sigma SdB_t \quad (1)$$

$$dV = b(V)dt + \epsilon v(V)dW \quad (2)$$

$$dBdW = \rho(V)dt \quad (3)$$

where r is the short rate, d is the dividend yield, ϵ is a constant, and $b(V)$ and $v(V)$ are independent of ϵ . We assume parameters r and d to be constant for the sake of simplicity. The series expansion consists in writing the option price formula as a series in ϵ .

Fourier methods (*see* **Fourier Methods in Options Pricing**) tell us that the call option price is given by

$$C(S, V, T) = Se^{-dT} - \frac{Ke^{-rT}}{2\pi} \int_{i/2-\infty}^{i/2+\infty} \exp(-iuX) \frac{\Phi(u, V, T)}{u(u-i)} du \quad (4)$$

where $X = \ln(S/K) + (r - d)T$.

$$\frac{\partial f}{\partial \tau} = \frac{1}{2}\epsilon^2 v^2(V) \frac{\partial^2 f}{\partial V^2} + \left[b(V) - iu\epsilon\rho(V)v(V)\sqrt{V} \right]$$

$$\times \frac{\partial f}{\partial V} - \frac{u(u-i)}{2} Vf \quad (5)$$

We look for solutions which can be written as a power series of ϵ .

$$f(u, V, T) = f^{(0)}(u, V, T) + \epsilon f^{(1)}(u, V, T) + \epsilon^2 f^{(2)}(u, V, T) \quad (6)$$

Thus, we can obtain the power series of the call price using either equation (4) directly

$$C(u, V, T) = C^{(0)}(u, V, T) + \epsilon C^{(1)}(u, V, T) + \epsilon^2 C^{(2)}(u, V, T) \quad (7)$$

or expanding first the implied volatility

$$V_{\text{imp}}(u, V, T) = V_{\text{imp}}^{(0)}(u, V, T) + \epsilon V_{\text{imp}}^{(1)}(u, V, T) + \epsilon^2 V_{\text{imp}}^{(2)}(u, V, T) \quad (8)$$

and then plugging it into the option price with Black–Scholes formula.

As a matter of fact, these two methods differ significantly. The former—denoted by series A in the remainder of this article—gives the call price first and implied volatility while the latter—denoted by series B—gives the implied volatility and call price is obtained afterward. Nevertheless, in most cases, there is a slight numerical difference between the two series. However, regarding far out-of-the money options, the two series give different results as shown in Figure 1. Empirical evidence shows that series B is very often better than series A. Even though this is not a general rule, series B should be usually preferred over series A.

We now explicitly compute the two series for the following model. In particular, this model encompasses the Heston model for the special case $\phi = 0.5$.

$$dS = (r - d)Sdt + \sigma SdB_t \quad (9)$$

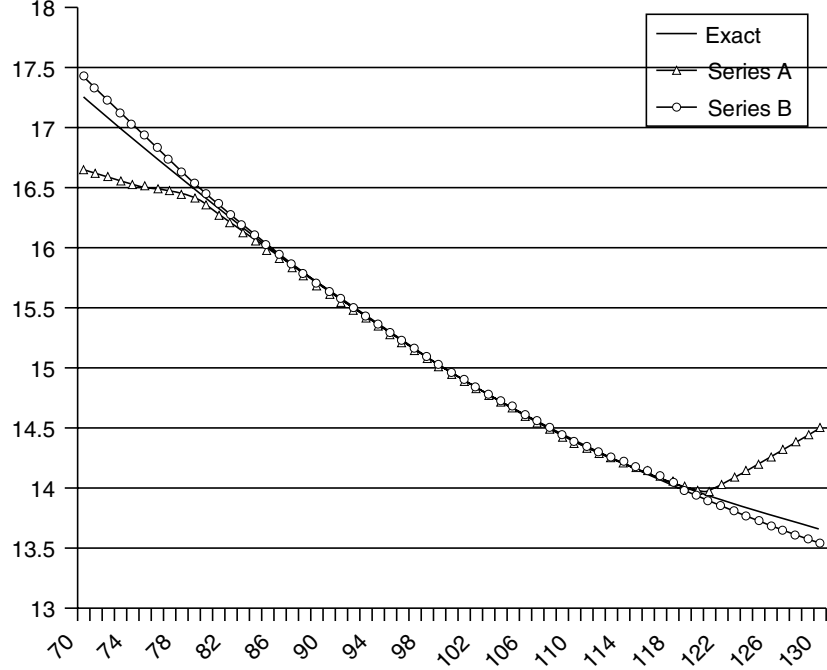

Figure 1 Series A (expansion on price), series B (expansion on implied volatility), and exact volatility

$$dV = (\omega - \theta V)dt + \epsilon V^\phi dW \quad (10)$$

$$dBdW = \rho(V)dt \quad (11)$$

First, the expansion is on the fundamental transform of the closed formula, which is presented by $\Phi(u, V, T)$ in equation (4). The idea is that we can expand this function into a simpler form, so that the integration in the equation (4) can be reduced to analytic form. Here, we do not discuss the detailed derivation but only give the result. Interested readers can refer to [2]. For series A, the expansion on price is

$$\begin{aligned} C(S, V, \tau) &= c(S, v, \tau) + \epsilon \tau^{-1} J^{(1)} \tilde{R}^{(1,1)} c_V(S, v, \tau) \\ &+ \epsilon^2 \left\{ \tau^{-1} J^2 + \tau^{-2} J^{(3)} \tilde{R}^{(2,0)} \right. \\ &\left. + \tau^{-1} J^{(4)} \tilde{R}^{(1,2)} + \frac{\tau^{-2}}{2} (J^{(1)})^2 \tilde{R}^{(2,2)} \right\} \\ &\times c_V(S, v, \tau) + O(\epsilon^3) \end{aligned} \quad (12)$$

For series B, the expansion on price is

$$\begin{aligned} V^{\text{imp}} &= v(S, v, \tau) + \epsilon \tau^{-1} J^{(1)} \tilde{R}^{(1,1)} \\ &+ \epsilon^2 \left\{ \tau^{-1} J^2 + \tau^{-2} J^{(3)} \tilde{R}^{(2,0)} \right. \\ &\left. + \tau^{-1} J^{(4)} \tilde{R}^{(1,2)} + \frac{\tau^{-2}}{2} (J^{(1)})^2 \right. \\ &\left. \times \left[\tilde{R}^{(2,2)} - \left(\tilde{R}^{(1,1)} \right)^2 \tilde{R}^{(2,0)} \right] \right\} \\ &+ O(\epsilon^3) \end{aligned} \quad (13)$$

In the above formulae, term $c(S, v, \tau)$ presents the corresponding Black-Scholes price. When volvol $\epsilon = 0$, the stochastic model reduces to a Black-Scholes model. v here is the equivalent variance for Black-Scholes, which is basically the integration of the variance from 0 to τ .

The functions $\tilde{R}^{(p,q)}$ and $J^{(s)}$ are the derivative ratios and integration, respectively. Here, for academic and practitioners' interest their expressions are listed.

$$dv_t = \kappa(\theta_t - v_t)dt + \xi_t \sqrt{v_t} dB_t, \quad v_0 \quad (20)$$

$$d\langle W, B \rangle_t = \rho_t dt \quad (21)$$

$$\begin{aligned} \tilde{R}^{(2,0)} &= \tau \left[\frac{1}{2} \frac{X^2}{Y^2} - \frac{1}{2Z} - \frac{1}{8} \right], \quad \tilde{R}^{(1,1)} = \left[-\frac{X}{Z} + \frac{1}{2} \right] \\ \tilde{R}^{(1,2)} &= \left[\frac{X^2}{Z^2} - \frac{X}{Z} - \frac{1}{4Z}(4-Z) \right], \quad \tilde{R}^{(2,2)} = \tau \left[\frac{1}{2} \frac{X^4}{Z^4} - \frac{1}{2} \frac{X^3}{Z^3} - 3 \frac{X^2}{Z^3} + \frac{1}{8} \frac{X}{Z^2}(12+Z) + \frac{1}{32} \frac{1}{Z^2}(48-Z^2) \right] \end{aligned} \quad (14)$$

with $Z = V\tau$ and

Here, we have adjusted to risk neutral probability; as a consequence, it introduces the drift term in spot process by the change of probability.

$$J^{(1)}(V, \tau) = \frac{\rho}{\theta} \int_0^\tau (1 - e^{-\theta(\tau-s)}) \left[\frac{\omega}{\theta} + e^{-\theta s} \left(V - \frac{\omega}{\theta} \right) \right]^{\phi+\frac{1}{2}} ds, \quad J^{(2)}(V, \tau) = 0 \quad (15)$$

$$J^{(3)}(V, \tau) = \frac{1}{2\theta^2} \int_0^\tau (1 - e^{-\theta(\tau-s)})^2 \left[\frac{\omega}{\theta} + e^{-\theta s} \left(V - \frac{\omega}{\theta} \right) \right]^{2\phi} ds \quad (16)$$

$$J^{(4)}(V, \tau) = \left(\phi + \frac{1}{2} \right) \int_0^\tau \left[\frac{\omega}{\theta} + e^{-\theta(\tau-s)} \left(V - \frac{\omega}{\theta} \right) \right]^{\phi+\frac{1}{2}} J^{(6)}(V, \tau) ds \quad (17)$$

$$\text{with } J^{(6)}(V, \tau) ds = \int_0^\tau (e^{-\theta(\tau-s)} - e^{-\theta s}) \left[\frac{\omega}{\theta} + e^{-\theta(\tau-u)} \left(V - \frac{\omega}{\theta} \right) \right]^{\phi-\frac{1}{2}} du \quad (18)$$

Example of Volvol Expansion: Heston Model

We will now show the expansion of volvol for the Heston model (*see Heston Model*). By the asymptotic expansion, we can finally obtain an approximate analytic formula for the European call option. This work comes from the result of Benhamou *et al.* [1]. Consider a Heston model

$$dX_t = \sqrt{v_t} dW_t - \frac{v_t}{2} dt, \quad X_0 = x_0 \quad (19)$$

To expand the model, we add ϵ in the model.

$$dX_t^\epsilon = \sqrt{v_t^\epsilon} dW_t - \frac{v_t^\epsilon}{2} dt, \quad X_0^\epsilon = x_0 \quad (22)$$

$$dv_t^\epsilon = \kappa(\theta_t - v_t^\epsilon)dt + \epsilon \xi_t \sqrt{v_t^\epsilon} dB_t, \quad v_0^\epsilon = v_0 \quad (23)$$

Now, we will expand the European call option price formula with respect to ϵ . Note that, when $\epsilon = 0$, we have a Black-Scholes model; while $\epsilon = 1$, we have a Heston model. We already have the closed

formula of Black–Scholes for $\epsilon = 0$. We expand at $\epsilon = 0$, and let $\epsilon = 1$ to obtain the approximate formula. In mathematical language, this can be written as follows:

$$P_{\text{Heston}} = P_{\text{BS}} + \mathbb{E} \left[\frac{\partial P_{\text{BS}}}{\partial \epsilon} \right] + \frac{1}{2} \mathbb{E} \left[\frac{\partial^2 P_{\text{BS}}}{\partial \epsilon^2} \right] + \mathcal{E} \quad (24)$$

Here, we will take another approximation to simulate the partial derivatives in the above equation by the linear combination of the Greek letters of Black–Scholes. Here, the idea is that use of the chain rule in the derivative can result in $\frac{\partial P_{\text{BS}}}{\partial \epsilon} = \frac{\partial P_{\text{BS}}}{\partial S} \frac{\partial S}{\partial \epsilon} + \frac{\partial P_{\text{BS}}}{\partial \sigma} \frac{\partial \sigma}{\partial \epsilon}$. The same idea holds for the second derivative.

$$P_{\text{Heston}} = P_{\text{BS}}(x_0, \text{var}_T) + \sum_{i=1}^2 a_{i,T} \frac{\partial^{i+1} P_{\text{BS}}}{\partial x^i y} (x_0, \text{var}_T) + \sum_{i=0}^1 b_{2i,T} \frac{\partial^{2i+2} P_{\text{BS}}}{\partial x^{2i} y^2} (x_0, \text{var}_T) + \mathcal{E} \quad (25)$$

We refer to [1] for proofs and intermediate derivation. The parameters in the formula are as follows:

$$\begin{aligned} \text{var}_T &= m_0 v_0 + m_1 \theta, \quad a_{1,T} = \rho \xi (p_0 v_0 + p_1 \theta) \\ a_{2,T} &= (\rho \xi)^2 (q_0 v_0 + q_1 \theta), \quad b_{0,T} = \xi^2 (r_0 v_0 + r_1 \theta) \end{aligned} \quad (26)$$

$$\text{var}_T = \int_0^T v_{0,t} dt \quad (27)$$

$$m_0 = \frac{e^{-\kappa T} (-1 + e^{\kappa T})}{\kappa},$$

$$m_1 = T - \frac{e^{-\kappa T} (-1 + e^{\kappa T})}{\kappa},$$

$$p_0 = \frac{e^{-\kappa T} (-\kappa T + e^{\kappa T} - 1)}{\kappa^2},$$

$$p_1 = \frac{e^{-\kappa T} (\kappa T + e^{\kappa T} (\kappa T - 2) + 2)}{\kappa^2},$$

$$q_0 = \frac{e^{-\kappa T} (-\kappa T (\kappa T + 2) + 2e^{\kappa T} - 2)}{2\kappa^3},$$

$$q_1 = \frac{e^{-\kappa T} (2e^{\kappa T} (\kappa T - 3) + \kappa T (\kappa T + 4) + 6)}{2\kappa^3},$$

$$r_0 = \frac{e^{-2\kappa T} (-4e^{\kappa T} \kappa T + 2e^{2\kappa T} - 2)}{4\kappa^3},$$

$$r_1 = \frac{e^{-2\kappa T} (4e^{\kappa T} (\kappa T + 1) + e^{2\kappa T} (2\kappa T - 5) + 1)}{4\kappa^3} \quad (28)$$

The advantage is that there is no integration in the approximate formula. So the calculations are done much faster than in the exact formula. We will discuss this point in the section Numerical Results.

The error in the approximation is estimated as $\mathcal{E} = O([\xi_{\text{Sup}} \sqrt{T}]^3 \sqrt{T})$.

Numerical Results

We test the approximate formula with the following strikes. We take strikes from 70% to 130% for short maturity and 10% to 730% for long maturity. Implied Black–Scholes volatilities of the closed formula, of the approximation formula, and related errors (in bp), are expressed as a function of maturities in fractions of years and relative strikes. The values of the parameters are as follows: $\theta = 6\%$, $\kappa = 3$, $\xi = 30\%$, and $\rho = 0\%$. Except for short maturity plus very small strikes, where we observe the largest difference (18.01 bp); the difference is less than 5 bp (1 bp = 0.01%) in almost all other cases. With regard to the speed of calculation, the approximate formula is about 100 times quicker than the exact formula (with the optimization in integral).

Implied Volatility: Long Maturity Behavior

We discuss some properties of implied volatility surfaces (*see Implied Volatility Surface*) for large times to maturity. The key result is that the implied volatility smile flattens at long maturities, independently of the model of the underlying asset price, so long as there exists an equivalent martingale measure. An asymptotic formula for the long implied volatility is given and illustrated by examples from stochastic volatility models. The dynamics of the long implied volatility are shown to be almost surely non-decreasing as a function of calendar time, in complete analogy with the Dybvig *et al.* [2] theorem for long interest rates. For a more in-depth treatment of these issues, consult [3, 4], and [7].

Flattening of the Smile

To set up notation and present the main result, we consider in this section a market in which the riskless interest rate is zero, and the underlying stock pays no dividends. The results described here are valid for price processes with either continuous or discontinuous sample paths, or even discrete-time models.

We let $S = (S_t)_{t \geq 0}$ be a nonnegative martingale with $S_0 > 0$ modeling the price of a given stock under a fixed risk-neutral measure. All calculations will be performed with respect to this measure, so we do not include it in the notation.

Introduce a function $C_{BS} : \mathbb{R} \times [0, \infty) \rightarrow [0, 1)$ by

$$C_{BS}(k, v) = \begin{cases} \Phi\left(-\frac{k}{\sqrt{v}} + \frac{\sqrt{v}}{2}\right) - e^k \Phi\left(-\frac{k}{\sqrt{v}} - \frac{\sqrt{v}}{2}\right) & \text{if } v > 0 \\ (1 - e^k)^+ & \text{if } v = 0 \end{cases} \quad (1)$$

where $a^+ = \max\{a, 0\}$ denotes the positive part of the real number a as usual. Since $v \mapsto C_{BS}(k, v)$ is strictly increasing for each $k \in \mathbb{R}$, we now define the Black-Scholes implied volatility $\Sigma(k, T)$ for log moneyness k and maturity T as the unique

nonnegative solution to the equation

$$\mathbb{E} \left[\left(\frac{S_T}{S_0} - e^k \right)^+ \right] = C_{BS}(k, T \Sigma(k, T)^2) \quad (2)$$

Note that we are using the convention that the log moneyness k corresponds to the strike $K = S_0 e^k$.

The main result is that the implied volatility smile flattens at long maturities:

Theorem 1 *For any $M > 0$, we have*

$$\lim_{T \rightarrow \infty} \sup_{k_1, k_2 \in [-M, M]} |\Sigma(k_2, T) - \Sigma(k_1, T)| = 0 \quad (3)$$

That the implied volatility smile flattens at long maturities seems to be a folk theorem, and has been verified for various models for which the long implied volatility can be calculated explicitly. The result is sometimes attributed erroneously to the central limit theorem, but it is true in complete generality without any notion of mean reversion of the spot volatility process. Indeed, Theorem 1 contains no assumption on the dynamics of the stock price other than that it is a nonnegative martingale. Also note that we have not even assumed that $\lim_{T \rightarrow \infty} \Sigma(k, T)$ exists for any k .

A proof of the flattening of the implied volatility smile under some mild regularity assumptions appears in [1]. A proof of Theorem 1 in the form that it appears here can be found in [9].

It turns out that the rate of flattening can be precisely bounded:

Theorem 2

1. *For any $0 \leq k_1 < k_2$, we have*

$$\frac{\Sigma(k_2, T)^2 - \Sigma(k_1, T)^2}{k_2 - k_1} \leq \frac{4}{T} \quad (4)$$

2. *For any $k_1 < k_2 \leq 0$, we have*

$$\frac{\Sigma(k_2, T)^2 - \Sigma(k_1, T)^2}{k_2 - k_1} \geq -\frac{4}{T} \quad (5)$$

3. *If $S_t \rightarrow 0$ in probability as $t \rightarrow \infty$, for any $M > 0$, we have*

$$\limsup_{T \rightarrow \infty} \sup_{\substack{k_1, k_2 \in [-M, M] \\ k_1 \neq k_2}} T \left| \frac{\Sigma(k_2, T)^2 - \Sigma(k_1, T)^2}{k_2 - k_1} \right| \leq 4 \quad (6)$$

The inequality in part 3 of Theorem 2 is sharp, as there exists a martingale $(S_t)_{t \geq 0}$ such that $S_t \rightarrow 0$ in probability and such that

$$T \frac{\partial}{\partial k} \Sigma(k, T)^2 \rightarrow -4 \quad (7)$$

as $T \rightarrow \infty$ uniformly for $k \in [-M, M]$. A proof of Theorem 2 is in [9].

Remark The condition $S_t \rightarrow 0$ in probability appearing in part 3 of Theorem 2 has a natural financial interpretation. Indeed, we have $S_t \rightarrow 0$ in probability (equivalently, almost surely) if and only if $C(K, T) \rightarrow S_0$ as $T \rightarrow \infty$ for some $K > 0$ (equivalently, for all $K > 0$) where

$$C(K, T) = \mathbb{E}[(S_T - K)^+] \quad (8)$$

is the price of a European call option. Since the long maturity call prices converge to stock price in many models of interest (including, of course, the Black–Scholes model), we see that the assumption $S_t \rightarrow 0$ is not particularly onerous.

In fact, since $(S_t)_{t \geq 0}$ is a nonnegative martingale, it must converge almost surely to some random variable S_∞ by the martingale convergence theorem. If $S_\infty > 0$ with positive probability, then $\lim_{T \rightarrow \infty} \sqrt{T} \Sigma(k, T)$ exists and is finite for each k , and hence $\lim_{T \rightarrow \infty} \Sigma(k, T) = 0$.

A Representation Formula

Now that we know that the volatility smile flattens in the limit as the maturity goes to infinity, we can study the behavior of the long implied volatility.

Theorem 3 *For any $M > 0$, we have*

$$\lim_{T \rightarrow \infty} \sup_{k \in [-M, M]} \left| \Sigma(k, T) - \left(-\frac{8}{T} \log \mathbb{E}[S_T \wedge 1] \right)^{1/2} \right| = 0 \quad (9)$$

where $a \wedge b = \min\{a, b\}$ as usual. In particular, we have the following representation formula

$$\Sigma(\infty) = \lim_{T \rightarrow \infty} \left(-\frac{8}{T} \log \mathbb{E}[S_T \wedge 1] \right)^{1/2} \quad (10)$$

whenever the limit exists.

Formula (10) of Theorem 3 can be found, for instance, in [8]. It can be used to calculate the long implied volatility for some examples.

Example (Exponential Lévy Models (see **Exponential Lévy Models**)). The simple inequality

$$\mathbb{1}_{[1, \infty)}(x) \leq x \wedge 1 \leq x^p \quad (11)$$

which holds for all $0 \leq p \leq 1$ and $x \geq 0$, gives the bound

$$\limsup_{T \rightarrow \infty} \sup_{p \in [0, 1]} \left(-\frac{8}{T} \log \mathbb{E}[S_T^p] \right)^{1/2} \leq \Sigma(\infty) \leq \liminf_{T \rightarrow \infty} \left(-\frac{8}{T} \log \mathbb{P}[S_T \geq 1] \right)^{1/2} \quad (12)$$

If $(\log(S_t))_{t \geq 0}$ has independent identically distributed increments, then the above bounds hold with equality by the large deviation principle. Indeed, let $(L_t)_{t \geq 0}$ be a Lévy process with cumulant-generating function

$$\Lambda(p) = \log \mathbb{E}(e^{pL_1}) \quad (13)$$

such that $\Lambda(1) < \infty$, and model the stock price by the martingale $S_t = e^{L_t - t\Lambda(1)}$. Then the long implied volatility satisfies

$$\Sigma(\infty)^2 = 8 \sup_{p \in [0, 1]} \{p\Lambda(1) - \Lambda(p)\} \quad (14)$$

which is eight times the Legendre transform of the cumulant generating function evaluated at $\Lambda(1)$.

Example (*Stochastic volatility model.*) Lewis [8] has proposed a saddle-point approximation method for calculating long implied volatility in stochastic volatility models. For instance, suppose that the asset price satisfies the following system of stochastic differential equations:

$$dS_t = S_t \sqrt{V_t} dW_t \quad (15)$$

$$dV_t = \kappa(\theta - V_t) dt + \eta \sqrt{V_t} dZ_t \quad (16)$$

where κ , θ , and η are real constants, and $(W_t)_{t \geq 0}$ and $(Z_t)_{t \geq 0}$ are correlated standard Wiener processes with $\langle W, Z \rangle_t = \rho t$. Lewis [8] has shown that the long implied volatility is given by the following formula:

$$\Sigma(\infty)^2 = \frac{4\kappa\theta}{(1 - \rho^2)\eta^2} \times \left[\sqrt{(2\kappa - \rho\eta)^2 + (1 - \rho^2)\eta^2} - (2\kappa - \rho\eta) \right] \quad (17)$$

See [5] for further asymptotics of stochastic volatility models based on this method, and see [4] for asymptotics based on perturbation methods.

Long Implied Volatility Cannot Fall

In many models of interest, the long implied volatility, if it exists, is constant as a function of the calendar time. However, the long implied volatility need not be a constant in general. In this section, we consider the dynamics of the long implied volatility, and in fact, we will see that the long implied volatility can never fall. In this section, we also assume that the stock price is strictly positive, rather than merely non-negative. We define the implied volatility $\Sigma_t(k, \tau)$ for log moneyness k and time to maturity τ as the unique nonnegative $\mathcal{F}_t$ -measurable random variable that satisfies

$$\mathbb{E} \left[\left(\frac{S_{t+\tau}}{S_t} - e^k \right)^+ \right] = C_{BS}(k, \tau \Sigma_t(k, \tau)^2) \quad (18)$$

The following theorem was proved in [9].

Theorem 4 For all k_1, k_2 and $0 \leq s \leq t$ we have

$$\limsup_{\tau \rightarrow \infty} \Sigma_t(k_1, \tau) - \Sigma_s(k_2, \tau) \geq 0 \quad (19)$$

almost surely.

This result is an exact analog of the Dybvig–Ingersoll–Ross theorem that long zero-coupon rates never fall. See [6] for a nice proof of this fact.

Extensions

The previous discussion has considered the case where the stock pays no dividend and the risk-free interest rate is zero. In the general case, a stock pays a dividend and there is a cost to borrow money. The situation is usually modeled as follows. Let S_t be the stock price, let D_t be the cumulative dividends, and let B_t be the price of a numéraire asset such as a bank account at time t . There is no arbitrage if there exists a probability measure such that the process

$$\frac{S_t}{B_t} + \int_0^t \frac{dD_s}{B_s} \quad (20)$$

is a martingale. In the case of proportional continuous dividends $dD_t = \delta S_t dt$ and constant interest rate

$dB_t = r B_t dt$, there is no arbitrage if $\tilde{S}_t = S_t e^{(\delta-r)t}$ defines a martingale. In this case, everything from above applies if we define the implied volatility by

$$\mathbb{E} \left[\left(\frac{\tilde{S}_T}{\tilde{S}_0} - e^k \right)^+ \right] = C_{BS}(k, T \Sigma(k, T)^2) \quad (21)$$

where the log-moneyness parameter k now corresponds to the strike $K = S_0 e^{k+(r-\delta)T}$.

However, it is unclear which of the above results can be suitably extended to the general case with arbitrary increasing adapted processes $(D_t)_{t \geq 0}$ and $(B_t)_{t \geq 0}$.

MICHAEL R. TEHRANCHI

SABR Model

The SABR model [4] is a stochastic volatility (*see Stochastic Volatility Models*) model in which the forward asset price follows the dynamics in a forward measure $\mathbb{P}^T$:

$$df_t = a_t C(f_t) dW_t \quad (1)$$

$$da_t = \nu a_t dZ_t, \quad \alpha \equiv a_0 \quad (2)$$

$$dW_t dZ_t = \rho dt, \quad C(f) \equiv f^\beta, \quad \beta \in [0, 1) \quad (3)$$

The stochastic volatility a_t , is described by a geometric Brownian motion. The model depends on four parameters: α , ν , ρ , and β . By using singular perturbation techniques, Hagan *et al.* [4] obtained a closed-form formula for the implied volatility $\sigma_{BS}(\tau, K)$, at the first-order in the maturity τ . Here, we display a corrected version of the formula [8]:

$$\sigma_{BS}(\tau, K) = \frac{\nu \ln \frac{f_0}{K}}{\hat{x}(\zeta)} (1 + \sigma_1(f_{av})\tau) \quad (4)$$

with

$$\begin{aligned} \hat{x}(\zeta) &= \ln \left(\frac{\sqrt{1 - 2\rho\zeta + \zeta^2} - \rho + \zeta}{1 - \rho} \right) \\ \zeta &= \frac{\nu}{\alpha} \int_K^{f_0} \frac{dx}{C(x)}, \quad f_{av} = \sqrt{f_0 K} \\ \sigma_1(f) &= \frac{\alpha \nu \partial_f C(f) \rho}{4} + \frac{2 - 3\rho^2}{24} \nu^2 + \frac{(\alpha C(f))^2}{24} \\ &\quad \times \left(\frac{1}{f^2} + \frac{2\partial_{ff} C(f)}{C(f)} - \left(\frac{\partial_f C(f)}{C(f)} \right)^2 \right) \end{aligned} \quad (5)$$

Though this formula is popular, volatility does not mean-revert in the underlying SABR model, so for given α , ν , β , and ρ , the SABR formula cannot simultaneously calibrate to the implied volatility smile at more than one expiry.

By mapping Hagan *et al.*'s computations into a geometrical framework based on the heat kernel expansion, approximate implied volatility formulae may be derived for more general stochastic volatility models (SVMs), in particular for the models where

volatility mean-reverts. The use of geometrical methods in quantitative finance originates from [1, 2] and was investigated in detail in [5, 6, 7].

A More General Stochastic Process

In the following, we will assume arbitrary local volatility functions $C(\cdot)$ and a general time-homogeneous one-dimensional stochastic differential equation (SDE) for the stochastic volatility process

$$da_t = b(a_t) dt + \sigma(a_t) dZ_t \quad (6)$$

In principle, $b(\cdot)$ and $\sigma(\cdot)$ could depend on the forward f as well, but the models we are interested in here do not exhibit this additional dependence.

This strategy for computing the short-time implied volatility asymptotics induced by the SVM involves two main steps:

- Derive the short-time limit of the *effective* local volatility function. The computation involves the use of the heat kernel expansion.
- Derive an approximate expression for the implied volatility corresponding to this effective local volatility function.

Effective Local Volatility Model

The square of the Dupire effective local volatility function (*see Model Calibration*) [3] is equal to the mean of the square of the stochastic volatility when the forward is fixed to the strike

$$\begin{aligned} \sigma_{loc}(t, K)^2 &= C(K)^2 \mathbb{E}^{\mathbb{P}}[a_t^2 | f_t = K] \\ &= C(K)^2 \frac{\int_{-\infty}^{\infty} a^2 p(t, K, a | f_0, \alpha) da}{\int_{-\infty}^{\infty} p(t, K, a | f_0, \alpha) da} \end{aligned} \quad (7)$$

where $p(t, K, a | f, \alpha)$ is the conditional probability density for the forward and the volatility at time t . As we now proceed to explain, $p(t, K, a | f, \alpha)$ is the fundamental solution of a heat kernel equation depending on two important geometrical quantities: first a metric tensor in equation (9), which is the inverse of the local covariance matrix and second an

Abelian connection in equation (10) which depends on the drift $b(a)$.

Heat Kernel Expansion

A short-time expansion of the density for a multi-dimensional $It\hat{o}$ diffusion process can be obtained using the heat kernel expansion: the Kolmogorov equation is rewritten as a heat kernel equation on an n -dimensional Riemannian manifold endowed with an Abelian connection as explained in [7].

Suppose the stochastic equations are written as

$$dx^\mu = b^\mu(x) dt + \sigma^\mu(x) dW^\mu \quad (8)$$

with $dW^\mu dW^\nu = \rho_{\mu\nu} dt$. The associated metric $g_{\mu\nu}$ depends only on the diffusion terms σ_μ , while the connection $\mathcal{A}_\mu(x)$ involves drift terms b^μ as well:

$$\begin{aligned} g_{\mu\nu}(x) &= 2 \frac{\rho^{\mu\nu}}{\sigma_\mu(x)\sigma_\nu(x)} \\ \rho^{\mu\nu} &\equiv [\rho^{-1}]_{\mu\nu}, \quad \mu, \nu = 1 \cdots n \\ \mathcal{A}^\mu(x) &= \frac{1}{2} \left(b^\mu(x) - g^{-\frac{1}{2}} \partial_\nu (g^{1/2} g^{\mu\nu}(x)) \right) \end{aligned} \quad (9)$$

with

$$g(x) \equiv \det[g_{\mu\nu}(x)] \quad (10)$$

Here, we have used the Einstein convention meaning that two repeated indices are implicitly summed. We set

$$\mathcal{A}_\mu(x) = g_{\mu\nu}(x) \mathcal{A}^\nu(x) \quad (11)$$

The asymptotic solution to the Kolmogorov equation in the short-time limit is given by

$$\begin{aligned} p(t, x|x_0) &= \frac{\sqrt{g(x)}}{(4\pi t)^{\frac{n}{2}}} \sqrt{\Delta(x)} \mathcal{P}(x^0, x) e^{-\frac{d(x)^2}{4t}} \\ &\times \sum_{n=1}^{\infty} a_n(x) t^n \end{aligned} \quad (12)$$

- $d(x)$ is the geodesic distance between x and x^0 measured in the metric $g_{\mu\nu}$. $d(x)$ is defined as

the minimizer of

$$d(x)^2 = \min_{\mathcal{C}} \int_0^1 g_{\mu\nu} \frac{dx^\mu}{d\lambda} \frac{dx^\nu}{d\lambda} d\lambda \quad (13)$$

where λ parameterizes the curve $\mathcal{C}(x^0, x)$ joining $x(\lambda = 0) \equiv x^0$ and $x(\lambda = 1) \equiv x$.

- $\Delta(x)$ is the so-called Van Vleck-Morette determinant:

$$\Delta(x) = g(x)^{-\frac{1}{2}} \det \left(-\frac{\partial^2 d(x)^2}{2\partial x \partial x^0} \right) g(x^0)^{-\frac{1}{2}} \quad (14)$$

- $\mathcal{P}(x^0, x)$ is the parallel transport of the Abelian connection along the geodesic $\mathcal{C}(x^0, x)$ from the point x^0 to x :

$$\mathcal{P}(x^0, x) = e^{-\int_{\mathcal{C}(x^0, x)} \mathcal{A}_\mu(x) dx^\mu} \quad (15)$$

- The $a_i(x)$ coefficients ($a_0(x) = 1$) are smooth functions and depend on geometric invariants such as the scalar curvature. More details can be found in [7].

The Short-time Limit

Plugging the general short-time limit for p at the first-order in time as given by equation (12) in equation (7) and using a saddle-point approximation for the integration over a , we obtain the short-time limit of the effective local volatility function.

Getting implied volatility from the effective local volatility function boils down to calculating the geodesic distance between any two given points in the metric defined by the SVM. While this is generally a nontrivial task, the geodesic distance is known analytically in the special case of the geometry associated with the SVM defined by equations (1) and (6). Details are given in [7].

Asymptotic Implied Volatility

Applying these techniques, we find that the general asymptotic implied volatility at the first order for any

time-homogeneous SVM, depending implicitly on the metric g_{ij} (9) and the connection $\mathcal{A}_i$ (10) is given by

$$\begin{aligned} \sigma_{BS}(\tau, K) = & \frac{\ln \frac{K}{f_0}}{\int_{f_0}^K \frac{df'}{\sqrt{2g^{ff}}}} \left(1 + \frac{g^{ff} \tau}{12} \right. \\ & \left(-\frac{3}{4} \left(\frac{\partial_f g^{ff}}{g^{ff}} \right)^2 + \frac{\partial_f^2 g^{ff}}{g^{ff}} + \frac{1}{f_{av}^2} \right) \\ & + \frac{g^{ff'} \tau}{2g^{ff} \phi''(a_{\min})} \\ & \left. \left(\ln(\Delta g \mathcal{P}^2)'(a_{\min}) - \frac{\phi'''(a_{\min})}{\phi''(a_{\min})} + \frac{g^{ff''}}{g^{ff'}} \right) \right) \end{aligned} \quad (16)$$

with $a_{\min}$ the volatility a , which minimizes the geodesic distance $d(a, f_{av} | \alpha, f_0)$. The g^{ff} are the ff -components of the inverse metric evaluated at $a_{\min}$. Δ is the Van Vleck–Morette determinant as in equation (14), g is the determinant of the metric, and $\mathcal{P}$ is the parallel gauge transport as in equation (15). The prime symbol $'$ indicates a derivative according to a . This formula in equation (16) is particularly useful as we can use it to rapidly calibrate any given SVM. In the following, we apply it to the SABR model with an arbitrary local volatility $C(\cdot)$.

Improved SABR Formula

The asymptotic implied volatility in the SABR model with arbitrary local volatility $C(\cdot)$ is then given by

$$\sigma_{BS}(\tau, K) = \frac{\ln \frac{K}{f_0}}{\sigma(K)} (1 + \sigma_1(f_{av}) \tau) \quad (17)$$

with

$$\begin{aligned} \sigma_1(f) = & \frac{\alpha \nu \rho}{4} \partial_f C(f) \frac{\sinh(d(f))}{d(f)} + \frac{(C(f) a_{\min})^2}{24} \\ & \left(\frac{1}{f^2} + \frac{2 \partial_{ff} (C(f) a_{\min})}{C(f) a_{\min}} \right. \\ & \left. - \left(\frac{\partial_f (C(f) a_{\min})}{C(f) a_{\min}} \right)^2 \right) \end{aligned} \quad (18)$$

with

$$\begin{aligned} \sigma(f) = & \frac{1}{\nu} \\ & \times \ln \left(\frac{q \nu + \alpha \rho + \sqrt{\alpha^2 + q^2 \nu^2 + 2q \alpha \nu \rho}}{\alpha(1 + \rho)} \right) \\ q = & \int_{f_0}^f \frac{dx}{C(x)} \\ a_{\min}(f) = & \sqrt{\alpha^2 + 2\alpha \nu \rho q + \nu^2 q^2} \\ d(f) = & \cosh^{-1} \left(\frac{-q \nu \rho - \alpha \rho^2 + a_{\min}(f)}{\alpha(1 - \rho^2)} \right) \end{aligned} \quad (19)$$

The original SABR formula (6) can be reproduced by approximating $a_{\min}$ for strikes near the money by

$$a_{\min} \simeq \alpha + q \rho \nu$$

and

$$\frac{\sinh(d(a_{\min}))}{d(a_{\min})} \simeq 1 \quad (20)$$

An asymptotic formula for a SABR model with a mean-reversion term, called λ -SABR, has been obtained similarly in [7].

Calibration of the Short-term Smile

Moreover, by inverting equation (17) to lowest order in τ , we see that for any values α , ρ , and ν , a given short-term smile $\sigma_{BS}(f)$ is calibrated by construction if the local volatility function is chosen as

$$\begin{aligned} C(f) = & \frac{f \sigma_{BS}(f) \left(1 - f \ln \left(\frac{f}{f_0} \right) \frac{\sigma'_{BS}(f)}{\sigma_{BS}(f)} \right)^{-1}}{\alpha \sqrt{1 - \rho^2} \cosh \left(\frac{\rho}{|\rho|} \nu \frac{\ln \left(\frac{f}{f_0} \right)}{\sigma_{BS}(f)} + \cosh^{-1} \left(\frac{1}{\sqrt{1 - \rho^2}} \right) \right)} \end{aligned} \quad (21)$$

PIERRE HENRY-LABORDÈRE

Implied Volatility: Large Strike Asymptotics

Let S_t be the price of a risky asset at time $t \in [0, T]$ and $B_t = B(t, T)$ the time- t value of one monetary unit received at time T . Assuming suitable no-arbitrage conditions, there exists a probability measure $\mathbb{P} = \mathbb{P}_T$, called the *(T -forward) pricing measure*, under which the B_t -discounted asset price

$$F_t = F(t, T) = S(t) / B(t, T) \quad (1)$$

is a martingale and so are B_t -discounted time- t option prices, such as $C_t / B(t, T)$, where C_t denotes the time- t value of a European call option with maturity T and payoff $(S_T - K)^+$. With focus on $t = 0$ and writing C instead of C_0 , we have

$$C = B(0, T) \mathbb{E} [C_T / B(T, T)] \quad (2)$$

$$\begin{aligned} &= B(0, T) \mathbb{E} [(F_T - K)^+] \\ &= S_0 \mathbb{E} \left[\left(\frac{F_T}{F_0} - \frac{K}{F_0} \right)^+ \right] \end{aligned} \quad (3)$$

Let us remark that in the case of deterministic interest rates $r(\cdot)$, one can rewrite this as^a

$$C = \mathbb{E} \left[\exp \left(- \int_0^T r(u) du \right) (S_T - K)^+ \right] \quad (4)$$

If we now make the assumption that there exists $\sigma > 0$, the *Black–Scholes volatility*, such that F_t satisfies

$$dF_t = \sigma F_t dW \quad (5)$$

where W is a Brownian motion under $\mathbb{P}$, then we have *normal returns* $X_{BS} := \log(F_T / F_0)$. More precisely,

$$X_{BS} \sim \text{Normal}(-V^2/2, V^2) \text{ with } V \equiv \sigma\sqrt{T} \quad (6)$$

and an elementary integration of equation (3) yields the classical Black–Scholes formula,^b

$$C_{BS} = S_0 \left\{ \Phi(d_1) - \frac{K}{F_0} \Phi(d_2) \right\} \quad (7)$$

with $d_{1,2} = -\log(K/F_0)/V \pm V/2$. It follows that we can express the *normalized Black–Scholes call price*

$$c_{BS} := C_{BS} / S_0 \quad (8)$$

as a function of two variables: *log-strike* $k := \log(K/F_0)$ and (scaled) *Black–Scholes volatility* $V = \sigma\sqrt{T}$,

$$\begin{aligned} c_{BS}(k, V) &= \Phi(d_1) - e^k \Phi(d_2) \\ \text{with } d_{1,2} &= -k/V \pm V/2 \end{aligned} \quad (9)$$

Let us now return to the general setting and just assume that, for fixed T , the *returns*

$$X := \log \frac{F_T}{F_0} \quad (10)$$

have a known distribution, fully specified by the probability distribution function

$$F(x) := \mathbb{P}[X \leq x] \quad (11)$$

From equation (2), the value of a normalized call price $c = C/S_0$ is then given by

$$\begin{aligned} \mathbb{E} \left[\left(\frac{F_T}{F_0} - e^k \right)^+ \right] &= \int_{-\infty}^{\infty} (e^x - e^k)^+ dF(x) \\ &=: c(k) \end{aligned} \quad (12)$$

Definition 1 (Implied volatility). *Let $T > 0$ be a fixed maturity and assume F is the distribution function of the returns $\log(F_T/F_0)$ under the pricing measure. Then, the scaled (Black–Scholes) implied volatility is the unique value $V(k)$ such that*

$$c(k) = c_{BS}(k, V(k)) \text{ for all } k \in \mathbb{R} \quad (13)$$

We also write $\sigma(k, T) := V(k)/\sqrt{T}$ for the (annualized, Black–Scholes) implied volatility.

By the very definition, the volatility smile $V(\cdot, T)$ is flat, namely constant equal to $V = \sigma\sqrt{T}$, in the Black–Scholes model. To see existence/uniqueness of implied volatility, in general, it suffices to note that $c_{BS}(k, \cdot)$ is strictly increasing in the volatility parameter and that

$$\begin{aligned} c_{BS}(k, V = 0) &= (1 - e^k)^+ \leq \mathbb{E} \left[(F_T/F_0 - e^k)^+ \right] = c(k) \\ c(k) &\leq \mathbb{E} [F_T/F_0] = 1 = c_{BS}(k, V = +\infty) \end{aligned} \quad (14)$$

$$c(k) \leq \mathbb{E} [F_T/F_0] = 1 = c_{BS}(k, V = +\infty) \quad (15)$$

It is clear from the afore mentioned monotonicity of $c_{BS}(k, \cdot)$ that the fatness of the tail of the returns, for example, the behavior of

$$\bar{F}(k) = 1 - F(k) = \mathbb{P}[X > k] \text{ as } k \rightarrow \infty \quad (16)$$

is related to the shape of the “wing” of the implied volatility (smile) for far-out-of-the-money calls, $V(k)$ as $k \rightarrow \infty$, and similarly, for $F(k)$, $V(k)$ as $k \rightarrow -\infty$. Surprisingly, perhaps, this link can be made very explicit. Let us agree that if F admits a density, it is denoted by $f = F'$. Let us also adopt the common convention that

$$g(k) \sim h(k) \text{ means } g(k)/h(k) \rightarrow 1 \text{ as } k \rightarrow \infty \quad (17)$$

The (meta) result is the following *tail-wing formula*: as $k \rightarrow \infty$ we have

$$\begin{aligned} V(k)^2/k &\sim \psi[-1 - \log \bar{F}(k)/k] \\ &\sim \psi[-1 - \log f(k)/k] \end{aligned} \quad (18)$$

$$\begin{aligned} V(-k)^2/k &\sim \psi[-\log F(-k)/k] \\ &\sim \psi[-\log f(-k)/k] \end{aligned} \quad (19)$$

where

$$\psi(x) \equiv 2 - 4 \left(\sqrt{x^2 + x} - x \right) \quad (20)$$

An interesting special case arises when either

$$p^* = \sup \{ p \in \mathbb{R} : M(1+p) < \infty \} \quad (21)$$

$$q^* = \sup \{ q \in \mathbb{R} : M(-q) < \infty \} \quad (22)$$

is finite, where M is the *moment generating function* of F , and this is equivalent to *moment explosion* of the underlying since

$$M(u) := \int e^{ux} dF(x) = \frac{1}{F_0^u} \mathbb{E}[F_T^u] = \frac{1}{F_0^u} \mathbb{E}[S_T^u] \quad (23)$$

In this case, one expects an exponential tail so that

$$-\log \bar{F}(k) \sim (p^* + 1)k \quad (24)$$

$$-\log F(-k) \sim q^*k \quad (25)$$

and one is led to *Lee's moment formula*

$$V(k)^2/k \sim \psi(p^*)$$

$$V(-k)^2/k \sim \psi(q^*) \quad (26)$$

Recall that $g(k) \sim h(k)$ stands for the precise mathematical statement that $\lim g(k)/h(k) \rightarrow 1$ as $k \rightarrow \infty$. In the same spirit, let us agree that

$$g(k) \lesssim h(k) \text{ means } \limsup g(k)/h(k) \rightarrow 1 \text{ as } k \rightarrow \infty \quad (27)$$

Proposition 1 (Lee's Moment Formula; [3, 8]). *Assume $\mathbb{E}[e^X] = \mathbb{E}[S_T]/F_0 < \infty$. The moment formula then holds in complete generality in “limsup” form. More precisely, as $k \rightarrow \infty$,*

$$V(k)^2/k \lesssim \psi(p^*) \quad (28)$$

$$V(-k)^2/k \lesssim \psi(q^*) \quad (29)$$

The power of the moment formula comes from the fact that the critical exponents p^*, q^* can often be obtained by sheer inspection of a moment generating function known in closed form. One can also make use of the recent literature on moment explosions to obtain such critical exponents in various stochastic volatility models; *see Moment Explosions* and the references therein. Let us note that it is possible [4] to construct (pathological) examples to see that one cannot hope for a genuine limit form of the above moment formula, as was suggested in (26). Another remark is that the moment formula provides little information in the absence of moment explosion. For instance, $p^* = +\infty$ only implies $V(k)^2 = o(k)$ but gives no further information about the behavior of $V(k)$ for large k . Both the issues are dealt with by the tail-wing formula. The key assumptions is a certain well behavedness of F ; but only on a crude logarithmic scale and, therefore, rather easy to check in many examples.

Definition 2 (Regular Variation; [5]). *A positive, real-valued function f , defined at least on $[M, \infty)$ for some large M , is said to be regularly varying of index α if for all $\lambda > 0$*

$$f(\lambda k) \sim \lambda^\alpha f(k) \text{ as } k \rightarrow \infty \quad \forall \lambda > 0 \quad (30)$$

and in this case we write $f \in R_\alpha$.

Theorem 1 (Right-hand Tail-wing Formula; [2]). Assume $\exists \epsilon > 0 : \mathbb{E}[e^{(1+\epsilon)X}] = \mathbb{E}[S_T^{1+\epsilon}] / F_0^{1+\epsilon} < \infty$. Let also $\alpha > 0$ and set

$$\psi(x) \equiv 2 - 4 \left(\sqrt{x^2 + x} - x \right) \quad (31)$$

Then (i) $\implies$ (ii) $\implies$ (iii) $\implies$ (iv) where

- (i) $-\log f(k) \in R_\alpha;$
- (ii) $-\log \bar{F}(k) \in R_\alpha;$
- (iii) $-\log c(k) \in R_\alpha;$

and

$$(iv) \quad V(k)^2/k \sim \psi[-\log c(k)/k].$$

If (ii) holds, then $-\log c(k) \sim -k - \log \bar{F}$ and

$$(iv') \quad V(k)^2/k \sim \psi[-1 - \log \bar{F}(k)/k],$$

if (i) holds, then $-\log f \sim -\log \bar{F}$ and

$$(iv'') \quad V(k)^2/k \sim \psi[-1 - \log f(k)/k].$$

Of course, there is a similar left-hand result, which we state such as to involve far-out-of-the-money (normalized) European puts,

$$p(k) := \int_{-\infty}^{\infty} (e^k - e^x)^+ dF(x) \quad (32)$$

Theorem 2 (Left-hand Tail-wing Formula). Assume $\exists \epsilon > 0 : \mathbb{E}[e^{-\epsilon X}] < \infty$. Then (i) $\implies$ (ii) $\implies$ (iii) $\implies$ (iv) where

- (i) $-\log f(-k) \in R_\alpha;$
- (ii) $-\log F(-k) \in R_\alpha;$
- (iii) $-\log p(-k) \in R_\alpha;$

and

$$(iv) \quad V(-k)^2/k \sim \psi[-1 - \log p(-k)/k].$$

If (ii) holds, then $-\log p(-k) \sim k - \log F(-k)$

and

$$(iv') \quad V(-k)^2/k \sim \psi[-\log F(-k)/k],$$

if (i) holds, then $-\log f(-k) \sim -\log F(-k)$

and

$$(iv'') \quad V(-k)^2/k \sim \psi[-\log f(-k)/k].$$

With focus on the right-hand tail-wing, let us single out two cases of particular importance in applications.

1. **(Asymptotically Linear Regime)** If $-1 - \log f(k)/k$ or $-1 - \log \bar{F}(k)/k$ converges to $p^* \in (0, \infty)$ then

$$V(k)^2 \sim \psi(p^*) \times k \quad (33)$$

and the *implied variance*, defined as the square of implied volatility, is asymptotically linear with slope $\psi(p^*)$. One can, in fact, check this from the moment generating function of X . Indeed, it is shown in [3] that if

$$s \mapsto M(1 + p^* - 1/s) \quad (34)$$

is regularly varying then $-\log f(k)/k \rightarrow p^* + 1$. In other words, to ensure equation (26), that is, a genuine limit in Lee's moment formula, one needs some well behavedness of the M as its argument approaches the critical exponent $1 + p^*$. Similar conditions can be given with M replaced by M' or $\log M$ and these conditions are, indeed, easy to check in a number of familiar exponential Lévy models (including Barndorff-Nielsen's Normal Inverse Gaussian model, Carr-Madan's Variance Gamma model, or Kou's Double Exponential model) and various time changes of these models (see [3] for details).

2. **(Asymptotically Sublinear Regime)** If $-\log f(k)/k \rightarrow \infty$, we can use $\psi(x) \sim 1/(2x)$ as $x \rightarrow \infty$ to see that

$$V(k)^2 \sim \frac{1}{-2 \log f(k)/k} \times k = \frac{k^2}{-2 \log f(k)} \quad (35)$$

so that the implied variance is asymptotically sublinear. As sanity check, consider the Black-Scholes model where f is the density of the (normally distributed) returns with variance $V^2 \equiv \sigma^2 T$, as given in (6); then $-\log f(k) \sim k^2/(2V^2)$ and it follows that $V(k) \sim V$, in trivial agreement with the flat smile in the Black-Scholes model. Following [2], other examples are given by Merton's jump diffusion as a borderline example

in which the sublinear behavior comes from a subtle logarithmic correction term, and *Carr–Wu’s Finite Moment Logstable model*. The tail behavior of the latter, as noted in [2], can be derived from the growth of the (nonexplosive) moment generating function by means of *Kasahara’s Tauberian theorem* [5]. Another example where this methodology works is the SABR model

$$dF = \sigma F^\beta dW, \quad d\sigma = \eta \sigma dZ \quad (36)$$

with $\sigma, \eta > 0, \beta < 1$ and two Brownian motions W, Z assumed (here) to be independent. Using standard stochastic calculus [4], one can give good enough estimates on $\mathbb{E}[|F_T/F_0|^u]$, from above and below, to see that

$$\begin{aligned} \log \mathbb{E}[|F_T/F_0|^u] &= \log \mathbb{E}[\exp(uX)] \\ &\sim \frac{\eta^2 T}{(1-\beta)^2} \frac{u^2}{2} \text{ as } u \rightarrow \infty \end{aligned} \quad (37)$$

From this, Kasahara’s theorem allows to deduce the tail behavior of X , namely

$$-\log \mathbb{P}[X > x] \sim \frac{(1-\beta)^2}{\eta^2 T} \frac{x^2}{2} \quad (38)$$

and the (right hand) tail-wing formula reveals that the implied volatility in the SABR model is asymptotically flat, $\sigma(k, T) \sim \eta/(1-\beta)$ as $k \rightarrow \infty$.

Early contributions in the study of smile asymptotics are [1, 6]. The moment formula appears in [8], the tail-wing formula in [2] with some additional criteria in [3]. A survey on the topic, together with some new examples (including CEV and SABR) is found in [4]. Further developments in the field include the refined asymptotic results of Gulisashvili and Stein [7]; in a simple log-normal stochastic volatility model of the form $dF = \sigma F dW, \quad d\sigma = \eta \sigma dZ$, with two independent Brownian motions W, Z they find

$$\sigma(k, T) \sqrt{T} = \sqrt{2k} - \frac{\log k + \log \log k}{2\eta \sqrt{T}} + O(1) \quad (39)$$

The leading order term $\sqrt{2k}$ says that implied variance grows linearly with slope 2, as one expects in a model with immediate moment explosion.

Constant Elasticity of Variance (CEV) Diffusion Model

The CEV Process

The constant elasticity of variance (CEV) model is a one-dimensional diffusion process that solves a stochastic differential equation (SDE)

$$dS_t = \mu S_t dt + a S_t^{\beta+1} dB_t \quad (1)$$

with the instantaneous volatility $\sigma(S) = aS^\beta$ specified to be a power function of the underlying spot price. The model has been introduced by Cox [7] as one of the early alternative processes to the geometric Brownian motion to model asset prices. Here β is the elasticity parameter of the local volatility, $d\sigma/dS = \beta\sigma/S$, and a is the volatility scale parameter. For $\beta = 0$, the CEV model reduces to the constant volatility geometric Brownian motion process employed in the Black, Scholes, and Merton model. When $\beta = -1$, the volatility specification is that of Bachelier (the asset price has the constant diffusion coefficient, while the logarithm of the asset price has the a/S volatility). For $\beta = -1/2$ the model reduces to the square-root model of Cox and Ross [8].

Cox [7] originally studied the case $\beta < 0$ for which the volatility is a decreasing function of the asset price. This specification captures the leverage effect in the equity markets: the stock price volatility increases as the stock price declines. The result of this inverse relationship between the price and volatility is the implied volatility skew exhibited by options prices in the CEV model with negative elasticity. The elasticity parameter β controls the steepness of the skew (the larger the $|\beta|$, the steeper the skew), while the scale parameter a fixes the at-the-money volatility level. This ability to capture the skew has made the CEV model popular in equity options markets.

Emanuel and MacBeth [14] extended Cox's analysis to the positive elasticity case $\beta > 0$, where the asset price volatility is an increasing function of the asset price. The driftless process with $\mu = 0$ and with positive β is a strict local martingale. It has been applied to modeling commodity prices that exhibit increasing implied volatility skews with the volatility

increasing with the strike price, but care should be taken when working with this model (see the discussion below).

The CEV diffusion has the following boundary characterization (see, e.g., [4] for Feller's boundary classification for one-dimensional diffusions). For $-1/2 \leq \beta < 0$, the origin is an exit boundary, and the process is killed the first time it hits the origin. For $\beta < -1/2$, the origin is a regular boundary point. The SDE (1) does not uniquely specify the diffusion process, and a boundary condition is needed at the origin. In the CEV model, it is specified as a killing boundary. Thus, the CEV process with $\beta < 0$ naturally incorporates the possibility of bankruptcy—the stock price can hit zero with positive probability, at which time the bankruptcy occurs. For $\beta \geq 0$, the origin is an inaccessible natural boundary.

Reduction to Bessel Processes, Transition Density, and Probability of Default

The CEV process is analytically tractable. Its transition probability density and cumulative distribution function are known in closed form.^a It is closely related to Bessel processes and inherits their analytical tractability. The CEV process with drift ($\mu \neq 0$) is obtained from the process without drift ($\mu = 0$) via a scale and time change:

$$S_t^{(\mu)} = e^{\mu t} S_{\tau(t)}^{(0)}, \quad \tau(t) = \frac{(e^{2\mu\beta t} - 1)}{2\mu\beta} \quad (2)$$

Let $\{R_t^{(\nu)}, t \geq 0\}$ be a Bessel process of index ν . Recall that for $\nu \geq 0$, zero is an unattainable entrance boundary. For $\nu \leq -1$, zero is an exit boundary. For $\nu \in (-1, 0)$, zero is a regular boundary. In our application, we specify zero as a killing boundary to kill the process at the first hitting time of zero (see, e.g., [4, pp. 133–134], for a summary of Bessel processes). Before the first hitting time of zero, the CEV process without drift can be represented as a power of a Bessel process:

$$S_t^{(0)} = (a|\beta|R_t^{(\nu)})^{-\frac{1}{\beta}} \quad (3)$$

where $\nu = 1/(2\beta)$.

The CEV transition density is obtained from the well-known expression for the transition density of

the Bessel process (see [4, p. 115, 21, p. 446]). For the driftless process, it is given by

$$p_{(0)}(S_0, S_t; t) = \frac{S_t^{-2\beta-3/2} S_0^{1/2}}{a^2 |\beta| t} I_{|\nu|} \left(\frac{S_0^{-\beta} S_t^{-\beta}}{a^2 \beta^2 t} \right) \times \exp \left(-\frac{S_0^{-2\beta} + S_t^{-2\beta}}{2a^2 \beta^2 t} \right) \quad (4)$$

where I_ν is the modified Bessel function of the first kind of order ν . From equation (2), the transition density with drift is obtained from the density equation (4) according to

$$p_{(\mu)}(S_0, S_t; t) = e^{-\mu t} p_{(0)}(S_0, e^{-\mu t} S_t; \tau(t)) \quad (5)$$

The density (5) was originally obtained by Cox [7] for $\beta < 0$ and by Emanuel and MacBeth [14] for $\beta > 0$ on the basis of the result due to Feller [15].

For $\beta < 0$, in addition to the continuous transition density, we also have a positive probability for the process started at S_0 at time zero to hit zero by time $t \geq 0$ (probability of default or bankruptcy) that is given explicitly by

$$G \left(|\nu|, \frac{\mu S_0^{-2\beta}}{a^2 \beta (e^{2\mu\beta t} - 1)} \right) \quad (6)$$

where $G(\nu, x) = (1/\Gamma(\nu)) \int_x^\infty u^{\nu-1} e^{-u} du$ is the complementary Gamma distribution function. This expression can be obtained by integrating the continuous density (5) from zero to infinity and observing that the result is less than one, that is, the density is defective. The defect is equal to the probability mass at zero equation (6).

While killing the process at zero is desirable for stock price modeling, it may be undesirable in other contexts, where one would prefer the process that stays strictly positive (e.g., in stock index models). A regularized version of the CEV process that never hits zero has been constructed by Andersen and Andreasen [1] (see also [9]). The positive probability of hitting zero comes from the explosion of instantaneous volatility as the process falls toward zero. The regularized version of the CEV process fixes a small value $\epsilon > 0$. For $S > \epsilon$, the volatility is according to the CEV specification. For $S \leq \epsilon$, the volatility is fixed at the constant level $a\epsilon^\beta$. We thus have a sequence of regularized strictly positive processes

indexed by ϵ that converge to the CEV process in the limit $\epsilon \rightarrow 0$.

The CEV process with $\beta > 0$ can similarly be regularized to prevent the volatility explosion as the process tends to infinity by picking a large value $\mathcal{E} > 0$ and fixing the volatility above $\mathcal{E}$ to equal $a\mathcal{E}^\beta$. The regularized processes with $\mu = 0$ are true martingales, as opposed to the failure of the martingale property for the driftless CEV process with $\beta > 0$ and $\mu = 0$, which is only a strict local martingale. The failure of the martingale property for the nonregularized process with $\beta > 0$ can be explicitly illustrated by computing the expectation (using the transition density (5)):

$$\mathbb{E}[S_t] = e^{\mu t} S_0 \left(1 - G \left(\nu, \frac{\mu S_0^{-2\beta}}{a^2 \beta (e^{2\mu\beta t} - 1)} \right) \right) \quad (7)$$

CEV Options Pricing

The closed-form CEV call option pricing formula with strike K , time to expiration T , and the initial asset price S can be obtained in closed form by integrating the call payoff with the risk-neutral CEV density (5) with the risk-neutral drift $\mu = r - q$ (r is the risk-free interest rate and q is the dividend yield). The result can be expressed in terms of the complementary noncentral chi-square distribution function $Q(z; \nu, k)$ ([7] for $\beta < 0$, [14] for $\beta > 0$; see also [11, 22]):

$$C(S; K, T) = e^{-rT} \mathbb{E}[(S_T - K)^+] = \begin{cases} e^{-qT} S Q(\xi; 2\nu, y_0) - e^{-rT} K (1 - Q(y_0; 2(1+\nu), \xi)), & \beta > 0 \\ e^{-qT} S Q(y_0; 2(1+|\nu|), \xi) - e^{-rT} K (1 - Q(\xi; 2|\nu|, y_0)), & \beta < 0 \end{cases} \quad (8)$$

where

$$\xi = \frac{2\mu S^{-2\beta}}{a^2 \beta (e^{2\mu\beta T} - 1)}, \quad y_0 = \frac{2\mu K^{-2\beta}}{a^2 \beta (1 - e^{-2\mu\beta T})} \quad (9)$$

and $S = S_0$ is the initial asset price at time zero. The price of the put option is obtained from the put-call parity relationship:

$$P(S; K, T) = C(S; K, T) + K e^{-rT} - S e^{-qT} \quad (10)$$

The complementary noncentral chi-square distribution function can be expressed as the series of complementary Gamma distribution functions ([22, pp. 214]):

$$Q(z; v, k) = \sum_{n=0}^{\infty} e^{-k/2} \frac{(k/2)^n}{\Gamma(n+1)} G\left(n + \frac{v}{2}, \frac{z}{2}\right) \quad (11)$$

for $k, z > 0$. Further efficient numerical methods to compute the noncentral chi-square cumulative distribution function (CDF) can be found in [3, 12, 13, 22].

The first passage time problem for the CEV diffusion can be solved analytically and, hence, barrier and lookback options can be priced analytically under the CEV process. Davydov and Linetsky [9, 10] obtained the analytical expressions for the Laplace transforms of single- and double-barrier and lookback options pricing formulas in time to expiration. Davydov and Linetsky [10] and Linetsky [18] inverted the Laplace transforms for barrier options and lookback options in terms of eigenfunction expansions, respectively.

Other types of options under the CEV process, such as American options, require numerical treatment. The pricing partial differential equation (PDE) for European options reads as follows:

$$\frac{a^2}{2} S^{2\beta+2} \frac{\partial^2 V}{\partial S^2} + (r - q) S \frac{\partial V}{\partial S} + \frac{\partial V}{\partial t} = r V \quad (12)$$

The early exercise can be dealt with in the same way as for other diffusion models *via* dynamic programming, free boundary PDE formulations, or variational inequality formulations.

Jump-to-Default Extended CEV Model

While the CEV process can hit zero and, as a result, the CEV equity model includes the positive probability of bankruptcy, the term structure of credit spreads in the CEV model is such that the instantaneous credit spread vanishes. There is no element of surprise—the event of default is a hitting time. Moreover, the probability of default is too small for practical applications of modeling stocks of firms other than the highest rated investment grades. Carr and Linetsky [6] extend the CEV model by allowing a jump to default to occur from a positive stock price. They introduce a default

intensity that is an affine function of the instantaneous variance:

$$\lambda(S) = b + c\sigma^2(S) = b + ca^2 S^{2\beta} \quad (13)$$

where $b \geq 0$ is the constant part of the default intensity and $c \geq 0$ is the sensitivity of the default intensity to the instantaneous variance. The predefault stock price follows a diffusion process solving the SDE:

$$dS_t = [\mu + \lambda(S_t)] S_t dt + a S_t^{\beta+1} dB_t \quad (14)$$

The addition of the default intensity in the drift compensates for the jump to default and makes the process with $\mu = 0$ a martingale. The diffusion process with the modified drift (14) and killed at the rate (13) is called *jump-to-default extended constant elasticity of variance (JDCEV) process*. In the JDCEV model, the stock price evolves according to equation (14) until a jump to default arrives, at which time the stock price drops to zero and equity becomes worthless. The jump to default time has the intensity (13).

The JDCEV model can be reduced to Bessel processes similar to the standard CEV model. Consequently, it is also analytically tractable. Closed-form pricing formulas for call and put options and the probability of default can be found in [6]. The first passage time problem for the JDCEV process and the related problem of pricing equity default swaps are solved in [20]. Atlan and Leblanc [2] and Campi *et al.* [5] investigate related applications of the CEV model to hybrid credit–equity modeling.

Volatility Skews and Credit Spreads

Figure 1(a) illustrates the shapes of the term structure of zero-coupon credit spreads in the CEV and JDCEV models, assuming zero recovery. The credit spread curves start at the instantaneous credit spread equal to the default intensity $b + c\sigma_*^2$ (σ_* is the volatility at a reference level S^*).^b The instantaneous credit spreads for the CEV model vanish, while they are positive for the JDCEV model. Figure 1(b) plots the Black–Scholes implied volatility against the strike price in the CEV and JDCEV models (we calculate the implied volatility by equating the price of an option under the Black–Scholes model to the corresponding option price under the (JD)CEV model). One can observe the decreasing and convex implied

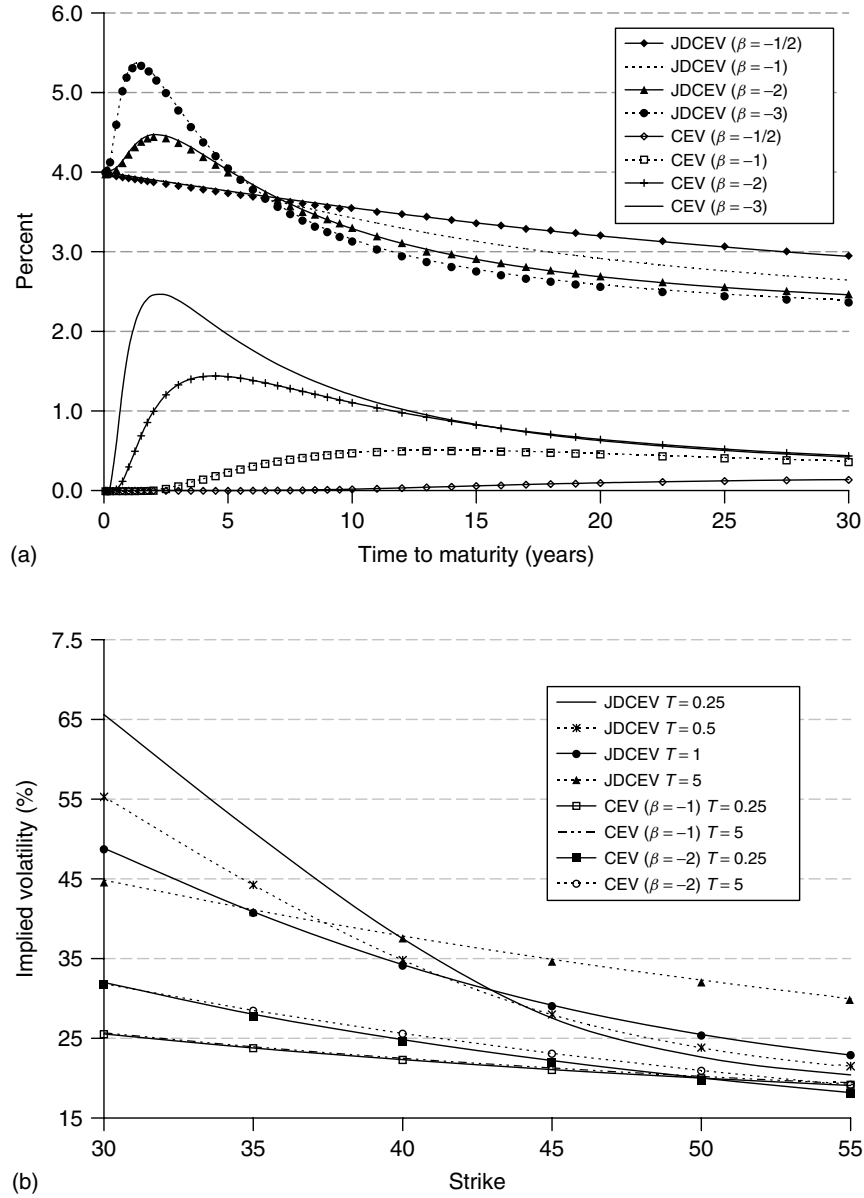

Figure 1 (a) Term structures of credit spreads. Parameter values: $S = S^* = 50$, $\sigma_* = 0.2$, $\beta = -1/2, -1, -2, -3$, $r = 0.05$, $q = 0$. JDCEV: $b = 0.02$ and $c = 1/2$. CEV: $b = 0$ and $c = 0$. (b) Implied volatility skews. Parameter values: $S = S^* = 50$, $\sigma_* = 0.2$, $r = 0.05$, $q = 0$. For JDCEV model: $b = 0.02$, $c = 1/2$ and $\beta = -1$, the times to expiration are $T = 0.25, 0.5, 1, 5$ years. For CEV model: $b = c = 0$, $\beta = -1, -2$ and times to expiration are $T = 0.25, 5$. Implied volatilities are plotted against the strike price

volatility skew with implied volatilities increasing for lower strikes, as the local volatility and the default intensity both increase as the stock price declines. The volatility elasticity β controls the slope of the

skew in the CEV model. The slope of the skew in the JDCEV model is steeper and is controlled by β , as well as the default intensity parameters b and c .

Implied Volatility and the SABR model

By using singular perturbation techniques, Hagan and Woodward [17] obtained explicit asymptotic formulas for the Black–Scholes implied volatility σ_{BS} of European calls and puts on an asset whose forward price $F(t)$ follows the CEV dynamics, that is, $dF_t = aF_t^{\beta+1} dB_t$,

$$\sigma_{BS} = af_{av}^{\beta} \left\{ 1 - \frac{\beta(\beta+3)}{24} \left(\frac{F_0 - K}{f_{av}} \right)^2 + \frac{\beta^2}{24} a^2 \tau f_{av}^{2\beta} + \dots \right\} \quad (15)$$

where τ is time to expiration, $f_{av} = (F_0 + K)/2$ and F_0 is today's forward price (Hagan and Woodward's β is equal to our $\beta + 1$). This asymptotics for the implied volatility approximates the exact CEV-implied volatilities well when the ratio F_0/K is not too far from one and when K and F_0 are far away from zero. The accuracy tends to deteriorate when the values are close to zero since this asymptotic approximation does not take into account the killing boundary condition at zero.

Hagan *et al.* [16] introduced the SABR model, which is a CEV model with stochastic volatility. More precisely, the volatility scale parameter a is made stochastic, so that the forward asset price follows the dynamics:

$$\begin{aligned} dF_t &= a_t F_t^{\beta+1} dB_t^{(1)} \quad \text{and} \\ da_t &= \eta a_t dB_t^{(2)} \end{aligned} \quad (16)$$

where $dB_t^{(1)}, dB_t^{(2)} = \rho dt$. Hagan *et al.* derive the asymptotic expression for the implied volatility in the SABR model.

Introducing Jumps and Stochastic Volatility into the CEV Model

Mendoza *et al.* [19] introduce jumps and stochastic volatility into the JDCEV model by time changing the JDCEV process. Lévy subordinator time changes introduce state-dependent jumps into the process, while absolutely continuous time changes introduce stochastic volatility. The result is a flexible family of models that exhibit the leverage effect, default

intensity linked to the stock price volatility, jumps, and stochastic volatility. These models inherit the analytical tractability of the CEV and JDCEV models as long as the Laplace transform of the time-change process is analytically tractable. The stochastic volatility version of the CEV model obtained in this approach is different from the SABR model in two respects. The advantage of the time-change approach is that it preserves the analytical tractability for more realistic choices for the stochastic volatility process, such as the Cox–Ingersoll–Rand (CIR) process with mean-reversion. Another advantage is that jumps, including the jump to default, can also be incorporated. The weakness is that it is hard to incorporate the correlation between the price and volatility.

End Notes

^aIn this article we present the results for the CEV model with constant parameters. We note that the process remains analytically tractable when μ and a are taken to be deterministic functions of time [6].

^bIt is convenient to parameterize the local volatility function as $\sigma(S) = aS^{\beta} = \sigma_*(S/S^*)^{\beta}$ so that at some reference spot price level $S = S^*$ (e.g., the at-the-money level at the time of model calibration) the volatility takes the reference value, $\sigma(S^*) = \sigma_*$. In the example presented here, the reference level is taken to equal the initial spot price level, $S^* = S_0$, and the volatility scale parameter is $a = \sigma_*/(S_0^{\beta})$.

Bates Model

The Bates [3] and Scott [13] option pricing models were designed to capture two features of the asset returns: the fact that conditional volatility evolves over time in a stochastic but mean-reverting fashion, and the presence of occasional substantial outliers in the asset returns. The two models combined the Heston [9] model of stochastic volatility (*see Heston Model*) with the Merton [11] model of independent normally distributed jumps in the log asset price (*see Jump-diffusion Models*). The Bates model ignores interest rate risk, while the Scott model allows interest rates to be stochastic. Both models evaluate European option prices numerically, using the Fourier inversion approach of Heston (*see also Fourier Transform and Fourier Methods in Options Pricing* for a general discussion of Fourier transform methods in finance). The Bates model also includes an approximation for pricing American options (*see American Options*). The two models were historically important in showing that the tractable class of affine option pricing models includes jump processes as well as diffusion processes.

All option pricing models rely upon a risk-neutral representation of the data generating process that includes appropriate compensation for the various risks. In the Bates and Scott models, the risk-neutral processes for the underlying asset price S_t and instantaneous variance V_t are assumed to be of the form

$$\begin{aligned} dS_t/S_t &= (b - \lambda^* \bar{k}^*) dt + \sqrt{V_t} dZ_t + k^* dq_t \\ dV_t &= (\alpha - \beta^* V_t) dt + \sigma_v \sqrt{V_t} dZ_{vt} \end{aligned} \quad (1)$$

where b is the cost of carry; Z_t and Z_{vt} are Wiener processes with correlation ρ ; q_t is an integer-valued Poisson counter with risk-neutral intensity λ^* that counts the occurrence of jumps; and k^* is the random percentage jump size, with a Gaussian distribution $\ln(1 + k^*) \sim N\left[\ln(1 + \bar{k}^*) - \frac{1}{2}\delta^2, \delta^2\right]$ conditional upon the occurrence of a jump. The Bates model assumes b is constant, while the Scott model assumes it is a linear combination of V_t and an additional state variable that follows an independent square-root process. Bates [3] examines foreign currency options, for which b is the domestic/foreign interest differential, while Scott's application [13] to nondividend paying stock options implies

the cost of carry is equal to the risk-free interest rate.

The postulated process has an associated conditional characteristic function that is exponentially affine in the state variables. For the Bates model, the characteristic function is

$$\begin{aligned} \varphi(i\Phi) &= E_0^*[e^{i\Phi S_T} | S_0, V_0, T] \\ &= \exp [i\Phi S_0 + C(T; i\Phi) + D(T; i\Phi) V_0 \\ &\quad + \lambda^* T E(i\Phi)] \end{aligned} \quad (2)$$

where $E_0^*[\cdot]$ is the risk-neutral expectational operator associated with equation (1), and

$$\gamma(z) = \sqrt{(\rho\sigma_v z - \beta^*)^2 - \sigma_v^2(z^2 - z)} \quad (3)$$

$$\begin{aligned} C(T; z) &= bTz - \frac{\alpha T}{\sigma_v^2} [\rho\sigma_v z - \beta^* - \gamma(z)] - \frac{2\alpha}{\sigma_v^2} \\ &\quad \times \ln \left\{ 1 + [\rho\sigma_v z - \beta^* - \gamma(z)] \frac{1 - e^{\gamma(z)T}}{2\gamma(z)} \right\} \end{aligned} \quad (4)$$

$$D(T; z) = \frac{z^2 - z}{\gamma(z) \frac{e^{\gamma(z)T} + 1}{e^{\gamma(z)T} - 1} + \beta^* - \rho\sigma_v z} \quad (5)$$

$$E(z) = \left(1 + \bar{k}^*\right)^z e^{\frac{1}{2}\delta^2(z^2 - z)} - 1 - \bar{k}^* z \quad (6)$$

The terms $C(\cdot)$ and $D(\cdot)$ are identical to those in the Heston [9] stochastic volatility model, while $E(\cdot)$ captures the additional distributional impact of jumps. Scott's generalization to stochastic interest rates uses an extended Fourier transform of the form

$$\begin{aligned} \varphi^*(z) &= E_0^* \left[\exp \left(- \int_0^T r_t dt + z \ln S_T \right) | S_0, r_0, V_0, T \right] \end{aligned} \quad (7)$$

which has an analytical solution for complex-valued z that is also exponentially affine in the state variables S_0 , r_0 , and V_0 .

European call option prices take the form $c = B(FP_1 - XP_2)$, where B is the price of a discount bond of maturity T , F is the forward price on the underlying asset, X is the option's exercise price, and

P_1 and P_2 are upper tail probability measures derivable from the characteristic function. The papers of Bates [3] and Scott [13] present Fourier inversion methods for evaluating P_1 and P_2 numerically. However, faster methods were subsequently developed for directly evaluating European call options, using a single numerical integration of the form

$$c = BF - BX \times \left\{ \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \operatorname{Re} \left[\frac{f(i\Phi) e^{-i\Phi \ln X}}{i\Phi(1 - i\Phi)} \right] d\Phi \right\} \quad (8)$$

where $\operatorname{Re}[z]$ is the real component of a complex variable z (see **Fourier Methods in Options Pricing**). For the Bates model, $f(i\Phi) = \varphi(i\Phi)$; for the Scott model, $f(i\Phi) = \varphi^*(i\Phi)/B$. European put options can be evaluated from European call option prices using the put–call parity relationship $p = c + B(X - F)$ (see **Put–Call Parity** for details on put–call parity).

Evaluating equation (8) typically involves integration of a dampened oscillatory function. While there exist canned programs for integration over a semi-infinite domain, most papers use various forms of integration over a truncated domain. Bates [3] uses Gauss–Kronrod quadrature (see **Quadrature Methods**). Fast Fourier transform approaches have also been proposed, but these involve substantially more functional evaluations. The integration is typically well behaved, but there do exist extreme parameter values (e.g., $|\rho|$ near 1) for which the path of integration crosses the branch cut of the log function. As all contemporaneous option prices of a given maturity use the same values of $f(i\Phi)$ regardless of the strike price X , evaluating options jointly greatly increases numerical efficiency.

Related Models

Related affine models can be categorized along four lines:

1. alternate specifications of jump processes;
2. the Bates [5] extension to stochastic-intensity jump processes;
3. models in which the underlying volatility can also jump; and
4. multifactor specifications.

Alternate jump specifications (including Lévy processes) with independent and identically distributed jumps involve modification of the functional form of $E(\cdot)$, and are discussed in other articles: **Tempered Stable Process**; **Normal Inverse Gaussian Model**; **Variance-gamma Model**; **Kou Model**; **Exponential Lévy Models**. The Bates [5] model with (risk-neutral) stochastic jump intensities of the form $\lambda^* + \lambda_1^* V_t$ involves modifying $\gamma(\cdot)$ and $D(\cdot)$:

$$\gamma(z) = \sqrt{(\rho\sigma_v z - \beta^*)^2 - \sigma_v^2[z^2 - z + 2\lambda_1^* E(z)]} \quad (9)$$

$$D(T; z) = \frac{z^2 - z + 2\lambda_1^* E(z)}{\gamma(z) \frac{e^{\gamma(z)T} + 1}{e^{\gamma(z)T} - 1} + \beta^* - \rho\sigma_v z} \quad (10)$$

See also **Time-changed Lévy Process** for other stochastic-intensity jump models.

Bates [5] also contains multifactor specifications for the instantaneous variance and jump intensity. The general class of affine jump-diffusion models is presented in [8], including the volatility-jump option pricing model. Scott's extended Fourier transform approach for stochastic interest rates was subsequently also used by Bakshi and Madan [2] and Duffie *et al.* [8]

Further Reference Material

Bates [7, pp. 943–4] presents a simple derivation of equation (8), and cites earlier papers that develop the single-integration approach. Numerical integration issues are discussed by Lee [10]. Bates [3] and Bakshi *et al.* [1] estimate and test the Bates and Scott models, respectively, while Pan [12] provides additional estimates and tests of the Bates [5] stochastic-intensity model. Bates [4, 6] surveys empirical option pricing research.

DAVID S. BATES

Barndorff-Nielsen and Shephard (BNS) Models

Stochastic volatility models based on non-Gaussian Ornstein–Uhlenbeck (OU)-type processes were introduced in [3]. The motivation was to construct a mathematically tractable model that provides an adequate description of price fluctuations on various timescales. The main idea is to model the volatility with a non-Gaussian OU process: solution of a linear Stochastic differential equation (SDE) with Lévy increments. The non-Gaussian increments allow to build a process that is positive and linear, meaning that many computations are very simple.

Non-Gaussian Ornstein–Uhlenbeck-type Processes

The OU-type process (see [8, 11, 12] for original introduction or [2, 4, 10] for a more modern treatment) is defined as the solution of the stochastic differential equation

$$dy_t = -\lambda y_t + dZ_t \quad (1)$$

where Z is a Lévy process. It can be explicitly written as

$$y_t = y_0 e^{-\lambda t} + \int_0^t e^{-\lambda(t-s)} dZ_s \quad (2)$$

At any time t , the distribution of y_t is infinitely divisible. If the characteristic triplet of Z is (A, ν, γ) , the characteristics of y_t are given by

$$\begin{aligned} A_t^y &= \frac{A}{2\lambda} \{1 - e^{-2\lambda t}\} \\ \gamma_t^y &= \frac{\gamma}{\lambda} \{1 - e^{-\lambda t}\} + y_0 e^{-\lambda t} \\ \nu_t^y &= \int_1^{e^{\lambda t}} \nu(\xi B) \frac{d\xi}{\lambda \xi} \quad \forall B \in \mathcal{B}(\mathbb{R}) \end{aligned} \quad (3)$$

and the characteristic function of y_t is

$$E[e^{iu y_t}] = \exp\left(iu y_0 e^{-\lambda t} + \int_0^t \psi(u e^{\lambda(s-t)}) ds\right) \quad (4)$$

with $\psi(u) = \ln E[e^{iu Z_1}]$. Under the integrability condition $\int_{|x|>1} \ln |x| \nu(dx) < \infty$, the process (y_t) has a stationary distribution with characteristics

$$\begin{aligned} A^y &= \frac{A}{2\lambda}, \quad \gamma^y = \frac{\gamma}{\lambda}, \quad \nu^y(B) \\ &= \int_1^\infty \nu(\xi B) \frac{d\xi}{\lambda \xi}, \quad \forall B \in \mathcal{B}(\mathbb{R}) \end{aligned} \quad (5)$$

In the stationary case, an OU-type process has an exponential (short memory) autocorrelation structure:

$$\text{Cov}(y_t, y_{t+s}) = e^{-\lambda s} \text{Var } y_t \quad (6)$$

To obtain more interesting correlation structures, one can add up several OU-type processes [1]: if y and $\tilde{y}$ are independent stationary OU-type processes with parameters λ and $\tilde{\lambda}$ then

$$\begin{aligned} \text{Cov}(y_t + \tilde{y}_t, y_{t+s} + \tilde{y}_{t+s}) &= e^{-\lambda s} \text{Var } y_t \\ &+ e^{-\tilde{\lambda} s} \text{Var } \tilde{y}_t \end{aligned} \quad (7)$$

The price to be paid is an increased model dimension: the two-dimensional process $(y, \tilde{y})$ is Markov but the sum $y + \tilde{y}$ is not. Superpositions of OU-type processes can also be used to construct finite-dimensional approximations to non-Markov (e.g., long memory) processes.

Positive OU-type processes

Positive OU-type processes can be used as linear models for stationary financial time series such as volatility (discussed below) or commodity prices (see [6]). An OU-type process is positive if the driving Lévy process Z is a positive Lévy process, also known as a *subordinator*. In this case, the trajectory consists of a series of positive jumps with exponential decay between them like in Figure 1.

Model Specification and Examples

The “econometric” (as opposed to risk-neutral) version of the Barndorff-Nielsen and Shephard (BNS) stochastic volatility model has the form

$$\begin{aligned} S_t &= S_0 \exp(X_t) \\ dX_t &= (\mu + \beta \sigma_t^2) dt + \sigma_t dW_t + \rho dZ_t \quad \rho \leq 0 \\ d\sigma_t^2 &= -\lambda \sigma_t^2 dt + dZ_t \quad \sigma_0^2 > 0 \end{aligned} \quad (8)$$

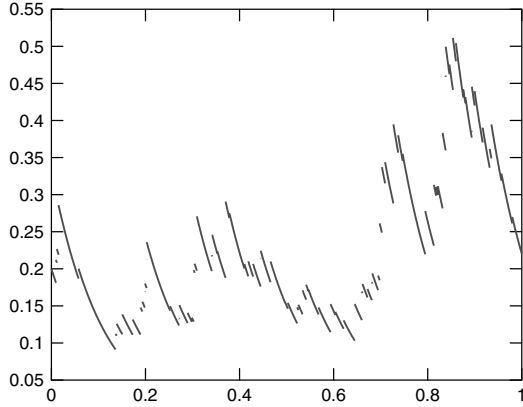

Figure 1 Sample trajectory of a positive OU-type process

The log stock price is a stochastic volatility process with downward jumps (Z has only positive jumps) and the volatility is a positive OU-type process. Introducing Z into the equation for the log price with a negative coefficient accounts for the *leverage effect*: volatility jumps up when price jumps down.

Nicolato and Venardos [9] have shown that model (8) is arbitrage-free, that is, one can always find an equivalent martingale measure. Under a martingale measure, the model takes the form

$$\begin{aligned} S_t &= S_0 \exp(X_t) \\ dX_t &= (r - l(\rho) - \frac{1}{2}\sigma_t^2) dt + \sigma_t dW_t \\ &\quad + \rho dZ_t \\ d\sigma_t^2 &= -\lambda\sigma_t^2 dt + dZ_t, \quad \sigma_0^2 > 0 \end{aligned} \quad (9)$$

where r is the interest rate and $l(u) := \ln E[e^{uZ_1}]$.

As an example of a concrete specification, suppose that the stationary distribution μ of the squared volatility process σ_t^2 is the gamma distribution with density $\mu(x) = \alpha^c / \Gamma(c) x^{c-1} e^{-\alpha x} 1_{x \geq 0}$ (this is the same as the stationary distribution of the volatility in Heston's stochastic volatility model). In this case, (Z_t) has zero drift and a Lévy measure with density $\nu(x) = \alpha \lambda c e^{-\alpha x}$, that is, it is a compound Poisson process with exponential jump size distribution. The Laplace exponent of Z is $l(u) = \lambda c u / \alpha - u$.

Option Pricing and Hedging

The BNS models are a subclass of *affine processes* (see **Affine Models**) [7]: there is an explicit

expression for the characteristic function of log stock price X . Under the risk-neutral probability,

$$\begin{aligned} \phi_t(u) &= E[e^{iuX_t}] \\ &= \exp \left\{ iu(r - l(\rho))t - i\sigma_0^2 \frac{u^2 + iu}{2} \varepsilon(\lambda, t) \right. \\ &\quad \left. + \int_0^t l \left(i\rho u - \frac{u^2 + iu}{2} \varepsilon(\lambda, t-s) \right) ds \right\} \end{aligned} \quad (10)$$

with $\varepsilon(\lambda, t) := 1 - e^{-\lambda t} / t$. This means that if the risk-neutral parameters are known, European options can be priced by Fourier inversion (see **Exponential Lévy Models**). The expected integrated variance is

$$\begin{aligned} E \left[\int_0^t \sigma_s^2 ds \right] &= \sigma_0^2 \frac{1 - e^{-\lambda t}}{\lambda} \\ &\quad + E[Z_1] \frac{e^{-\lambda t} - 1 + \lambda t}{\lambda^2} \end{aligned} \quad (11)$$

leading to a simple explicit formula for the fair rate of a variance swap.

The market being generally incomplete, there exist many risk-neutral probabilities and the prices of contingent claims are not unique. The solution is to select the risk-neutral probability implied by the market, calibrating the model parameters to a set of quoted option prices. Nicolato and Venardos [9] carry out the calibration exercise by the usual technique of nonlinear least squares:

$$\min_{\theta} \sum_{i=1}^N (C_i^M - C^\theta(T_i, K_i))^2 \quad (12)$$

where N is the total number of observations, C_i^M is the observed price of the option with strike K_i and time to maturity T_i , and $C^\theta(T_i, K_i)$ is the price of this option evaluated in a model with parameter vector θ . This method appears to work well in [9] but in other situations two problems may arise:

- **Lack of flexibility:** in BNS models, the same parameter ρ determines the size of jumps in the price process (and hence the short-maturity skew or asymmetry of the implied volatility smile) and the correlation between the price process and the volatility (the long-dated skew). For this reason, the model may be difficult to calibrate in markets

with pronounced skew changes from short to long maturities such as FX markets.

- Lack of stability: since the calibration functional (12) is not convex and the number of model parameters may be large, the calibration algorithm may be caught in a local minimum, which leads to instabilities in the calibration procedure. Usual remedies for this problem include the use of global minimization algorithms such as simulated annealing or adding a convex penalty term to the functional (12) to make the problem well posed.

The minimal variance hedging in BNS models is discussed in [5]. Let the option price at time t be given by $C(t, S_t, \sigma_t^2)$ (this can be computed by Fourier transform). The hedging strategy minimizing the variance of the residual hedging error under the risk-neutral probability is then given by

$$\begin{aligned} \phi_t = & \left[\sigma_{t-}^2 \frac{\partial C}{\partial S} + \frac{1}{S_{t-}} \int v(dz)(e^{\rho z} - 1) \right. \\ & \times [C(t, S_{t-}e^{\rho z}, \sigma_{t-}^2 + z) - C(t, S_{t-}, \sigma_{t-}^2)] \\ & \left. \times \left[\sigma_{t-}^2 + \int (e^{\rho z} - 1)^2 v(dz) \right]^{-1} \right] \end{aligned} \quad (13)$$

When there are no jumps in the stock price ($\rho = 0$), the optimal hedging strategy is just delta-hedging: $\phi_t = \partial C / \partial S$; even though there are jumps in the option price, they cannot be hedged using stock only, because the stock does not jump.

Heston Model

In the class of stochastic volatility models (*see Stochastic Volatility Models*), Heston's is probably the most well-known model. The model was published in 1993 by S. Heston in his seminal article the title of which readily reveals much of its popularity, *A Closed-Form Solution for Options with Stochastic Volatility with Applications to Bond and Currency Options*. It is probably the only stochastic volatility model for equities which both allows very efficient computing of European option prices and fits reasonably well to market data in very different conditions.

In fact, the model was used successfully (in the sense explained below) during the boom of the end of the 1990s, in the brief recession 2001, in the very low volatility regime until 2007, and it still performed well during the very volatile period of late-2008.

However, the model also has several questionable properties: critics point out that its inherent structure as a square-root diffusion does not reflect statistical properties seen in real market data. For example, typical calibrated parameters allow the instantaneous volatility of the stock to become zero with a positive probability. From a practical point of view, the most challenging property of Heston's model is the interdependence of its parameters and the resulting inability to give these parameters a real idiosyncratic meaning. One example is the fact that moving the term structure of volatility has an impact on the shape of the implied volatility skew. This means that traders who use this model will have to have a very good understanding of the dynamics of the model and the interplay between its parameters.

Other stochastic volatility models with efficient pricing methods for European options are: SABR, Schobel–Zhou or Hull–White model (*see Hull–White Stochastic Volatility Model*) and Lewis' "3/2-model" presented in Lewis' book [13]. The n -dimensional extension of Heston's model is the class of affine models [9]. Related are Lévy'-based models that can also be computed efficiently (*see Time-changed Lévy Process*). The most natural model that is used frequently but which actually does not allow efficient pricing of Europeans is a lognormal model for instantaneous volatility.

Model Description

If we assume a prevailing instantaneous interest rate of $r = (r_t)_{t \geq 0}$ and a yield from holding a stock of $\mu = (\mu_t)_{t \geq 0}$, then Heston's model is given as the unique strong solution $Z = (S_t, v_t)_{t \geq 0}$ of the following stochastic differential equation (SDE):

$$\begin{aligned} dv_t &= \kappa(\theta - v_t) dt + \sigma \sqrt{v_t} dW_t \\ dS_t &= S_t (r_t - \mu_t) dt + S_t \sqrt{v_t} dB_t \end{aligned} \quad (1)$$

with starting values spot $S_0 > 0$ and "Short Vol" $\sqrt{v_0} > 0$. In this equation, W and B are two standard Brownian motions with a Correlation of $\rho \in (-1, +1)$. The model is usually specified directly under a risk-neutral measure.

This Correlation together with the "Vol Of Vol" $\sigma \geq 0$ can be thought of being responsible for the skew. This is illustrated in Figure 1: Vol Of Vol controls the volume of the smile and Correlation and its "tilt". A negative Correlation produces the desired downward skew of implied volatility. It is usually calibrated to a value around -70% .

The other parameters control the term structure of the model: in Figure 2, the impact of changing "Short Vol" $\sqrt{v_0} \geq 0$, "Long Vol" $\sqrt{\theta} \geq 0$, and "Reversion Speed" $\kappa > 0$ on the term structure of at-the-money (ATM) implied volatility is illustrated. It can be seen that Short Vol lives up to its name and controls the level of the short-date implied volatilities, whereas Long Vol controls the long end. Reversion Speed controls the skewness or "decay" of the curve from the Short Vol level to the Long Vol level.

This inherent mean-reversion property of Heston's stochastic volatility around a long-term mean $\sqrt{\theta}$ is one of the important properties of the model. Real market data are often mean-reverting, and it also makes economic sense to assume that volatility is not unbounded in its growth as, for example, a stock price process is. In historic data, the "natural" level of mean-reversion is often seen to be itself a mean-reverting process as Fouque *et al.* [10] have shown. Some extensions of Heston in this direction are discussed below.

Parameter Interdependence

Before we proceed, a note of caution: the above distinction of the parameters by their effect on

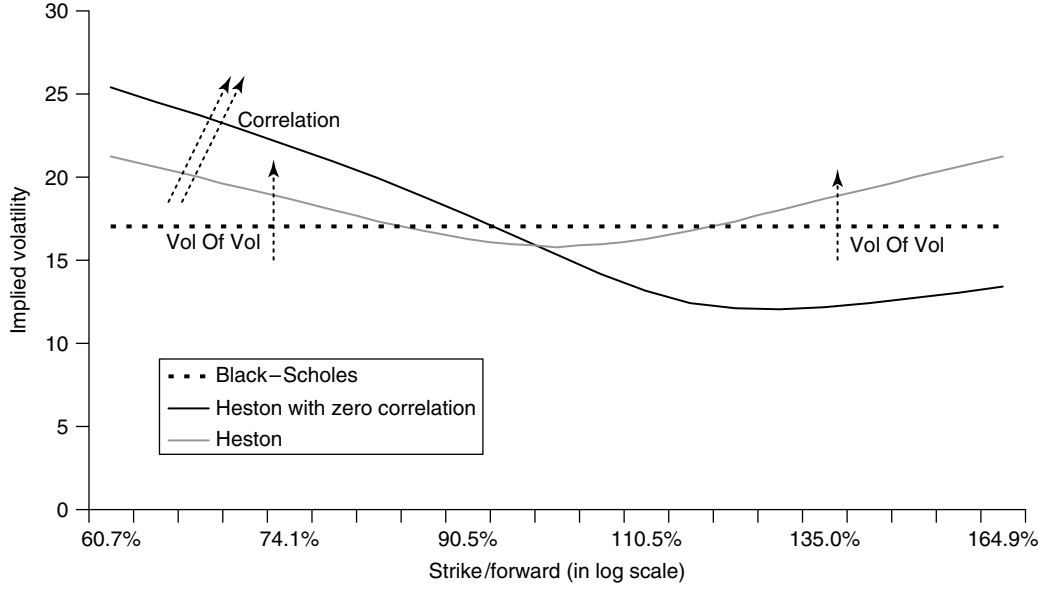

Figure 1 Stylized effects of changing Vol Of Vol and Correlation in Heston's model on the one-year implied volatility. The Heston parameters are $v_0 = 15\%^2$, $\theta = 20\%^2$, $\kappa = 1$, $\rho = -70\%$, and $\sigma = 35\%$

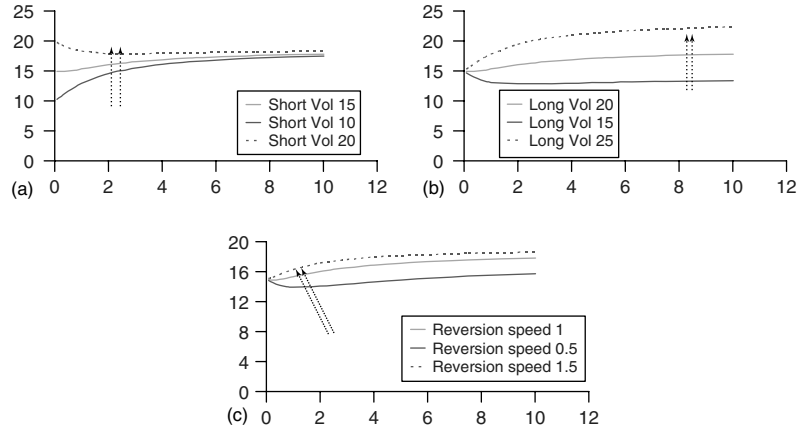

Figure 2 The effects of changing Short Vol (a), Long Vol (b), and Reversion Speed (c) on the ATM term structure of implied volatilities. Each graph shows the volatility term structure for 12 years. The reference Heston parameters are $v_0 = 15\%^2$, $\theta = 20\%^2$, $\kappa = 1$, $\rho = 70\%$, and $\sigma = 35\%$

term structure and strike structure, was made for illustration purposes only: in particular, κ and σ are strongly interdependent if the model is used in the form (1).

This is one of the most serious drawbacks of Heston's model since it means that a trader who uses it to risk-manage a position cannot independently

control the risk with the five available parameters, but has to understand very well their interdependency. For example, to hedge, say, convexity risk in strike direction of the implied volatility surface, the trader will also have to deal with the skew risk at the same time since in Heston, there is no one parameter to control either: convexity is mainly controlled

by Vol Of Vol, but the effect of Correlation on skew depends on the level of Vol Of Vol, too. Moreover, changes to the short end volatility skew will always affect the long-term skew. A similar strong codependency exists between Vol of Vol and Reversion Speed; as pointed out in [14], some of the strong interdependence between Vol Of Vol and Reversion Speed can be alleviated by using the alternative formulation

$$dv_t = (\theta - v_t)\kappa dt + \tilde{\sigma}\sqrt{v_t}\sqrt{\kappa} dW_t \quad (2)$$

In this parametrization, the new Vol Of Vol and reversion speed are much less interdependent, which stabilizes results of daily calibration to market data substantially. Mathematically, this parametrization much more naturally defines κ as the “speed” of the equation.

Such complications are a general issue with stochastic volatility models: since such models attempt to describe an unobservable, rather theoretical quantity (instantaneous variance), they do not produce very intuitive behavior when looked at through the lens of the observable measure of “implied volatility”. That said, implied volatility itself or, rather, its interpolations are also moving on a daily basis. This indicates that natural parameters such as convexity and skew of implied volatility might be a valuable tool for feeding a stochastic volatility model, but it is unreasonable to keep them as constant parameters inside the model.

Pricing European Options

Heston’s popularity is probably mainly derived from the fact that it is possible to price European options on the stock price S using semi-closed-form Fourier transformation, which in turn allows rapid calibration of the model parameters to market data. “Calibration” here means to infer values for the five unobservable parameters $\sqrt{v_0}, \sqrt{\theta}, \kappa, \sigma, \rho$ from market data by minimizing the distance between the models’ European option prices and observed market prices.

We focus on the call prices. Following Carr and Madan [7], we price them *via* Fourier inversion.^a The call price for a relative strike K at maturity T is given as

$$\mathbb{C}(T, K) := \text{DF}(T) \mathbb{E}[(S_T - K F_T)^+] \quad (3)$$

where $\text{DF}(T)$ represents the discount factor and F_T is the forward of the stock. Since the call price itself

is not an L^2 -function in K , we define a “dampened call”

$$c(T, k) := \frac{e^{\alpha k}}{\text{DF}(T) F_T} \mathbb{C}(T, e^k) \quad (4)$$

for an $\alpha > 0$,^b for which its characteristic function $\psi_t(z; k) := \int_{\mathbb{R}} e^{ikz} c(t, k) dk$ is well defined and given as

$$\psi_t(z; k) = \frac{\varphi_t(k - i(\alpha + 1))}{(ik + \alpha)(ik + \alpha + 1)} \quad (5)$$

The function $\varphi_t(z) := \mathbb{E}[\exp\{iz \log S_t/F_t\}]$ is the characteristic function of $X_t := \log S_t/F_t$. Since Heston belongs to the affine model class, its characteristic function has the form

$$\varphi_t(z) = e^{-v_0 A_t - m B_t} \quad (6)$$

with (cf. [14])

$$\begin{aligned} A_t &:= \frac{\alpha + a e^{\gamma t}}{\beta + b e^{\gamma t}} \quad \text{and} \\ B_t &:= \tilde{\kappa} \frac{\alpha b \gamma t + (a\beta - \alpha b) \log \frac{\beta + b e^{\gamma t}}{\beta + b}}{\beta b \gamma} \end{aligned} \quad (7)$$

where $\mu := (iz + z^2)/2$, $\tilde{\kappa} := \kappa - \rho i z \sigma$, $\gamma := -\sqrt{2\mu\sigma^2 + \tilde{\kappa}^2}$, $a := -2\mu$, $\alpha := 2\mu$, $b := -\tilde{\kappa} + \gamma$ and $\beta := \tilde{\kappa} + \gamma$.

We can then price a call on X using

$$\begin{aligned} \mathbb{C}(T, K) &= \text{DF}(T) F_T \frac{e^{-\alpha \ln(K)}}{\pi} \\ &\times \int_0^\infty e^{-iz \ln(K)} \psi_t(z; \ln(K)) dz \end{aligned} \quad (8)$$

The method also lends itself to Fast Fourier Transform if a range of option prices for a single maturity is required.

Similarly, various other payoffs can be computed very efficiently with the Fourier approach, for example, forward started vanilla options, options on integrated short variance, and digital options.

Time-Dependent Parameters

Moreover, for most of these products—and most importantly, plain European options—it is very straightforward to extend the model to time-dependent, piece-wise constant parameters. This is briefly

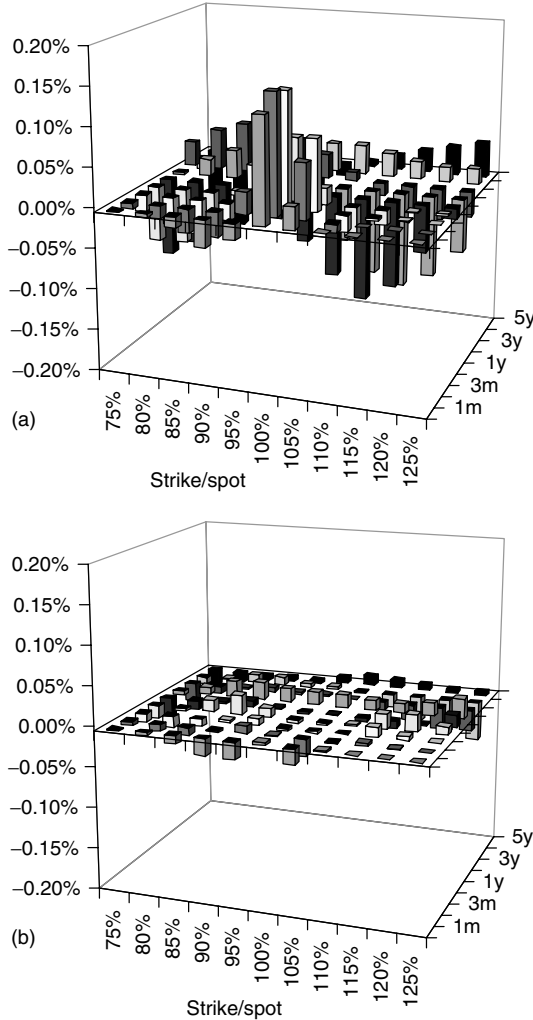

Figure 3 Heston (a) without and (b) with time-dependent parameters fitted to STOX50E for maturities from 1m to 5y. The introduction of time dependency clearly improves the fit

discussed in [14]. It improves the fit of the model to the market prices markedly, cf. Figure 3.

However, it should be noted that by introducing piecewise constant time-dependent parameters, we lose much of a model's structure. It is turned from a time-homogeneous model which "takes a view" on the actual evolution of the volatility *via* its SDE into a kind of an arbitrage-free interpolation of market data: if calibrated without additional constraints to ensure smoothness of the parameters over time, this

is reflected in large discrepancies of the parameter values for distinct periods. For example, the excellent fit of the time-dependent Heston model in Figure 3 is achieved with the following parameter values (short volatility $\sqrt{\zeta_0}$ was 15.0%):

	6m	1y	3y	∞
Long Vol $\sqrt{\theta}$	20.7%	23.6%	36.1%	46.5%
Reversion	5.0	3.2	0.4	0.3
Speed κ				
Correlation ρ	-55.2%	-70.9%	-80.1%	-69.4%
Vol Of Vol σ	78.7%	81.5%	35.3%	60.0

The increased number of parameters also makes it more difficult to hedge in such a model in practice; even though both Heston and the time-dependent Heston models create complete markets, we will always need to additionally protect our position against moves in the parameter values of our model. Just as for Vega in Black and Scholes, this is typically done by computing "parameter greeks" and neutralizing the respective sensitivities. Clearly, the more the parameters that are involved, and the less stable these are, this "parameter hedge" becomes less and less reliable.

Mathematical Drawbacks

The underlying mathematical reason for the relative tractability of Heston's model is that v is a squared Bessel process, which is well understood and reasonably tractable. In fact, a statistical estimation on S&P 500 by Aït-Sahalia and Kimmel [1] of $\alpha \in [1/2, 2]$ in the extended model

$$dv_t = \kappa(\theta - v_t) dt + \sigma v_t^\alpha dW_t^1 \quad (9)$$

has shown that, depending on the observation frequency, a value around 0.7 would probably be more adequate (see **Econometrics of Diffusion Models**). What is more, the square-root volatility terms mean that unless

$$2\kappa\theta \geq \sigma^2 \quad (10)$$

the process v can reach zero with nonzero probability. The crux is that this condition is regularly violated if the model is calibrated freely to observed market data. Although a vanishing short variance is not a problem in itself (after all, a variance of zero simply means absence of trading activity), it makes

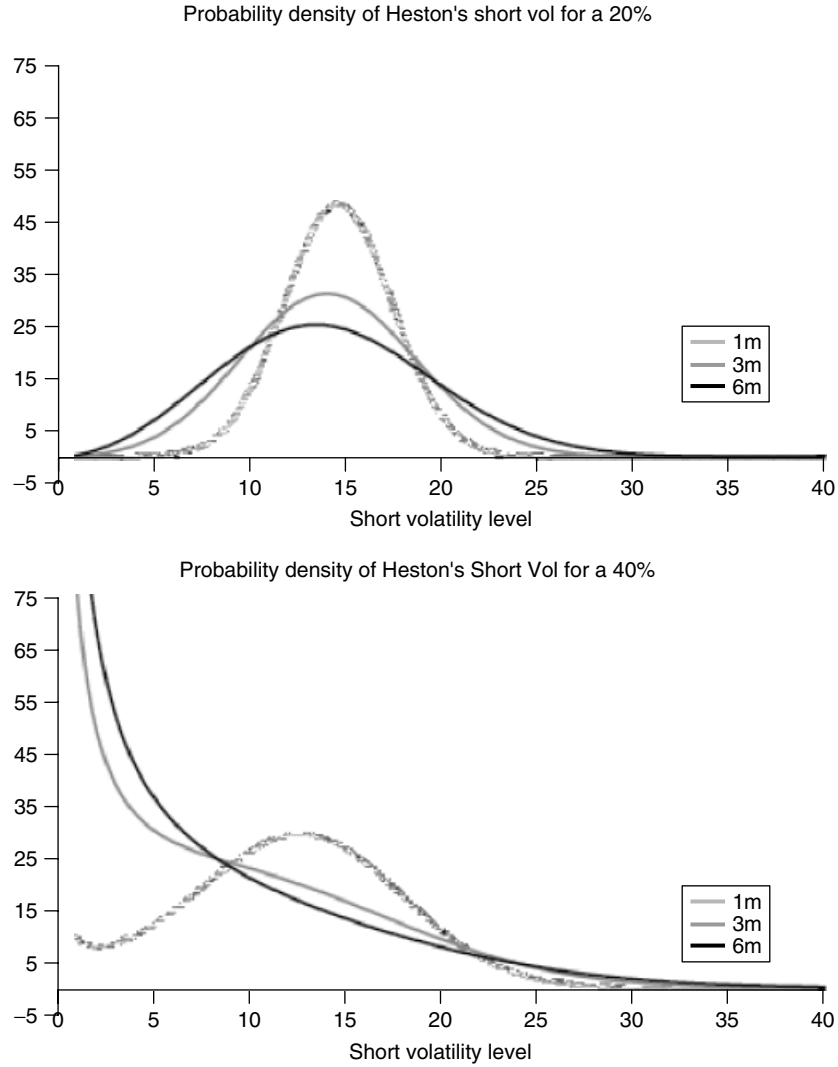

Figure 4 This graphs shows the density of v_t for one, three and six months for the case where condition (10) is satisfied (above) or not (below). Apart from Vol Of Vol, the parameters were $v_0 = 15\%^2$, $\theta = 20\%^2$ and $\kappa = 1$

numerical approximations more complicated. In a Monte Carlo simulation, for example, we have to take the event of v being negative into account. The same problem appears in a partial differential equation (PDE) solver: Heston's PDE becomes degenerate if Short Vol hits zero. A violation of Equation (10) also implies that the distribution of short variance V_t at some later time t is very wide, cf. Figure 4.

Additionally, if Equation (10) does not hold, then the stock price S may fail to have a second moment if the Correlation is not negative enough in the

sense detailed in proposition 3.1 in [2] (see **Moment Explosions** for more details). Again, this is not a problem from a purely mathematical point of view, but it makes numerical schemes less efficient. In particular, Monte Carlo simulations perform much worse: although an Euler scheme will still converge to the desired value, the speed of convergence deteriorates. Moreover, we cannot safely use control variates anymore if the payoff is not bounded.

Pricing Methods

Once we have calibrated the model using the aforementioned semiclosed form of solution for the European options, the question is how to evaluate complex products. At our disposal are PDEs and Monte Carlo schemes.

Since the conditional transition density of the entire process is not known, we have to revert to solving a discretization of the SDE (1) if we want to use a Monte Carlo scheme (*see Monte Carlo Simulation for Stochastic Differential Equations* for an overview of Monte Carlo concepts). To this end, assume that we are given fixing dates $0 = t_0 < \dots < t_N = T$ and let $\Delta t_i := t_{i+1} - t_i$ for $i = 0, \dots, N-1$. Moreover, we denote by ΔW_i for $i = 0, \dots, N-1$ a sequence of independent normal variables with variance Δt_i , and by ΔB_i a corresponding sequence where ΔB_i and ΔW_i have Correlation ρ .

When using a straightforward Euler scheme, we will face the problem that v can become negative. It works well simply to reduce the volatility term of the variance to the positive part of the variance, that is, to simulate

$$v_{t_{i+1}} = v_{t_i} + \kappa(\theta - v_{t_i})\Delta t_i + \sigma\sqrt{v_{t_i}^+}\Delta W_i \quad (11)$$

A flaw of this scheme is that it is biased. This is overcome by using the moment-matching scheme

$$v_{t_{i+1}} = \theta\Delta t_i + (\theta - v_{t_i})e^{-\kappa\Delta t_i} + \left(\sigma v_{t_i}^+ \sqrt{\frac{1 - e^{-2\kappa\Delta t_i}}{2\kappa}} \right) \Delta W_i \quad (12)$$

which works well in practice. To compute the stock price, we approximate the integrated variance over $[t_i, t_{i+1}]$ as

$$\Delta_i V := \theta\Delta t_i + (v_{t_i} - \theta) \frac{1 - e^{-\kappa\Delta t_i}}{\kappa} \quad (13)$$

and set

$$S_{t_k} := F_{t_k} \exp \left\{ \sum_{i=1}^{k-1} \left\{ \sqrt{\Delta_i V} \Delta B_i - \frac{1}{2} \Delta_i V \right\} \right\} \quad (14)$$

Note that this scheme is unbiased in the sense that $\mathbb{E}[S_T] = F_T$.

Heston's PDE

It is straightforward to derive the PDE for the previous model. Let

$$P_t(v, S) := DF_t(T) \mathbb{E}[F(S_T) | S_t = S, v_t = v] \quad (15)$$

be the price of a derivative with maturity T at time t . It satisfies

$$0 = r_t P_t + \partial_S P_t (r_t - \mu_t) S_t + \partial_v P_t \kappa (m - v_t) + \frac{1}{2} \partial_{SS}^2 P_t S_t^2 v_t + \frac{1}{2} \partial_{vv}^2 P_t \sigma^2 v_t + \partial_{vS}^2 P_t \rho v_t S_t \quad (16)$$

with boundary condition $P_T(S, v) = F(S_T)$. To solve this two-factor PDE with a potentially degenerate diffusion term in $\partial_{vv}^2 P_t$, it is recommended to use a stabilized alternating direction implicit (ADI) scheme such as the one described by Craig and Sneyd [8] (*see Alternating Direction Implicit (ADI) Method* for a discussion on ADI).

Risk Management

Provided that we consider not only the stock price itself but also a second liquid instrument V such as a listed option as hedging instrument, stochastic volatility models are complete, that is, in theory every contingent claim P can be replicated in the sense that there are hedging strategies $(\Delta_t, \mathcal{V}_t)_t$ such that

$$dP_t - r_t P_t dt = \Delta_t (dS_t - S_t(r_t - \mu_t) dt) + \mathcal{V}_t (dV_t - r_t V_t dt) \quad (17)$$

(*see Complete Markets* for a discussion on complete markets). In Heston's model, we can write the price process of both the derivative we want to hedge and the hedging instrument as a function of current spot level and short variance, that is, $P_t \equiv P_t(S_t, v_t)$ and $V_t \equiv V_t(S_t, v_t)$. Then, the correct hedging ratios are

$$\mathcal{V}_t = \frac{\partial_v P}{\partial_v V} \quad \text{and} \quad \Delta_t = \partial_S P_t - \frac{\partial_v P}{\partial_v V} \partial_S V_t \quad (18)$$

This is the equivalent of delta hedging in Black and Scholes (*see Delta Hedging*). However, as for the latter, plain theoretical hedging will not work since the other parameters in our model, Reversion Speed, Vol of Vol, Long Vol, and potentially Correlation, will not remain constant if we calibrate our model on a

daily basis. This is the effect of a change in volatility for Black and Scholes—a change of this parameter is not anticipated by the model itself and must be taken care of “outside the model”.

As a result, one way to control this risk is to engage in additional parameter hedging, that is, the desk also displays sensitivities with respect to the other model parameters including, potentially, second-order exposures. Those can then be monitored on a book level and managed explicitly. The drawback of this method is that to reduce risk with respect to those parameters, a portfolio of vanilla options has to be bought whose composition can change quickly if implemented blindly.^c

A second variant is to try to map standard risks of the desk such as implied volatility convexity, skewness, and so on into stochastic volatility risk by “recalibration”. The idea here is that, say, the convexity parameter of the implied volatility is modified, then Heston’s model is calibrated to this new implied volatility surface and the option priced off this model. The resulting change in model price is then considered the sensitivity of the option to convexity in implied volatility. This approach suffers from the fact that typical “implied vol risks” are very different from typical movements in the Heston model. For example, the standard Heston model is homogeneous so it cannot easily accommodate changes in short-term skew only.

Related Models

Owing to its numerical efficiency, Heston’s model is the base for many extensions. The first notable extension is Bates’ addition of jumps to the diffusion process in his article [3] (see **Bates Model**). Jumps are commonly seen as a necessary feature of any risk management model, even though the actual handling of the jump risk part is far from clear.

Bates’ approach can be written as follows: let X be given by

$$\begin{aligned} dv_t &= \kappa(\theta - v_t) dt + \sigma \sqrt{v_t} dW_t \\ dX_t &= X_t \sqrt{v_t} dB_t \end{aligned} \quad (19)$$

and let

$$S_t = F_t X_t e^{\sum_{j=1}^{N_t} \xi_j - \lambda m t} \quad (20)$$

where N_t is a Poisson process with intensity λ (see **Poisson Process**) and where $(\xi_j)_j$ are the normal jumps of the returns of S with mean μ and volatility v . To make sure that S_t/F_t is a martingale we stipulate that $\mu = e^{m + \frac{1}{2}v^2} - 1$.

Since the process X is independent of the jumps, the characteristic function of the log-stock process is the product of the separate characteristic functions. In other words, Bates’ model can be evaluated using the same approach as above and is equally efficient while allowing for a very pronounced short-term skew due to the jump part.^d Figure 5 shows the improvement of time-dependent Bates over time-dependent Heston.

The model has been further enhanced by Knudsen and Nguyen-Ngoc [12] who also added exponentially distributed jumps to the variance process.

Multifactor Models

Structurally, Heston’s model is a member of the class of “affine models” as introduced by Duffie *et al.* [9]. As such, it can easily be extended by mixing in further independent square-root processes. One obvious approach presented in [14] is simply to multiply several independent Heston processes. For the two-factor case, this means to set $S_t := F_t X_t^1 X_t^2$ where both X^1 and X^2 have the form (19). Jumps can be added, but to make the Fourier integration work efficiently, the processes X^1 and X^2 must remain independent.

The stochastic variance of the joint stock price is then simply the sum of the two separate variances, v^1 and v^2 , and it is intuitively assumed that one is a “short-term”, fast mean-reverting process whereas the other is mean reverting slowly. Such a structure is supported by statistical evidence, cf. [10]. However, the independence of the two processes makes it very difficult to impose enough skew into this model since the effective Correlation between instantaneous variance and stock price weakens. In practice, this model is used only rarely.

A related model “Double Heston” has been mentioned by Buehler [6], which is obtained by modeling the mean variance level θ in Heston itself as a square-root diffusion, that is,

$$\begin{aligned} dv_t &= \kappa(\theta_t - v_t) dt + \sigma \sqrt{v_t} dW_t \\ d\theta_t &= c(m - \theta_t) dt + v \sqrt{\theta_t} dW_t^\theta \\ dS_t &= S_t(r_t - \mu_t) dt + S_t \sqrt{v_t} dB_t \end{aligned} \quad (21)$$

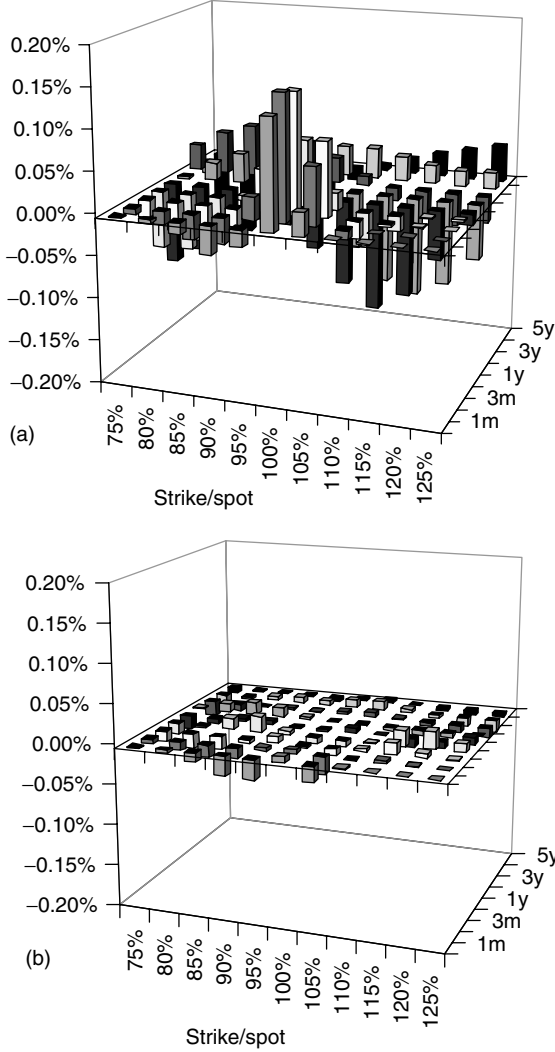

Figure 5 Heston (a) and Bates (b) with time-dependent parameters fitted to STOX50E for maturities from 1m to 5y

where W^θ is independent of W and B . While this model has a reasonably tractable characteristic function, it also suffers from the problem that long-term skew becomes too symmetric, contrary to what is observed in the market. Such a model, however, may have applications when pricing options on variance where the skew counts less and it is more important to be able to account for some dynamics of the term structure of variance. Refer to [6] for an extensive discussion on this.

Fitted Heston

A particular class of derivatives that has gained reasonable popularity in recent years are “Options on Variance”, that is, structures whose terminal payoff depends on the realized variance of the returns of the stock over a set of business days $0 = t_0 < \dots < t_n = T$,

$$\mathbb{R}\mathbb{V}(T) := \sum_{i=1}^n \left(\log \frac{S_{t_i}}{S_{t_{i-1}}} \right)^2 \quad (22)$$

The most standard of such products is a “variance swap” (see **Variance Swap**), which essentially pays the actual realized annualized variance over the period in exchange for a previously agreed fair strike. This strike is usually quoted in volatility terms, that is a variance swap with maturity T , and strike $\Sigma(T)$ pays

$$\frac{252}{n} \mathbb{R}\mathbb{V}(T) - \Sigma^2(T) \quad (23)$$

From this product, a market with options on realized variance has evolved naturally; these include capped variance swaps (mainly traded on single stocks), outright straddles on realized variance swaps, and also VIX futures and options (see **Realized Volatility Options**). Although there are several discussions around how best to approach the risk management of such products, a particularly useful Heston’s model is the “Fitted Heston” approach introduced by Buehler [4].

The main idea here is that to price an option on realized variance in a given model, it is crucial to price correctly a variance swap itself, that is, to make sure that

$$\mathbb{E}[\mathbb{R}\mathbb{V}(T)] = \frac{n}{252} \Sigma^2(T) \quad (24)$$

The idea of “fitting to the market”, say, Heston’s model (2) is now simply to force the model to satisfy this equation. First, assume that we have the term structure of the market’s expected realized variance, $M(T) = n \Sigma^2(T)/252 = \Sigma^2(T)T$, and define $m(t) := \partial_T|_{T=t} M(T)$. Take the original short variance of the model,

$$dv_t = (\theta - v_t)\kappa dt + \sigma \sqrt{v_t} \sqrt{\kappa} dW_t \quad (25)$$

and define the new “fitted” process as

$$w_t := m(t) \frac{v_t}{\mathbb{E}[v_t]} \quad (26)$$

with the stock price as

$$dS_t = S_t(r_t - \mu_t) dt + S_t\sqrt{w_t}dB_t \quad (27)$$

This now reprices all variance swaps automatically in the sense (24). Note that this method does not at all depend on using Heston's model and can be applied to any stochastic volatility model as long as the expectation of instantaneous variance is known.

As pointed out in [6], this model is naturally very attractive from a risk-management point of view if the input M is computed on the fly within the risk management system. In this case, the risk embedded in the variance swap level (called *VarSwapDelta*) is automatically reflected back in the standard implied volatility risk, and the underlying stochastic volatility model is used purely to control skew and convexity around the variance swap backbone.^c Further practical considerations and the impact of jumps are discussed by Buehler in [5].

End Notes

^aIn his original paper [11], Heston suggested a numerically more expensive approach via numerical integration that is twice as slow but still much faster than the same computation for most other models. The approach to price with Fourier inversion is due to Carr and Madan [7]; the interested reader finds more details on the subject in Lewis's book [13].

^bSee [7] for a discussion on the choice of α .

^cBermudez *et al.* discuss one approach to find such portfolios [14].

^dIn practice, calibrating all parameters (stochastic volatility plus jumps) together is relatively unstable since the two parts play similar roles for the short-term options. It is therefore customary to fix the jump parameters themselves or to calibrate them separately to very short-term options.

^eUsually, the parameters v_0 and θ are fixed to some "usual level" such as 20%. Then, they do not need to be calibrated anymore and, in addition, σ retains some comparability to the standard Heston model.

HANS BUEHLER

Hull–White Stochastic Volatility Model

Even before practitioners started using the **Black–Scholes formula** extensively, one had identified the assumption of constant volatility as unrealistic. Empirical observation of equity vanilla option market shows, indeed, that the implied volatility level depends on the strike. This feature, commonly known as the *volatility smile*, violates the constant volatility assumption. This essential remark motivated the birth of stochastic volatility models (*see Stochastic Volatility Models*).

Among the first authors to tackle this issue, Hull and White proposed in 1987 a simple extension of Black–Scholes model [1]. This article aims at presenting a sound introduction to the Hull–White stochastic volatility model and at indicating its implications in terms of volatility behavior and correlation.

Hull and White describe the variance $V = \sigma^2$ as a geometric Brownian motion. Therefore, the asset and variance satisfy the following **stochastic differential equation**:

$$dS = \phi S dt + \sigma S dw_t \quad (1)$$

$$dV = \mu V dt + \xi V dz_t \quad (2)$$

$$dw_t, dz_t = \rho dt \quad (3)$$

In its general formulation, the parameter ϕ may depend on S , σ , and t , while parameters μ and ξ may depend on σ and t . One may find that many models fall under these dynamics, including the **Heston model** for $\mu = \kappa (\theta/V - 1)$ and $\xi = (\nu/\sqrt{V})$. As in [1], we will restrict to the constant parameters case (Hull and White studied the mean-reverting variance case in [2]).

Option Pricing

Let f be the price of a security which depends on the stock price. f satisfies the **partial differential equation** (PDE)

$$\frac{\partial f}{\partial t} + \frac{1}{2} \left[\sigma^2 S^2 \frac{\partial^2 f}{\partial S^2} + 2\rho\sigma^3\xi S \frac{\partial^2 f}{\partial S \partial V} + \xi^2 V^2 \frac{\partial^2 f}{\partial V^2} \right]$$

$$-rf = -rS \frac{\partial f}{\partial S} - \mu\sigma^2 \frac{\partial f}{\partial V} \quad (4)$$

Assuming volatility and stock price are uncorrelated, we derive an analytic solution to equation (4) through risk-neutral valuation procedure

$$f(S_t, \sigma_t^2, t) = e^{-r(T-t)} \times \int_0^\infty f(S_T, \sigma_T^2, T) p(S_T | S_t, \sigma_t^2) dS_T \quad (5)$$

where T is the option maturity, S_t is the security at pricing time t , σ_t is the instantaneous volatility at time t , and $p(S_T | S_t, \sigma_t^2)$ is the conditional distribution of S_T given the security price and variance at time t .

Introducing the mean variance over the option life $\bar{V}$,

$$\bar{V} = \frac{1}{T-t} \int_t^T \sigma_\tau^2 d\tau \quad (6)$$

we express the call option value as

$$C_{\text{HW}}(S_t, \sigma_t^2, t) = \int_0^\infty C_{\text{BS}}(\bar{V}) h(\bar{V} | \sigma_t^2) d\bar{V} \quad (7)$$

where C_{BS} is the Black–Scholes call option value and $h(\cdot, \sigma_t^2)$ is the conditional density of $\bar{V}$ given σ_t^2 .

In some particular cases, such as when μ and σ are constant, this expression admits an explicit Taylor expansion which converges quickly for small values of $\xi^2(T-t)$.

Behavior of Volatility

Assuming that parameters μ and ξ are constant, the first two moments of the volatility process are given by

$$E[\sigma(t)] = \sigma(0) \times e^{\frac{1}{2} \left(\mu - \frac{1}{4} \xi^2 \right) t} \quad (8)$$

$$V[\sigma(t)] = \sigma(0)^2 \times e^{\mu t} \left(1 - e^{\frac{1}{8} \xi^2 t} \right) \quad (9)$$

For $\mu < \frac{1}{4} \xi^2$, the expectation of volatility converges to zero, whereas for $\mu > \frac{1}{4} \xi^2$, it diverges. Regarding the variance of volatility, it increases unbounded if $\mu > 0$.

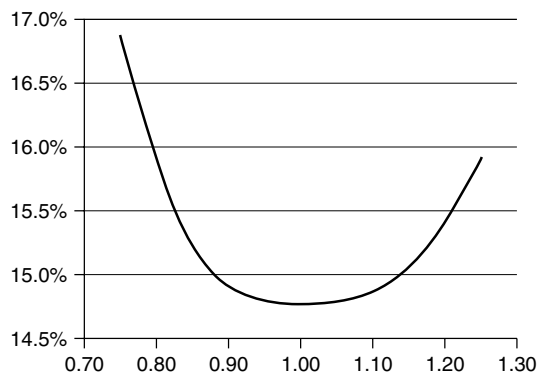

Figure 1 Implied volatility as a function of strike

When calibrating the model to the market, we are very likely to find $\mu \leq 0$, since variance of volatility is bounded. Hence, the expectation of volatility converges to either zero or its initial value.

Implied Volatility Smile

In Figure 1, we show implied volatility as a function of moneyness (strike divided by forward). The call option price has been computed using the Taylor expansion of equation (7) with $\sigma_0 = 0.15$, $\mu = 0$, $\xi = 0$, and $r = 0$. Compared to the Hull–White model, the Black–Scholes model overprices at-the-money options and underprices in- and out-of-the-money options.

Correlation between Stock Returns and Changes in Volatility

By introducing correlation between stock and variance Gaussian increments, Hull and White incorporate explicitly a cause of the volatility skew: the leverage effect. Even if they do not provide any analytic formula in the correlated case, one can still analyze the impact of correlation through numerical simulation.

As shown in Figure 2, this correlation has a huge impact since it enables to transform the smile into

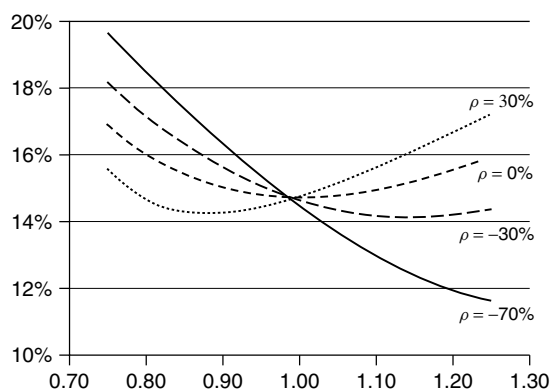

Figure 2 Volatility smile for various correlation levels

a skew. In order to fit market data, it is crucial to correctly set the correlation parameter.

One drawback of the Hull–White model is the lack of mean-reverting behavior in the volatility process (see **Stochastic Volatility Models**).

Tempered Stable Process

A tempered stable process is a pure-jump Lévy process (see **Lévy Processes**) with infinite activity (see **Exponential Lévy Models**) whose small jumps behave like a stable process, while the large jumps are “tempered” so that the tail of the density decays exponentially. Tempered stable processes can be constructed from stable processes by exponential tilting (see **Esscher Transform**) of the Lévy measure.

Tempered stable processes were introduced in [8] and introduced in financial modeling by Cont *et al.* [4] under the name truncated stable process, where it was noted that tempered stable processes have a short-time behavior similar to stable Lévy processes while retaining finite variance and finite exponential moments. Option pricing with tempered stable processes was studied in [1], [2], and [5].

The best known example of tempered stable processes is the CGMY process introduced in [2], which is a pure-jump Lévy process with Lévy density given by

$$k_{\text{CGMY}} = C \frac{\exp(-G|x|)}{|x|^{1+Y}} 1_{\{x < 0\}} + C \frac{\exp(-M|x|)}{|x|^{1+Y}} 1_{\{x > 0\}} \quad (1)$$

The model parameters of equation (1) fulfill $C > 0$, $G, M \geq 0$, and $Y \in (-\infty, 2)$. The restriction on the parameter Y ensures that the measure is a Lévy measure.

For a given stochastic process $X(t)$, its characteristic function is given by $\Phi(u, t) = \mathbb{E}[\exp(iuX(t))]$ (see **Fourier Transform; Fourier Methods in Options Pricing**). For the CGMY model, it is derived in [2] and it is given by

$$\Phi(u, t) = \exp(tC \Gamma(-Y)((M - iu)^Y - M^Y + (G + iu)^Y - G^Y)) \quad (2)$$

On this basis, Fourier-transform methods (see **Fourier Transform; Fourier Methods in Options Pricing**) can be applied to option pricing. Carr *et al.* show that the CGMY process has completely monotone Lévy density for $Y > -1$ and is of infinite activity for $Y > 0$. The drift parameter is chosen to

make $S(t)$ into a martingale and can be determined by using equation (2), which leads to $\omega = -\ln(\Phi(-i))$. Further methods to compute an equivalent martingale measure are discussed in [7].

Tempered Stable

The CGMY process is a special case of the tempered stable process considered in Boyarenko and Levendorskii [1], Cont and Tankov [5] or Rosinski [12]. The latter process has Lévy measure with density given by

$$k_{\text{TS}} = C_- \frac{\exp(-G|x|)}{|x|^{1+Y_-}} 1_{\{x < 0\}} + C_+ \frac{\exp(-M|x|)}{|x|^{1+Y_+}} 1_{\{x > 0\}} \quad (3)$$

The parameters of equation (3) fulfill $G, M > 0$, $C_{\pm} > 0$, and $Y_{\pm} \in (-\infty, 2)$. The characteristic function is available in closed form and hence option pricing and calibration can be performed using Fourier-transform methods. Choosing $C_- = C_+$ and $Y_- = Y_+$ leads to the CGMY process and $Y_- = Y_+ = 0$ leads to a variance gamma process (see **Variance-gamma Model**).

Interpretation of the Parameters

In order to show the impact of the model parameters to asset returns, we consider the properties of the process $X(t)$. Increasing C makes the density more peaked while decreasing C flattens it. C controls the frequency of jumps. While determining the probability of jumps larger than a certain level, this parameter is incorporated. The parameter Y governs the fine structure of the process and the choice affects the overall properties of the process as explained in the previous section. It determines if the process is of finite or infinite activity.

The parameters G and M control the rate of exponential decay, that is, the tail behavior, on the right and the left of k_{CGMY} . We consider three cases: $G = M$ leads to a symmetric Lévy measure, $G < M$ makes the left tail heavier than the right one, and *vice versa* for the case $G > M$. The last two cases lead to a skewed distribution.

This behavior is illustrated in Figure 1.

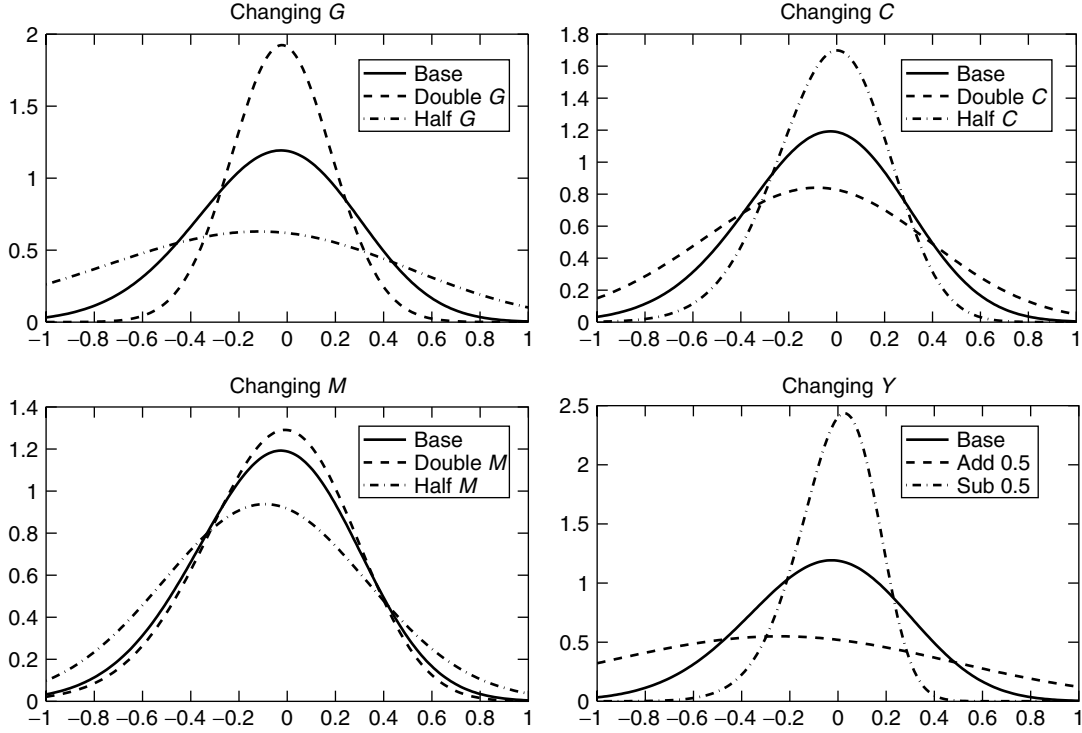

Figure 1 Illustration of the effect of changing the CGMY model parameters C , G , M , and Y on the probability density function

If variance, skewness, and kurtosis exist, they can be computed by

$$\text{Variance} = C\Gamma(2-Y) \left(\frac{1}{M^{2-Y}} + \frac{1}{G^{2-Y}} \right) \quad (4)$$

$$\text{Skewness} = \frac{C\Gamma(3-Y) \left(\frac{1}{M^{3-Y}} + \frac{1}{G^{3-Y}} \right)}{V^{3/2}} \quad (5)$$

$$\text{Kurtosis} = \frac{C\Gamma(4-Y) \left(\frac{1}{M^{4-Y}} + \frac{1}{G^{4-Y}} \right)}{V^2} \quad (6)$$

The equations for the higher moments suggest that the parameter C controls the overall size of the moments. This has already been verified by the expression for the density. In the case $\int_{\mathbb{R}} k(x) dx < +\infty$, it can be interpreted as a measure for the overall level of activity. In the case of finite activity, the process has a finite number of jumps on every compact interval.

Pricing and Calibration

We can use the characteristic function of the log-price $X(t)$ from equation (2) to apply Fourier methods described in Carr and Madan [3] or Eberlein *et al.* [6] to price European and path-dependent options (*see Fourier Methods in Options Pricing*).

Options may also be priced by Monte Carlo simulation [10, 11] using the representation of the tempered stable process as a subordinated Brownian motion [5, Proposition 4.1].

In contrast to the diffusion processes, for the pure-jump processes, the change in measure can be computed from the statistical measure, that is, using parameters computed from time-series data and risk-neutral measure, that is, using parameters obtained using quoted option prices. It holds that $k_{\tilde{\mathbb{P}}}(x) = Y(x)k_{\mathbb{P}}$; see [2] for details. Let us call the corresponding parameter sets $\mathcal{P} = \{C, G, M, Y, \mu\}$ and $\tilde{\mathcal{P}} = \{\tilde{C}, \tilde{G}, \tilde{M}, \tilde{Y}, r\}$, where r denotes the riskless rate and the corresponding measures by $\mathbb{P}$ and $\tilde{\mathbb{P}}$ respectively. If the characteristic functions are denoted by Φ and

$\tilde{\mathbb{P}}$ then using the results in [2] state that $\tilde{\mathbb{P}}$ is an equivalent martingale measure to $\mathbb{P}$ if and only if $C = \tilde{C}$, $Y = \tilde{Y}$, and $r - \Phi(-i) = \mu - \tilde{\Phi}(-i)$. The constraints on the parameters $G, M, \tilde{G}$, and $\tilde{M}$ are implicit in the last equality.

Path Properties

Path properties of the model affect the prices of exotic path-dependent options. We considered path variation when we gave the interpretation for the model parameters. Other concepts like hitting points, creeping, or regularity of the half-line are considered in [9]. We shortly introduce hitting points. The process X_t can hit a point $x \in \mathbb{R}$ if $\mathbb{P}(X_t = x \text{ for at least one } t > 0) > 0$. We denote the set of all points the process can hit by $H = \{x \in \mathbb{R} | \mathbb{P}(X_t = x \text{ for at least one } t > 0) > 0\}$. See [9] for details.

JÖRG KIENITZ

Lognormal Mixture Diffusion Model

Let us denote the time- t price of a given financial asset by $S(t)$, equivalently S_t . We say that S evolves according to a local-volatility model (see also **Local Volatility Model**) if, under the risk-neutral measure,

$$\begin{aligned} dS(t) &= \mu S(t)dt + \sigma(t, S(t))S(t)dW(t), \\ S(0) &= S_0 \end{aligned} \quad (1)$$

where S_0 is a positive constant, W is a standard Brownian motion, σ is a well-behaved deterministic function, and μ is the risk-neutral drift rate, which is assumed to be constant. For instance, in case of a stock paying a continuous dividend yield q , $\mu = r - q$, where r is the (assumed constant) continuously compounded risk-free rate.

Brigo and Mercurio [1–3] find an explicit expression for the function σ such that the resulting process has a density that, at each time, is given by a mixture of lognormal densities. Their result is briefly reviewed in the following.

Let us consider N functions σ_i 's that are deterministic and bounded from above and below by positive constants, and corresponding lognormal densities

$$\begin{aligned} p_i^j(y) &= \frac{1}{y V_i(t) \sqrt{2\pi}} \\ &\times \exp \left\{ -\frac{1}{2V_i^2(t)} \left[\ln \frac{y}{S_0} - \mu t + \frac{1}{2} V_i^2(t) \right]^2 \right\} \end{aligned} \quad (2)$$

$$V_i(t) := \sqrt{\int_0^t \sigma_i^2(u) du} \quad (3)$$

Proposition 1 *Let us assume that each σ_i is also continuous and that there exists an $\varepsilon > 0$ such that $\sigma_i(t) = \sigma_0 > 0$, for each t in $[0, \varepsilon]$ and $i = 1, \dots, N$. Then, if we set*

$$v(t, y) = \sqrt{\frac{\sum_{i=1}^N \lambda_i \sigma_i^2(t) \frac{1}{V_i(t)} \exp \left\{ -\frac{1}{2V_i^2(t)} \left[\ln \frac{y}{S_0} - \mu t + \frac{1}{2} V_i^2(t) \right]^2 \right\}}{\sum_{i=1}^N \lambda_i \frac{1}{V_i(t)} \exp \left\{ -\frac{1}{2V_i^2(t)} \left[\ln \frac{y}{S_0} - \mu t + \frac{1}{2} V_i^2(t) \right]^2 \right\}}} \quad (4)$$

for $(t, y) > (0, 0)$ and $v(t, y) = \sigma_0$ for $(t, y) = (0, S_0)$, the SDE

$$dS_t = \mu S_t dt + v(t, S_t) S_t dW_t \quad (5)$$

has a unique strong solution whose marginal density is given by the mixture of lognormals

$$\begin{aligned} p_t(y) &= \sum_{i=1}^N \lambda_i \frac{1}{y V_i(t) \sqrt{2\pi}} \\ &\times \exp \left\{ -\frac{1}{2V_i^2(t)} \left[\ln \frac{y}{S_0} - \mu t + \frac{1}{2} V_i^2(t) \right]^2 \right\} \end{aligned} \quad (6)$$

Moreover, for $(t, y) > (0, 0)$, we can write $v^2(t, y) = \sum_{i=1}^N \Lambda_i(t, y) \sigma_i^2(t)$, where, for each (t, y) and i , $\Lambda_i(t, y) \geq 0$ and $\sum_{i=1}^N \Lambda_i(t, y) = 1$. As a consequence, for each $t, y > 0$,

$$\begin{aligned} 0 < \tilde{\sigma} &:= \inf_{t \geq 0} \left\{ \min_{i=1, \dots, N} \sigma_i(t) \right\} \leq v(t, y) \leq \hat{\sigma} \\ &:= \sup_{t \geq 0} \left\{ \max_{i=1, \dots, N} \sigma_i(t) \right\} < +\infty \end{aligned} \quad (7)$$

A proof of this proposition can be found in [2], and more formally in [5].

The pricing of European options under the lognormal-mixture local-volatility model is quite straightforward (see also **Risk-neutral Pricing; Black–Scholes Formula**).

Proposition 2 *Consider a European option with maturity T , strike K , and written on the asset. The option value at the initial time $t = 0$ is given by the following convex combination of Black–Scholes prices:*

$$\pi(K, T) = \omega P(0, T) \sum_{i=1}^N \lambda_i \times \left[S_0 e^{\mu T} \Phi \left(\frac{\ln \frac{S_0}{K} + \left(\mu + \frac{1}{2} \eta_i^2 \right) T}{\eta_i \sqrt{T}} \right) - K \Phi \left(\frac{\ln \frac{S_0}{K} + \left(\mu - \frac{1}{2} \eta_i^2 \right) T}{\eta_i \sqrt{T}} \right) \right] \quad (8)$$

where $P(0, T)$ is the discount factor for maturity T , Φ is the normal cumulative distribution function, $\omega = 1$ for a call and $\omega = -1$ for a put, and

$$\eta_i := \frac{V_i(T)}{\sqrt{T}} = \sqrt{\frac{\int_0^T \sigma_i^2(t) dt}{T}} \quad (9)$$

The main advantage of the lognormal-mixture local-volatility model is its tractability (explicit marginal density and option prices). This model can be successfully used in practice to calibrate

smile-shaped implied volatility structures. Extensions allowing for nonzero slopes at the at-the-money level are introduced in [4].

FABIO MERCURIO

Normal Inverse Gaussian Model

The normal inverse Gaussian (NIG) process is an example of a Lévy process (see **Lévy Processes**) with no Brownian component.

We first discuss the NIG distribution and its main properties. The NIG process can be constructed either as process with NIG increments or, alternatively, defined *via* random time change of Brownian motion using the inverse Gaussian process to determine time. Further, we present the NIG market model and show how one can price European options under this model. Option pricing can be done using the NIG density function, the NIG Lévy characteristics, or the NIG characteristic function.

The Normal Inverse Gaussian Distribution

The NIG distribution with parameters $\alpha > 0$, $-\alpha < \beta < \alpha$, and $\delta > 0$ has characteristic function (see [1])

$$\phi(u; \alpha, \beta, \delta) = \exp \left\{ -\delta \left(\sqrt{\alpha^2 - (\beta + iu)^2} - \sqrt{\alpha^2 - \beta^2} \right) \right\} \quad (1)$$

We shall denote this distribution by $NIG(\alpha, \beta, \delta)$. The distribution is so named due to the fact that $NIG(\alpha, \beta, \delta)$ is a variance–mean mixture of a normal distribution with the inverse Gaussian as the mixing distribution. It follows immediately from expression (1) that this distribution is infinitely divisible. The distribution is defined on the whole real line and has the density function

$$f(x; \alpha, \beta, \delta) = \alpha \delta \pi^{-1} \exp \left\{ \delta \sqrt{\alpha^2 - \beta^2} + \beta x \right\} K_1(\alpha \sqrt{\delta^2 + x^2}) \left(\sqrt{\delta^2 + x^2} \right)^{-1}, \quad x \in \mathbb{R} \quad (2)$$

where K_1 is the modified Bessel function of third-order and index 1. If a random variable X follows an $NIG(\alpha, \beta, \delta)$ distribution and $c > 0$, then cX is $NIG(\alpha/c, \beta/c, c\delta)$ -distributed. Further, if $X \sim NIG(\alpha, \beta, \delta_1)$ is independent of $Y \sim NIG(\alpha, \beta, \delta_2)$, then $X + Y \sim NIG(\alpha, \beta, \delta_1 + \delta_2)$. If $\beta = 0$, the

distribution is symmetric. This can easily be seen from the characteristics of the NIG distribution given in Table 1.

Note that the NIG distribution is a special case of generalized hyperbolic distribution, and it can approximate most hyperbolic distributions very closely. In modeling, the NIG distribution can describe observations with considerably heavier tail behavior than the log linear rate of decrease that characterizes the hyperbolic shape (see [2]). The NIG distribution has semiheavy tails (see [3])

$$f(x; \alpha, \beta, \delta) \sim \text{const.} |x|^{-3/2} \exp\{-\alpha|x| + \beta x\}, \quad x \rightarrow \pm\infty$$

The Normal Inverse Gaussian Process

We define the NIG process

$$X^{(\text{NIG})} = \{X_t^{(\text{NIG})}, t \geq 0\} \quad (3)$$

as the Lévy process with stationary and independent NIG-distributed increments, where $X_0^{(\text{NIG})} = 0$ with probability 1. To be precise, $X_t^{(\text{NIG})}$ follows a $NIG(\alpha, \beta, \delta t)$ law.

The Lévy measure of the NIG process is given by

$$\nu_{\text{NIG}}(dx) = \delta \alpha \pi^{-1} \exp\{\beta x\} K_1(\alpha|x|) (|x|)^{-1} dx \quad (4)$$

An NIG process has no Brownian component and its Lévy triplet is given by $[\gamma, 0, \nu_{\text{NIG}}(dx)]$, where

$$\gamma = 2\delta \alpha \pi^{-1} \int_0^1 \sinh(\beta x) K_1(\alpha x) dx \quad (5)$$

The NIG Lévy process may alternatively be represented *via* random time change of Brownian motion, using the inverse Gaussian (IG) process to determine time, as

$$X_t^{\text{NIG}} = \beta \delta^2 I_t + \delta W_{I_t} \quad (6)$$

where $W = \{W_t, t \geq 0\}$ is a standard Brownian motion and $I = \{I_t, t \geq 0\}$ is an IG process with parameters $a = 1$ and $b = \delta \sqrt{\alpha^2 - \beta^2}$.

2 Normal Inverse Gaussian Model

Table 1 Mean, variance, skewness, and kurtosis of the normal inverse Gaussian distribution

	$NIG(\alpha, \beta, \delta)$
Mean	$\delta\beta(\alpha^2 - \beta^2)^{-1/2}$
Variance	$\alpha^2\delta(\alpha^2 - \beta^2)^{-3/2}$
Skewness	$3\beta\alpha^{-1}\delta^{-1}(\alpha^2 - \beta^2)^{-1/4}$
Kurtosis	$3(1 + (\alpha^2 + 4\beta^2)\delta^{-1}\alpha^{-2}(\alpha^2 - \beta^2)^{-1/2})$

The NIG Model

The NIG model belongs to the class of exponential Lévy models (*see Time-changed Lévy Process*). Consider a market with a riskless asset (the bond), with a price process given by $b_t = \exp\{rt\}$, and one risky asset (the stock or index). The model for the risky asset is

$$S_t = S_0 \exp\{X_t^{(NIG)}\} \quad (7)$$

where the log returns $\log(S_{t+s}/S_t)$ follow the $NIG(\alpha, \beta, \delta s)$ distribution (i.e., the distribution of increments of length s of the NIG process).

Equivalent Martingale Measure

Pricing financial derivatives requires that we work under an equivalent martingale measure. We present here two ways to attain equivalent martingale measures for the discounted price process $\{\exp(-(r - q)t)S_t, t \geq 0\}$, where r is the risk-free continuously compounded interest rate and q is the continuously compounded dividend yield.

One can find at least one equivalent martingale measure Q using the Esscher transform (see [6]). For the NIG model, the Esscher transform equivalent martingale measure follows an $NIG(\alpha, \theta^* + \beta, \delta)$ law (see [12]), where θ^* is the solution of the equation

$$r - q = \delta \left(\sqrt{\alpha^2 - (\beta + \theta)^2} - \sqrt{\alpha^2 - (\beta + \theta + 1)^2} \right) \quad (8)$$

Another way to obtain an equivalent martingale measure Q is by mean-correcting the exponential

of the $NIG(\alpha, \beta, \delta)$ process, that is, introducing the distribution $NIG(\alpha, \beta, \delta, m)$ with the characteristic function

$$\tilde{\phi}(u; \alpha, \beta, \delta, m) = \phi(u; \alpha, \beta, \delta) \exp\{ium\} \quad (9)$$

where

$$m = r - q + \delta \left(\sqrt{\alpha^2 - (\beta + 1)^2} - \sqrt{\alpha^2 - \beta^2} \right) \quad (10)$$

and $\phi(u; \alpha, \beta, \delta)$ is defined by expression (1).

Pricing of European Options

Given our NIG market model, we focus now on the pricing of European options whose payoffs are functions of the terminal asset value only. Denote the payoff of the option at its time of expiry T by $G(S_T)$ and let $F(X_T) = G(S_T)$

Pricing through Density Function

For a European call option with strike price K and time to expiration T , the value V_0 at time 0 is given by the expectation of the payoff under the martingale measure Q . If we take for Q the Esscher transform equivalent martingale measure, the value at time 0 is given by

$$V_0 = \exp\{-qT\}S_0 \int_c^\infty f_T^{(\theta^*+1)}(x) dx - \exp\{-rT\}K \int_c^\infty f_T^{(\theta^*)}(x) dx \quad (11)$$

where $c = \ln(K/S_0)$, $f_T^{(\theta^*)}(x)$ is the density function of the $NIG(\alpha, \theta^* + \beta, \delta)$ distribution. Similar formulas can be derived for other derivatives with a payoff function that depends only on the terminal value at time $t = T$.

Pricing through the Lévy Characteristics

Another way to find the value $V_t = V(t, X_t)$ at time t is by solving a partial integro-differential

equation (see **Partial Integro-differential Equations (PIDEs)**). If $V(t, x) \in C^{1,2}$ then the function $V(t, x)$ solves

$$\begin{aligned} rV(t, x) = & \gamma \frac{\partial}{\partial x} V(t, x) + \frac{\partial}{\partial t} V(t, x) \\ & + \int_{-\infty}^{+\infty} \left(V(t, x+y) - V(t, x) \right. \\ & \left. - y \frac{\partial}{\partial x} V(t, x) \right) \nu^Q(dy) \\ V(T, x) = & F(x) \end{aligned} \quad (12)$$

where $[\gamma, 0, \nu^Q(dy)]$ is the Lévy triplet of the NIG process under the risk-neutral measure Q .

Pricing through the Characteristic Functions

Pricing can also be done by using the characteristic function [4] (see **Fourier Transform**). Let α be a positive constant such that the α th moment of the stock price exists, then the value of the option is given by

$$\begin{aligned} V_0 = & \frac{\exp\{-\alpha \log(K)\}}{\pi} \\ & \times \int_0^{+\infty} \exp\{-iv \log(K)\} \varrho(v) dv \end{aligned} \quad (13)$$

where

$$\begin{aligned} \varrho(v) = & \frac{\exp\{-rT\} E \left[\exp\{i(v - (\alpha + 1)i) \log(S_T)\} \right]}{\alpha^2 + \alpha - v^2 + i(2\alpha + 1)v} \\ = & \frac{\exp\{-rT\} \varphi(v - (\alpha + 1)i)}{\alpha^2 + \alpha - v^2 + i(2\alpha + 1)v} \end{aligned} \quad (14)$$

and

$$\varphi(u) = E \left[\exp\{iu \log(S_T)\} \right] \quad (15)$$

Other methods for the valuation of European options by applying characteristic functions can be found in [7] and [8].

Monte Carlo Simulations

One can make use of the representation (6) to simulate an NIG process. In such a way, a sample path of the NIG is obtained by sampling a standard Brownian motion and an IG process. We refer to [5] for the details on the generation of an IG random number.

Origin

The NIG distribution was introduced in [1]. The potential applicability of the NIG distribution and Lévy process for the modeling and analysis of statistical data from turbulence and finance is discussed in [2] and [3]. See also [9–11] for the application of the NIG distribution in modeling logarithmic asset returns.

Generalized Hyperbolic Models

Generalized hyperbolic (GH) Lévy motions constitute a subclass of Lévy processes that are generated by *GH distributions*. GH distributions were introduced in Barndorff-Nielsen [1] in connection with a project with geologists. The Lebesgue density of this five-parameter class can be given in the following form:

$$\begin{aligned} d_{\text{GH}(\lambda, \alpha, \beta, \delta, \mu)}(x) &= a(\lambda, \alpha, \beta, \delta, \mu) \\ &\times (\delta^2 + (x - \mu)^2)^{\left(\lambda - \frac{1}{2}\right)/2} \\ &\times K_{\lambda - \frac{1}{2}}\left(\alpha \sqrt{\delta^2 + (x - \mu)^2}\right) \\ &\times \exp(\beta(x - \mu)) \end{aligned} \quad (1)$$

with the norming constant

$$a(\lambda, \alpha, \beta, \delta, \mu) = \frac{(\alpha^2 - \beta^2)^{\lambda/2}}{\sqrt{2\pi} \alpha^{\lambda - \frac{1}{2}} \delta^\lambda K_\lambda(\delta \sqrt{\alpha^2 - \beta^2})} \quad (2)$$

K_ν denotes the modified Bessel function of the third kind with index ν . The parameters can be interpreted as follows: $\alpha > 0$ determines the shape, β with $0 \leq |\beta| < \alpha$ the skewness and $\mu \in \mathbb{R}$ the location. $\delta > 0$ serves for scaling, and $\lambda \in \mathbb{R}$ characterizes subclasses. It is essentially the weight in the tails that changes with λ . There are two alternative parameterizations that are scale- and location-invariant, that is, they do not change under affine transformations $Y = aX + b$ for $a \neq 0$, namely, $\zeta = \delta \sqrt{\alpha^2 - \beta^2}$, $\rho = \beta/\alpha$ and $\xi = (1 + \zeta)^{-1/2}$, $\chi = \xi\rho$. Since $0 \leq |\chi| < \xi < 1$, for a fixed λ the distributions parameterized by χ and ξ can be represented by the points of a triangle, the so-called shape triangle.

GH distributions arise in a natural way as variance–mean mixtures of normal distributions. Let d_{GIG} denote the density of a generalized inverse Gaussian distribution (*see Normal Inverse Gaussian Model*) with parameters $\delta > 0$, $\gamma > 0$, and $\lambda \in \mathbb{R}$,

that is,

$$\begin{aligned} d_{\text{GIG}(\lambda, \delta, \gamma)}(x) &= \left(\frac{\gamma}{\delta}\right)^\lambda \frac{1}{2K_\lambda(\delta\gamma)} x^{\lambda-1} \\ &\times \exp\left(-\frac{1}{2}\left(\frac{\delta^2}{x} + \gamma^2 x\right)\right) \mathbb{1}_{\{x>0\}} \end{aligned} \quad (3)$$

Then if $N(\mu + \beta y, y)$ denotes a normal distribution with mean $\mu + \beta y$ and variance y , one can easily verify that

$$\begin{aligned} d_{\text{GH}(\lambda, \alpha, \beta, \delta, \mu)}(x) &= \int_0^\infty d_{N(\mu + \beta y, y)}(x) \\ &\times d_{\text{GIG}(\lambda, \delta, \sqrt{\alpha^2 - \beta^2})}(y) dy \end{aligned} \quad (4)$$

Using maximum likelihood estimation, one can fit GH distributions to empirical return distributions from financial time series such as the daily stock or index prices. Figure 1 shows a fit to the daily closing prices of Telekom over a period of seven years.

Figure 2 shows the same densities on a log scale in order to make the fit in the tails visible. One recognizes the hyperbolic shape of the GH density in comparison to the parabolic shape of the normal density. The characteristic function of the GH distribution is

$$\begin{aligned} \varphi_{\text{GH}}(u) &= e^{iu\mu} \left(\frac{\alpha^2 - \beta^2}{\alpha^2 - (\beta + iu)^2} \right)^{\frac{\lambda}{2}} \\ &\times \frac{K_\lambda\left(\delta \sqrt{\alpha^2 - (\beta + iu)^2}\right)}{K_\lambda(\delta \sqrt{\alpha^2 - \beta^2})} \end{aligned} \quad (5)$$

and expectation and variance are

$$E[GH] = \mu + \frac{\beta \delta^2}{\zeta} \frac{K_{\lambda+1}(\zeta)}{K_\lambda(\zeta)} \quad (6)$$

$$\begin{aligned} \text{Var}(GH) &= \frac{\delta^2}{\zeta} \frac{K_{\lambda+1}(\zeta)}{K_\lambda(\zeta)} + \frac{\beta^2 \delta^4}{\zeta^2} \\ &\times \left(\frac{K_{\lambda+2}(\zeta)}{K_\lambda(\zeta)} - \frac{K_{\lambda+1}^2(\zeta)}{K_\lambda^2(\zeta)} \right) \end{aligned} \quad (7)$$

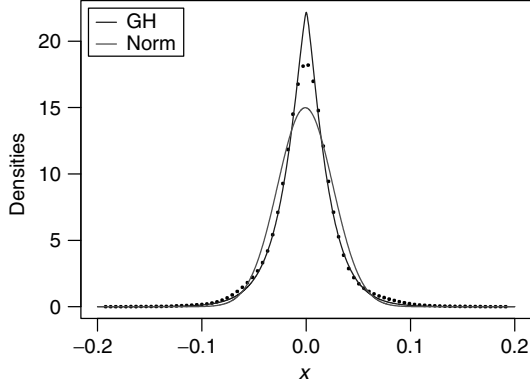

Figure 1 GH and normal density fitted to the daily Telekom returns

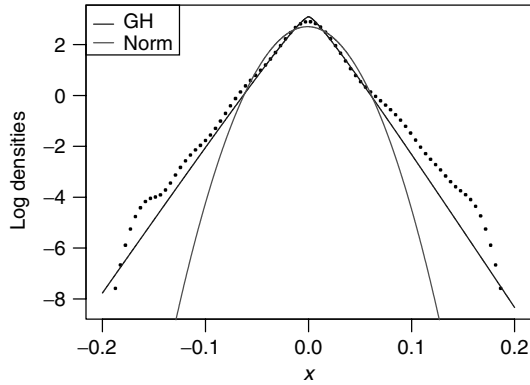

Figure 2 Fitted densities on a log scale

The moment-generating function exists for all u such that $-\alpha - \beta < u < \alpha - \beta$. Therefore, moments of all orders are finite.

There are two important subclasses. For $\lambda = 1$, one gets the class of *hyperbolic* distributions with density

$$d_{H(\alpha, \beta, \delta, \mu)}(x) = \frac{\sqrt{\alpha^2 - \beta^2}}{2\alpha\delta K_1(\delta\sqrt{\alpha^2 - \beta^2})} \times \exp\left(-\alpha\sqrt{\delta^2 + (x - \mu)^2} + \beta(x - \mu)\right) \quad (8)$$

whereas for $\lambda = -\frac{1}{2}$ one gets the class of normal inverse Gaussian (NIG) distributions with density

$$d_{\text{NIG}(\alpha, \beta, \delta, \mu)}(x) = \frac{\alpha}{\pi} \exp\left(\delta\sqrt{\alpha^2 - \beta^2} + \beta(x - \mu)\right) \times \frac{K_1\left(\alpha\delta\sqrt{1 + \left(\frac{x - \mu}{\delta}\right)^2}\right)}{\sqrt{1 + \left(\frac{x - \mu}{\delta}\right)^2}} \quad (9)$$

The latter one has a particularly simple characteristic function:

$$\varphi_{\text{NIG}}(u) = e^{iu\mu} \frac{\exp\left(\delta\sqrt{\alpha^2 - \beta^2}\right)}{\exp\left(\delta\sqrt{\alpha^2 - (\beta + iu)^2}\right)} \quad (10)$$

Many well-known distributions are limit cases of the class of GH distributions. For $\lambda > 0$ and $\delta \rightarrow 0$, one gets a variance-gamma distribution; in the special case of $\lambda = 1$ the result is a skewed and shifted Laplace distribution. Other limit cases are the Cauchy and the Student- t distribution as well as the gamma, the reciprocal gamma, and the normal distributions [4].

Exponential Lévy Models

GH distributions are infinitely divisible and therefore generate a Lévy process $L = (L_t)_{t \geq 0}$ such that the distribution of L_1 , $\mathcal{L}(L_1)$, is the given GH distribution. Analyzing the characteristic function in the Lévy–Khintchine form, one sees that the Lévy measure has an explicit density. There is no Gaussian component. Consequently the generated Lévy process is a process with purely discontinuous paths. The paths have infinite activity, which means that there are infinitely many jumps in any finite time interval (see **Jump Processes; Exponential Lévy Models**).

As a model for asset prices such as stock prices, indices, or foreign exchange rates, we take the exponential of the Lévy process L

$$S_t = S_0 \exp L_t \quad (11)$$

For hyperbolic Lévy motions, this model was introduced in [6], NIG Lévy processes were considered in [2], and the extension to GH Lévy motions

appeared in [3, 8]. The log returns from this model taken along time intervals of length 1 are $L_t - L_{t-1}$ and therefore they have exactly the GH distribution that generates the Lévy process. It was shown in [7] that the model (9) is successful in producing empirically correct distributions on other time horizons as well. This time consistency property can, for example, be used to derive the correct VaR estimates on a two-week horizon according to the Basel II rules. Equation (9) can be expressed by the following stochastic differential equation:

$$dS_t = S_{t-} (dL_t + e^{\Delta L_t} - 1 - \Delta L_t) \quad (12)$$

The price of a European option with payoff $f(S_T)$ is

$$V = e^{-rT} \mathbb{E} [f(S_T)] \quad (13)$$

where r is the interest rate and expectation is taken with respect to a risk-neutral (martingale) measure. As shown in [5], there are many equivalent martingale measures due to the rich structure of the driving process L . The simplest choice is the so-called Esscher transform, which was used in [6]. For the process L to be again a GH Lévy motion under an equivalent martingale measure (see **Equivalent Martingale Measures**), the parameters δ and μ have to be kept fixed [9]. Since the density of the distribution of S_T can be derived via inversion of the characteristic function, the expectation in equation (11) can be computed directly. A numerically much more efficient method based on two-sided Laplace transforms, which is applicable to a wide variety of options, has been developed in [9]. Assume that $e^{-Rx} f(e^{-x})$ is bounded and integrable for some R such that the moment-generating function of L_T is finite at $-R$. Write $g(x) = f(e^{-x})$ and $\psi_g(z) = \int_{\mathbb{R}} e^{-zx} g(x) dx$ for the bilateral Laplace transform of g . If $\zeta := -\log S_0$, then the option price V can be expressed in the following form:

$$V(\zeta) = \frac{e^{\zeta R - rT}}{2\pi} \int_{\mathbb{R}} e^{iu\zeta} \psi_g(R + iu) \varphi_{L_T}(iR - u) du \quad (14)$$

whenever the integral exists. φ_{L_T} denotes the characteristic function of the distribution of L_T .

Regime-switching Models

Many financial time series exhibit sudden changes in the structure of the data-generating process. Examples include financial crises, exchange rate swings, and jumps in the volatility. Sometimes, this sudden switch is due to a change in policy, for example, when moving from a fixed to a floating exchange rate regime. In other cases, the behavior of the series is influenced by an exogenous fundamental variable, such as the current position on the business or the credit cycle.

Regime-switching models attempt to capture this behavior by allowing the data-generating process to change in time, depending on an underlying, discrete but unobserved state variable. Typically, the functional form of the data-generating process remains the same across the different regimes with only the parameter values being state-dependent, as, for example, in a random walk equity return model where the drift and volatility change with the regime. However, it is feasible to set up models where the data-generating process itself changes, for example, moving from a deterministic fixed exchange to a stochastic floating one.

From a statistical point of view, regime-switching models will produce mixtures of distributions (*see Mixture of Distribution Hypothesis*), offering a very stylized and intuitive way of accommodating features such as fat tails, skewness, and volatility clustering (*see Stylized Properties of Asset Returns*). It is very easy to calibrate regime-switching models on historical data using maximum likelihood techniques, implementing what can be thought of as a discrete version of the Kalman filter (*see Filtering*). Virtually all economic and financial time series have been analyzed under the regime-switching framework, including interest and exchange rates, equity returns, commodity prices, energy prices, and credit spreads.

Derivative prices can be computed for regime-switching models by using transform methods (*see Hazard Rate*). The characteristic function of a regime-switching process can be computed in closed form if the characteristic functions conditional on each regime are available. This makes such processes a viable alternative to the stochastic volatility models, where one has to also resort to transform methods for pricing.

The Regime-switching Framework

A regime-switching model can be cast in either a discrete or continuous time setting. The model is built conditional to a Markov chain $s(t)$, the realization of which is not directly observed by economic agents. The chain can take a discrete set of values, and here we label them as $s(t) \in \{1, 2, \dots, N\} = \mathcal{S}$. The Markov chain is determined by its transition probability matrix in discrete time or its rate matrix in continuous time. In particular, in a discrete time setting, we write the transition probabilities $p_{i,j}$

$$P[S(t+1) = j | S(t) = i] = p_{i,j} \quad (1)$$

and we collect the elements $\{p_{i,j}\}$ in the transition probability matrix $\mathbf{P}$. The columns of $\mathbf{P}$ must sum up to 1, and all transition probabilities must be nonnegative. For a continuous time process, we define the transition rates $q_{i,j}$:

$$P[S(t+dt) = j | S(t) = i] = \mathbf{1}(i = j) + q_{i,j}dt \quad (2)$$

where $\mathbf{1}$ is the indicator function. The elements $\{q_{i,j}\}$ are collected in the rate matrix $\mathbf{Q}$. Note that by this definition, the columns of the rate matrix must sum up to 0, and the diagonal elements will be negative. The infinitesimal transition probability matrix is given as

$$\mathbf{P}(dt) = \mathbf{I} + \mathbf{Q}dt \quad (3)$$

where $\mathbf{I}$ is the unit ($N \times N$) matrix.

At each point in time, the data-generating process will vary, according to the regime $s(t)$ that prevails at that time. Thus, for a discrete time process, we can write

$$x(t) = g[t, s(t), \mathbf{y}(t), \epsilon(t); \boldsymbol{\beta}] \quad (4)$$

In the above expression, $\mathbf{y}(t)$ includes variables known at time t , including exogenous variables and lagged values of $x(t)$, and $\epsilon(t)$ represents the error term. In continuous time, we can write the stochastic differential equation:

$$dx(t) = \mu[t, s(t), \mathbf{y}(t); \boldsymbol{\beta}]dt + \sigma[t, s(t), \mathbf{y}(t); \boldsymbol{\beta}]dB(t) \quad (5)$$

Again, $\mathbf{y}(t)$ can include exogenous variables and the history of $x(t)$, while now $B(t)$ is a standard Brownian motion. The above equation can be extended to a multidimensional setting and can be generalized to include jumps or Lévy processes.

A standard simple example is a regime-dependent random walk process, where

$$\begin{aligned}\Delta x(t) &= \mu[s(t)] + \sigma[s(t)]\epsilon(t) \text{ in discrete time} \\ dx(t) &= \mu[s(t)]dt + \sigma[s(t)]dB(t) \\ &\text{in continuous time}\end{aligned}\quad (6)$$

The parameter set in this example is $\beta = \{\mu(1), \sigma(1), \mu(2), \sigma(2), \dots, \mu(N), \sigma(N)\}$.

Estimation from Historical Data

Given a set of historical values, the parameter vector β can be calibrated using maximum likelihood. As data are available over a discrete time grid, we focus on the calibration of the discrete time model. We give the switching random walk model with Gaussian noise as an example, but it should be straightforward to generalize this to more complex structures.

We denote the conditional density of $x(t)$ by $f_t(x|j) = P[x(t) \in dx|s(t) = j]$, given that the underlying Markov chain is in state j . In our example, this is a Gaussian density, with mean $\mu(j)$ and variance $\sigma^2(j)$. In addition, for future reference, we define the vector of conditional probabilities $\xi(t|t')$, with elements

$$\xi(t|t') = \{P[S(t) = j|\mathcal{F}(t')]\}_{j \in \mathcal{S}} \quad (7)$$

An important component of the calibration procedure is the vector of filtered probabilities $\xi_{t|t}$.

Given the parameter set β , the filtered probabilities can be computed based on the following recursion:

- Assume that the filtered probabilities are available up to time t .
- Compute the forecast probabilities $\xi(t+1|t) = \mathbf{P}\xi(t|t)$.
- The Bayes theorem yields the filtered probability:

- The numerator of the above expression is the product of the conditional density with the forecast probability for each state.
- The denominator, which is the sum of all numerators computed in the previous step, is also the conditional density of $P[x(t+1) \in dx|\mathcal{F}(t)]$. This is the likelihood function of the observation $x(t+1)$.

In the Kalman filtering terminology, the above computation can be compactly written in two steps:

$$\text{Prediction: } \xi(t+1|t) = \mathbf{P}\xi(t|t) \quad (9)$$

$$\begin{aligned}\text{Correction: } \xi(t+1|t+1) &= \frac{\mathbf{f}(t+1) \odot \xi(t+1|t)}{\mathbf{1}' \cdot (\mathbf{f}(t+1) \odot \xi(t+1|t))}\end{aligned}\quad (10)$$

The vector $\mathbf{f}(t)$ above collects the conditional distributions, across all possible regimes. In the Gaussian regime-switching model, the elements of $\mathbf{f}(t)$ would have the following elements:

$$\mathbf{f}(t) = \left\{ \frac{1}{\sqrt{2\pi}\sigma(j)} \exp\left(-\frac{(x(t) - \mu(j))^2}{2\sigma^2(j)}\right) \right\}_{j \in \mathcal{S}} \quad (11)$$

The symbol “ $\odot$ ” denotes element-by-element multiplication, and $\mathbf{1}$ is an $(N \times 1)$ vector of ones.

More details on estimation methods can be found in [18]. A small sample of the vast number of empirical applications that utilize the regime-switching framework is provided in [3, 15, 17, 19, 23, 27]. Generalizations include time-varying transition probabilities that depend on explanatory variables [14], switching generalized autoregressive conditionally heteroskedastic (GARCH)-type processes [16, 20], and models that resemble a multifractal setting [6]. A Bayesian alternative to maximum likelihood is sought in [1].

$$\begin{aligned}P[s(t+1) = j|\mathcal{F}(t+1)] &= P[s(t+1) = j|x(t+1), \mathcal{F}(t)] \\ &= P[x(t+1) \in dx|s(t+1) = j, \mathcal{F}(t)] \cdot \frac{P[s(t+1) = j|\mathcal{F}(t)]}{P[x(t+1) \in dx|\mathcal{F}(t)]} \\ &= \frac{P[x(t+1) \in dx|s(t+1) = j, \mathcal{F}(t)] \cdot P[s(t+1) = j|\mathcal{F}(t)]}{\sum_{\ell \in \mathcal{S}} P[x(t+1) \in dx|s(t+1) = \ell, \mathcal{F}(t)] \cdot P[s(t+1) = \ell|\mathcal{F}(t)]}\end{aligned}\quad (8)$$

Derivative Pricing under Regime Switching

Derivative pricing is typically carried out in a continuous time setting.^a For a vanilla payoff with maturity T , say $z(T) = h(x(T))$, the time-zero price is given by the risk neutral expectation:

$$z(0) = E^Q[D(T)z(T)] \quad (12)$$

where $D(t)$ is the discount factor.

In the regime-switching framework, pricing is routinely carried out using the Fourier inversion techniques (see **Fourier Transform**) outlined in [7]. In particular, if the log asset price $x(T)$ follows a regime-switching Brownian motion

$$dx(t) = \mu(s(t))dt + \sigma(s(t))dB(t) \quad (13)$$

then the characteristic function $\phi(u; T) = E \exp(iu x(T))$ is given by the matrix exponential

$$\phi(u; T) = e^{T \mathbf{A}(u)} \boldsymbol{\xi}(0|0) \quad (14)$$

where the $(N \times N)$ matrix $\mathbf{A}(u)$ has the following form:

$$a_{i,j}(u) = \begin{cases} q_{i,i} + g(u; i) & \text{if } i = j \\ q_{i,j} & \text{if } i \neq j \end{cases} \quad (15)$$

for $g(u; i) = iu\mu(i) - \frac{1}{2}u^2\sigma^2(i)$.

The first implementation that prices options where a two-regime process is present is that in [26]. In a more general setting with N regimes, vanilla call option prices can be easily retrieved using the Fast Fourier Transform (FFT) approach of Carr and Madan [7] or the fractional variant that allows explicit control of the discretization grids [10].

The above prototypical process can be extended in two directions. Rather than having switching Brownian motions that generate the conditional paths, one can consider switching Lévy processes (see **Lévy Processes; Exponential Lévy Models**) between the regimes (see [24], for the special two-regime case, and [11], for a more general setting). In that case, the function $g(u; i)$ in $\mathbf{A}(u)$ is replaced by the characteristic exponent of the Lévy process that is active in the i th regime. In addition, to introduce a correlation structure between the regime changes and the log-price changes, a jump in the log-price is introduced when the Markov chain switches. In that

case, the off-diagonal elements of $\mathbf{A}(u)$ are multiplied by the characteristic function of the jump size.

Pricing of American options can be done by setting up the continuation region [5] or by employing a variant of Carr's randomization procedure [4]. More exotic products can be handled by setting up a system of partial (integro-)differential equations (see **Partial Integro-differential Equations (PIDEs)**) or by explicitly using Fourier methods as in [22]. As the conditional distribution can be recovered from the characteristic function numerically, the density-based approach of [2] (see **Quadrature Methods**) can be a viable alternative.

Regime Switching as an Approximation

Rather than serving as the fundamental latent process, the Markov chain can serve as an approximation to more complex jump-diffusive dynamics. Then, one can use the regime-switching framework to tackle problem in a nonaffine (see **Affine Models**) setting, both in terms of calibration and derivative pricing. To achieve that, the number of regimes must be large, but the transition rates and conditional dynamics will be functions of a small number of parameters. The book by Kushner and Dupuis [25] outlines the convergence conditions for the approximation of generic diffusions and shows how one can implement the Markov chain approximation in practice.

Following this approach, many stochastic volatility problems can be cast as regime-switching ones. Chourdakis [8] shows how a generic stochastic volatility process can be approximated in that way, whereas Chourdakis [9] extends this method to produce the counterpart of the [21] stochastic volatility model (see **Heston Model**) in a regime-switching framework where the equity is driven by a Lévy noise.

Variance-gamma Model

The variance-gamma (VG) process is a stochastic process with independent stationary increments, which allows for flexible parameterization of skewness and kurtosis of increments. It has gained popularity, especially in option pricing, because of its analytical tractability. It is an example of a pure-jump Lévy process (*see Lévy Processes*).

The VG model is derived from the (symmetric) VG probability distribution, which is so named because it is the distribution of a random variable X that results from mixing a normal variable on its variance by a gamma distribution. Specifically, the conditional distribution of X is given by $X|W \sim \mathcal{N}(\mu, \sigma^2 W)$, $\mu \in \mathbb{R}$, $\sigma > 0$, where $W \sim \Gamma(\alpha, \alpha)$, $\alpha > 0$. The symbol “ $\sim$ ” stands for “is distributed as”. The symbol $\Gamma(\alpha, \lambda)$ indicates a gamma probability distribution, with probability density function (PDF), for $\alpha, \lambda > 0$,

$$f_{\Gamma}(w; \alpha, \lambda) = \frac{\lambda^{\alpha}}{\Gamma(\alpha)} w^{\alpha-1} e^{-\lambda w}, \quad w > 0; = 0 \text{ elsewhere} \quad (1)$$

The choice $\lambda = \alpha$ implies that $\mathbb{E}(W) = 1$ and $\mathbb{V}\text{ar}(W) = \frac{1}{\alpha}$. Thus, X is a random variable symmetrically distributed about its mean $\mathbb{E}(X) = \mu$, with $\mathbb{V}\text{ar}(X) = \sigma^2$ and a simple characteristic function (CF), so that when X is mean-corrected to $Y = X - \mu$, the CF is

$$\mathbb{E}(e^{iuY}) = \left(1 + \frac{\sigma^2 u^2}{2\alpha}\right)^{-\alpha} \quad (2)$$

A random variable X having (symmetric) VG distribution may also be viewed as

$$X \stackrel{\mathcal{D}}{=} \mu + \sigma W^{\frac{1}{2}} Z, \quad \mathbb{E}(W) = 1 \quad (3)$$

where the symbol $\stackrel{\mathcal{D}}{=}$ means “has the same distribution as”. Here $Z \sim \mathcal{N}(0, 1)$ and W is a positive nondegenerate random variable distributed independently of Z . In the case of the VG distribution, $W \sim \Gamma(\alpha, \alpha)$.

Log returns of financial assets

$$X_t = \log P_t - \log P_{t-1}, \quad t = 1, 2, \dots, N \quad (4)$$

reveal a kurtosis well in excess of 3, suggesting that the modeling of returns should be done by a symmetric distribution with heavier tails than the normal (*see Stylized Properties of Asset Returns; Heavy Tails*). For example, in 1972, Praetz [20] argued in favor of variance-dilation of the normal through variance-mixing and found that mixing according to $X|W \sim \mathcal{N}(\mu, \sigma^2 W)$, where W has reciprocal (inverse) gamma PDF with $\mathbb{E}W = 1$, gives the scaled t -distribution symmetric about μ for the returns. This is a slight generalization of the classical Student’s t -distribution, in that fractional degrees of freedom are permitted.

Influenced by Praetz’s work, Madan and Seneta [16] took the distribution of the mixing variable W itself to be gamma (rather than reciprocal gamma). This resulted in a continuous-time model, which is now known as the (*symmetric*) *variance-gamma model*.

The VG model may be placed within the context of a more general subordinator (*see Time Change*) model [10], which gives the price P_t of a risky asset over continuous time $t \geq 0$ as

$$P_t = P_0 \exp \{ \mu t + \sigma B(T_t) \} \quad (5)$$

where μ and $\sigma (> 0)$ are real constants. $\{T_t\}$, the (market) activity time, is a positive, increasing random process (with stationary differences $W_t = T_t - T_{t-1}$, $t = 1, 2, \dots$), which is independent of the standard Brownian motion $\{B(t)\}$. The corresponding returns are then given as

$$X_t = \log P_t - \log P_{t-1} = \mu + \sigma (B(T_t) - B(T_{t-1})) \quad (6)$$

We assume that $\mathbb{E}(W_t) < \infty$, and so without loss of generality that

$$\mathbb{E}(W_t) = 1 \quad (7)$$

to make the expected activity time change over unit calendar time equal to one unit, the scaling change in time being absorbed into σ , while noting that

$$X_t \stackrel{\mathcal{D}}{=} \mu + \sigma W_t^{\frac{1}{2}} B(1) \quad (8)$$

which is of form (3). The case $T_t = t$ of the model (5) is the classical geometric Brownian motion (GBM) model for the process $\{P_t\}$, with corresponding returns being independently $\mathcal{N}(\mu, \sigma^2)$ distributed.

In the VG model, $\{T_t\}$ for $t \geq 0$, is the gamma process, a process of stationary-independent increments. The distribution of an increment over a time interval of length t is $\Gamma(\alpha t, \alpha)$. It is a remarkable feature that the distributional form for any t is the same; this is inherited by the VG model for $\{\log(P_t/P_0)\}$, $t \geq 0$, which is a process of stationary-independent increments, with the distribution of an increment over any time period t having CF

$$e^{i\mu u t} \left(1 + \frac{\sigma^2 u^2}{2\alpha}\right)^{-\alpha t} \quad (9)$$

The corresponding distribution is also called a (*symmetric*) *VG distribution*. Its mean and variance are given by $\mathbb{E} \log(P_t/P_0) = \mu t$ and $\text{Var}(\log(P_t/P_0)) = \sigma^2 t$, respectively. The whole structure is redolent of Brownian motion, to which the VG process reduces in the limit as $\alpha \rightarrow \infty$.

An important consequence of the VG distributional form of an increment over any time interval of length t is that, irrespective of the size of unit of time between successive data readings, returns have a VG distribution.

The CF (2), clearly the CF of an infinitely divisible distribution, is also the CF of a difference of two independently and identically distributed (i.i.d.) gamma random variables, which reflects the fact shown in [16] that the process $\{\log(P_t/P_0) - t\mu\}$, $t \geq 0$, is the difference of two i.i.d. gamma processes.

The VG model is a pure-jump process [16] (*see Jump Processes*) reflecting this feature of a gamma process. This is seen from the Lévy–Khinchin representation (*see Lévy Processes*).

The analytical simplicity of the VG model and its pure-jump nature make it a leading candidate for modeling historical financial data. Further, the VG distribution's PDF has explicit structural form (see below), which is tractable for maximum-likelihood estimation of parameters from returns data.

Returns $\{X_t\}$, $t = 0, 1, 2, \dots$, considered in isolation, need not be taken to be i.i.d. as in the preceding discussion, but to form (more generally) a strictly stationary sequence, to which moment estimation methods, for example, will still apply [25]. The symmetric scaled t -distribution continues to enjoy favor as a model for the distribution of returns because of its power-law (Pareto-type) probability tails, a property manifested (in contrast to the VG) in the nonexistence of higher moments. For some data sets, empirical

investigations [10, 12] suggest the nonexistence of higher moments in a model for returns (*see Heavy Tails; Stylized Properties of Asset Returns*) and hence the scaled t -distribution.

On the other hand, other investigations [9] suggest that it is virtually impossible to distinguish between the symmetric scaled t and VG distributions in regard to distributional tail structure by taking compatible parameter values in the two distributions. In fact, the PDFs of the two distributions reveal that the concentration of probability near the point of symmetry μ and in the middle range of the distributions is qualitatively and quantitatively different. The VG distribution tends to increase the probability near μ and in the tails, at the expense of the middle range. The different natures in regard to shape are most significantly revealed by the Cauchy distribution as a special case of the t -distribution and the Laplace (two-sided exponential) distribution as a special case of the VG distribution.

The first monograph to include a study of the VG model was [4]. Since then it has found a place in monographs such as [22], where it is treated in the general context of Lévy processes (*see Lévy Processes*).

Both the VG distribution and the scaled t -distribution are extreme cases of the generalized hyperbolic (*see Generalized Hyperbolic Models*) distribution [23, 25].

Allowing for Skewness

A generalized normal mean–variance-mixing distribution is the distribution of X , where the conditional distribution of X is given as

$$X|W \sim \mathcal{N}(\mu + \theta W, \sigma^2 W + d^2) \quad (10)$$

Here, μ , θ , d , and $\sigma (> 0)$ are real numbers, and W is a nondegenerate positive random variable. The distribution is skew if $\theta \neq 0$, and it is symmetric otherwise. Press [21] studied a continuous-time model with this distribution for returns, where $W \sim \text{Poisson}(\lambda)$. This is a process of stationary-independent increments, resulting from adding a compound Poisson process of normal shocks to a Brownian motion, and has both continuous and jump components. Some special cases of equation (10) as a returns distribution, with focus on the estimation of parameters by the method of moments, are considered in [25].

A random variable X is said to have a normal variance–mean mixture (NVM) distribution [1] if equation (10) holds with $d = 0$.

The symmetric VG and scaled t -distributions are instances of equation (10), with $d = \theta = 0$.

The skew VG distribution, as introduced in [15], is the case of NVM where W is described by equation (1) with $\mathbb{E}W = 1$ as in the symmetric case. (The skewed scaled t -distribution is defined analogously by taking W to have a reciprocal gamma distribution.)

The skew VG distribution has PDF

$$f_{\text{VG}}(x) = \sqrt{\frac{2}{\pi}} \frac{\alpha^\alpha e^{\frac{(x-\mu)\theta}{\sigma^2}}}{\sigma \Gamma(\alpha)} \left(\frac{|x-\mu|}{\sqrt{\theta^2 + 2\alpha\sigma^2}} \right)^{\alpha-\frac{1}{2}} \times K_{\alpha-\frac{1}{2}} \left(\frac{|x-\mu|\sqrt{\theta^2 + 2\alpha\sigma^2}}{\sigma^2} \right), \quad x \in \mathbb{R} \quad (11)$$

and CF

$$\phi_{\text{VG}}(u) = \mathbb{E}(e^{iux}) = e^{i\mu u} \left(1 - \frac{1}{\alpha} \left(iu\theta - \frac{\sigma^2 u^2}{2} \right) \right)^{-\alpha} \quad (12)$$

$K_\eta(\omega)$ for $\eta \in \mathbb{R}$ and $\omega > 0$, given as

$$K_\eta(\omega) = \frac{1}{2} \int_0^\infty z^{\eta-1} e^{-\frac{\omega}{2} \left(z + \frac{1}{z} \right)} dz \quad (13)$$

is a modified Bessel function of the third kind with index η ($K_\eta(\omega)$ is referred to as a *modified Bessel function* of the *second* kind in some texts).

An equivalent representation is

$$X \stackrel{\mathcal{D}}{=} \mu + \theta W + \sigma W^{\frac{1}{2}} Z, \quad \mathbb{E}W = 1 \quad (14)$$

where Z and W are independently distributed, $Z \sim \mathcal{N}(0, 1)$, $W \sim \Gamma(\alpha, \alpha)$ as mentioned before. This distributional structure is consistent with the continuous-time model for prices

$$P_t = P_0 \exp \{ \mu t + \theta T_t + \sigma B(T_t) \} \quad (15)$$

where $\{T_t\}$, $t \geq 0$, is a gamma process, exactly as before. The process of independent stationary increments $\{\log(P_t/P_0)\}$, $t \geq 0$, with the distribution of returns described by equations (11)–(13), is also

called the *variance-gamma model*. Its properties are extensively studied in [15].

Dependence and Estimation

The VG model described above is a Lévy process (see **Lévy Processes**)—a stochastic process in continuous time with stationary independent increments—whose increments are independent and VG distributed. To discuss dependence, we consider the model for returns:

$$X_t = \log P_t - \log P_{t-1} = \mu + \theta W_t + \sigma W_t^{1/2} Z_t, \quad t = 1, 2, \dots \quad (16)$$

where Z_t , $t = 1, 2, \dots$, are identically distributed $\mathcal{N}(0, 1)$ random variables, independent of the strictly stationary process $\{W_t\}$, $t = 1, 2, \dots$. Here $\theta, \sigma (> 0)$ are constants as before.

When $\theta = 0$, this discrete-time model is equivalent in distribution to that described by the subordinator model of Heyde [10] given by equations (5)–(8). Note that $\text{Cov}(X_t, X_{t+k}) = 0$, while $\text{Cov}(X_t^2, X_{t+k}^2) \neq 0$, $k = 1, 2, \dots$. This is an important feature inasmuch as many asset returns display a sample autocorrelation function plot characteristic of white noise, but no longer do so in a sample autocorrelation plot of squared returns and of absolute values of returns [10, 12, 17].

McLeish [17] considered the distribution of individual $W_t \sim \Gamma(\alpha, \lambda)$, which gives the distribution of individual X_t as (symmetric) VG, which he regarded as a robust alternative to the normal. He suggested a number of ways of introducing the dependence in the process $\{W_t\}$, $t = 1, 2, \dots$.

The continuous-time subordinator model was expanded in [11] to allow for scaled t -distributed returns. Their specification of the activity time process in continuous time $\{T_t\}$ incorporated self-similarity (a scaling property) and long-range dependence (LRD) in the stochastic process of squared returns. (LRD in the Allen sense is expressed as divergence of the sequence of ultimately nonnegative autocorrelations of a discrete stationary process.)

The general form of the continuous-time model for prices over continuous time $t \geq 0$ as

$$P_t = P_0 \exp \{ \mu t + \theta T_t + \sigma B(T_t) \} \quad (17)$$

for which the returns are equivalent in distribution to equation (16) was given in [23] as a generalization of the subordinator model that allows for skewness in the distribution of returns in the same way as in [15], but the returns inherit the postulated strict stationarity of the sequence $\{W_t\}, t = 1, 2, \dots$. Following on from [11], Finlay and Seneta [5, 6] studied in detail and in parallel the continuous time structure of the skew VG model and the skew t -model, with focus on skewness, asymptotic self-similarity, and LRD.

Maximum-likelihood estimation for independent readings from a symmetric VG distribution is discussed in [17] and in [23], which however proposes moment estimation in the presence of dependence. Moment estimation, allowing for dependence, is further developed in [25], along with goodness of fit of various models for several sets of asset data. A method of simulating data from long-range dependent processes with skew VG or t -distributed increments is described in [7], and various estimation procedures (method of moments, product-density maximum likelihood, and nonstandard minimum χ^2 in particular) are tested on the data to assess their performance. In the simulations considered, the product-density maximum-likelihood method performs favorably. The conclusion, within the limited testing carried out, indicates then that, in practice, ordinary product density maximum-likelihood estimation is satisfactory even in the presence of LRD. This is tantamount to saying that one may treat such data on returns as i.i.d. This entails an enormous simplification in estimation procedures in fitting the skew VG and skew t -distributions.

Option Pricing Applications

Our discussion is based on the difference of gamma (DG) models for real-world (historical) data:

$$P_t = P_0 e^{\mu t + G_1(t; a, b) - G_2(t; c, d)} \quad (18)$$

where $\{G(t; \alpha, \beta)\}$ is a gamma process, and so $G(t; \alpha, \beta) \sim \Gamma(t\alpha, \beta)$ for any given t , and the two gamma processes are independent of each other. For each t , the returns (4) for P_t have the following CF:

$$\begin{aligned} \phi_{\text{DG}}(u; \mu, a, b, c, d) \\ = e^{i\mu u} \left(1 - \frac{i u}{b}\right)^{-a} \left(1 + \frac{i u}{d}\right)^{-c} \end{aligned} \quad (19)$$

Comparing equations (12) and (19), it is clear that choosing $c = a$ results in a (skew) VG distribution, with PDF (11) parameters $\alpha = a$, $\theta = a\left(\frac{1}{b} - \frac{1}{d}\right)$, and $\sigma^2 = \frac{2a}{bd}$. The further simplification $b = d$ results in the symmetric VG process for returns.

Using this model for option pricing requires imposing parameter restrictions to ensure that $\{e^{-rt} P_t\}$ is a martingale, where r is the interest rate. This amounts to ensuring that $\mathbb{E}(e^{-rt} P_t | \mathcal{F}_s) = e^{-rs} P_s$, where $\mathcal{F}_s$ represents information available to time $s \leq t$. In the case of the DG process,

$$\begin{aligned} \mathbb{E}(e^{-rt} P_t | \mathcal{F}_s) \\ = e^{-rs} P_s \times e^{(\mu-r)(t-s)} \left(\frac{b}{b-1}\right)^{a(t-s)} \left(\frac{d}{d+1}\right)^{c(t-s)} \end{aligned} \quad (20)$$

so that imposing the restriction

$$\mu = r - a \log\left(\frac{b}{b-1}\right) - c \log\left(\frac{d}{d+1}\right) \quad (21)$$

with $b > 1$ results in $\{e^{-rt} P_t\}$, which is a martingale with four free parameters: a , b , c , and d . We label it *MDG*.

The (skew) VG special case is obtained by choosing $c = a$. Relabeling the parameters as above, $\alpha = a$, $\theta = a\left(\frac{1}{b} - \frac{1}{d}\right)$, and $\sigma^2 = \frac{2a}{bd}$, results in a martingale that is a (skew) VG process. The mean constraint (21) now translates to

$$\mu = r + \alpha \log\left(1 - \frac{\theta + \frac{1}{2}\sigma^2}{\alpha}\right) \quad (22)$$

where we take $\alpha > \theta + \frac{1}{2}\sigma^2$. This martingale now has only three free parameters. We label it *MVG*. This corresponds to the labeling “VG” in [22] and is the martingale used in [15].

Both MDG and MVG are, in the terminology of the work by Schoutens [22], “mean-correcting martingales”, since the restriction (21), (22) is on the mean (μ) to produce a martingale.

Another way of producing a martingale from a (skew) VG process is to begin by noting from [5] and equation (17) that irrespective of the distribution of T_t ,

$$\begin{aligned} & \mathbb{E}(e^{-rt} P_t | \mathcal{F}_s) \\ &= e^{-rs} P_s \times e^{(\mu-r)(t-s)} \mathbb{E}\left(e^{(\theta + \frac{1}{2}\sigma^2)(T_t - T_s)} | \mathcal{F}_s\right) \end{aligned} \quad (23)$$

where the sequence $\{W_t\}$, where $W_t = T_t - T_{t-1}$, is strictly stationary.

Thus, if we take $\mu = r$ and $\theta = -\frac{1}{2}\sigma^2$ in (23), the right-hand side of equation (23) becomes $e^{-st} P_s$, and we have a martingale. This construction of a martingale, simple and quite general, is slightly restrictive, however, in that two parameters, μ and θ , are constrained. We shall refer to this construction as a *skew-correcting martingale*, since θ , the parameter that determines skewness, is constrained. We denote this martingale model by *MSK*. Out of the “external” parameters μ , θ , and σ , the only parameter that is retained is σ , which is called the *historical volatility* in the Black–Scholes (BS) context, which is a special case when $T_t = t$. Any additional parameters in the martingale (risk-neutral) process will be those emanating from the nature of $\{T_t\}$, which will need to be specified for any examination of estimation and goodness of fit.

When the CF of the risk-neutral distribution of price is of the closed form, option prices may be calculated using Fourier methods (*see Fourier Methods in Options Pricing*) as in [3, 14]. Specifically, for $C(\Upsilon, k)$, the price of a European call option with time to maturity Υ and strike price K and $k = \log(K)$, let $q_\Upsilon(p)$ be the risk-neutral density of $\log(P_\Upsilon)$, with CF $\phi_\Upsilon(u)$, at time Υ . Thus,

$$\begin{aligned} C(\Upsilon, k) &= e^{-r\Upsilon} \mathbb{E}(P_\Upsilon - K)^+ \\ &= \int_k^\infty e^{-r\Upsilon} (e^p - e^k) q_\Upsilon(p) dp \end{aligned} \quad (24)$$

Define the modified call price as

$$c(\Upsilon, k) = e^{\gamma k} C(\Upsilon, k) \quad (25)$$

for some γ such that $\mathbb{E}(P_\Upsilon^{\gamma+1}) < \infty$. The Fourier transform of $c(\Upsilon, k)$ is then given as

$$\begin{aligned} \Psi_\Upsilon(x) &= \int_{-\infty}^\infty e^{ikx} c(\Upsilon, k) dk \\ &= \frac{e^{-r\Upsilon} \phi_\Upsilon(x - (\gamma + 1)i)}{\gamma^2 + \gamma - x^2 + ix(2\gamma + 1)} \end{aligned} \quad (26)$$

Taking the inverse Fourier transform and using the fact that $c(\Upsilon, k)$ is real, and using equation (25) gives

$$\begin{aligned} C(\Upsilon, k) &= \frac{e^{-\gamma k}}{2\pi} \int_{-\infty}^\infty e^{-ixk} \Psi_\Upsilon(x) dx \\ &= \frac{e^{-\gamma k}}{\pi} \int_0^\infty \Re\{e^{-ixk} \Psi_\Upsilon(x)\} dx \end{aligned} \quad (27)$$

In fact, we shall use a modified version of equation (27) suggested in [14]:

$$C(\Upsilon, k) = R_\gamma + \frac{e^{-\gamma k}}{\pi} \int_0^\infty \Re\{e^{-ixk} \Psi_\Upsilon(x)\} dx \quad (28)$$

where $R_\gamma = \phi_\Upsilon(-i)$ for $-1 < \gamma < 0$. The choice of γ generally impacts on the error generated by the numerical approximation of equation (28). Finally, the option price (28) is computed *via* numerical integration.

The option price in this procedure is given simply by the sum of a number of function evaluations. Lee [14] shows that with a judicious choice of tuning parameters, one can calculate the option price up to 99.99% accuracy with less than 100, and in some cases less than 10, function evaluations. This CF-based pricing method lends itself easily to the fast Fourier transform, which allows for a very fast calculation of a range of option prices.

To numerically illustrate the method and the empirical performance of MVG against some competitors, we [8] use the data set in [22], Appendix C, which contains 77 call option prices on the S&P 500 index at the close of market on April 18, 2002. Fundamentally, each data point consists of the triple: strike, option price, and expiry date.

Fitting models involves estimating model parameters. To do this, we follow [22], p. 7, by minimizing with respect to the model parameters, the root-mean-square error (RMSE):

$$\begin{aligned} \text{RMSE} &= \sqrt{\left(\sum_{\text{options}} \frac{(\text{market price} - \text{model price})^2}{\text{number of options}} \right)} \end{aligned} \quad (29)$$

and then comparing the values of the minimized errors between models. If a model perfectly described

the asset price process, the RMSE value would be zero, with all model prices matching market prices, given the single true set of parameters.

The estimates of model parameters produced for a given model correspond to the current market status of that model. The procedure is thus, for a given model, a calibration procedure. No historical data are used in this procedure. The use of this data set for comparison of several different models in this way as already done in [22] allows for easy comparison of goodness of fit. We used the tuning parameter value $\gamma = -\frac{1}{2}$; the other nonmodel constants, q, r , were as in [22], Appendix C.

The RMSE surface for the MDG was reported in [8] to be quite flat, with a number of different parameter values giving essentially the same RMSE value of 2.24. The parameter values that gave the lowest value by 0.001 were as follows: $a = 4.35, b = 240.86, c = 9.79 \times 10^{-6}, d = 2.65 \times 10^{-7}$. The four-parameter MDG model thus did better than the four-parameter CGMY and GH models reported in [22], p. 83, and shown in Table 1.

The VG (skew) model fit reported in [22], p. 83, corresponded to the parameter values $\alpha (= a = c) = 5.4296 \times 10^{-3}, b = 14.2699, d = 5.8704$. The recalculation of RMSE with these parameter values reported in [8] gave the value 3.57. Optimization of RMSE reported in [8] with starting values $a = c = 0.01, b = d = 10$ resulted in the parameter estimates and RMSE as in [22]. Thus in Table 1, the RMSE values reported under VG and MVG are the same, 3.56.

As expected, this three-parameter model (MVG/VG) does not perform quite as well as the four-parameter models. The VG model is a special case of the GH model, so this is not unexpected.

Finlay and Seneta [8] discuss fitting an MSK martingale model, which allows for LRD in the historical data. This introduces two parameters in addition to the “historical volatility” parameter σ , namely, a parameter α corresponding to the gamma distribution with mean 1, as before, and a “Hurst” parameter H associated with dependence. The fit of MSK produces an RMSE of 6.35 and an estimate of $\sigma = 0.012$. There is almost no improvement on the BS situation reported in Table 1, which is the standard BS

martingale model; its RMSE and σ -estimate values are reported in [22], pp. 40-41, and are 6.73 and 0.011, respectively. This apparent insensitivity of the MSK model to departure from BS, possibly due to the skewness parameter being constrained in the martingale construction, is overcome, as reported in [8], by a four-parameter (“lack of static arbitrage” model: [2]) model, which is termed as C3. This model, though not a martingale model, gives an RMSE = 0.76, and its parameter estimates conform with estimates from historical data for an LRD VG model [7].

Thus, for a given maturity, the three-parameter MVG model and its associated (skew) VG model for historical data perform reasonably well in fitting option prices. If a four-parameter martingale model is to be used, the parent model of MVG that should be used is the MDG, in which the gamma process continues to play a fundamental role.

Historical Notes

In the case where $\sigma^2 = 2\alpha$ in the CF (2), the corresponding PDF (11) (with $\mu = \theta = 0$) already appears in [18], p. 184, equation (xlⁱⁱ), and is the theme of [19], where it is shown to be the distribution of difference of two i.i.d. gamma random variables, an idea clarified in [13]. The definition of the Bessel function $K_\eta(\omega)$ used differs from equation (13). Teichroew [24] obtained the PDF (11) (with $\mu = \theta = 0$), in terms of a Hankel function, from the normal variance-mixing structure of the distribution of X , using form (1) for the PDF of the mixing variable W . These themes are taken up by McLeish [17] as a starting point.

The skew VG distribution with $\alpha = 2n$, where n is a positive integer, and $-1 < \theta/\sigma^2 < 1$ appears in [26], a paper generalizing [19], which was also published in 1932.

Acknowledgments

Many thanks are due to Richard Finlay for his help.

Jump-diffusion Models

Jump-diffusion (JD) option pricing models are particular cases of exponential Lévy models (*see Exponential Lévy Models*) in which the frequency of jumps is finite. They can be considered as prototypes for a large class of more complex models such as the stochastic volatility plus jumps model of Bates (*see Bates Model*).

Consider a market with a riskless asset (the bond) and one risky asset (the stock) whose price at time t is denoted by S_t . In a JD model, the SDE for the stock price is given as

$$dS_t = \mu S_{t-} dt + \sigma S_{t-} dZ_t + S_{t-} dJ_t \quad (1)$$

where Z_t is a Brownian motion and

$$J_t = \sum_{i=1}^{N_t} Y_i \quad (2)$$

is a compound Poisson process where the jump sizes Y_i are independent and identically distributed with distribution F and the number of jumps N_t is a Poisson process with intensity λ . The asset price S_t thus follows geometric Brownian motion between jumps. Monte Carlo simulation of the process can be carried out by first simulating the number of jumps N_t , the jump times, and then simulating geometric Brownian motion on intervals between jump times.

The SDE (1) has the exact solution:

$$S_t = S_0 \exp\{\mu t + \sigma Z_t - \sigma^2 t/2 + J_t\} \quad (3)$$

Merton [5] considers the case where the jump sizes Y_i are normally distributed.

Risk-neutral Drift

If the above model is used as a pricing model, the drift μ in equation (1) is given by the risk-neutral drift $\hat{\mu}$, which contains a jump compensator μ_J :

$$\mu = \hat{\mu} + \mu_J \quad (4)$$

To identify μ_J , taking expectations of equation (1) and from the definition of $\hat{\mu}$,

$$\begin{aligned} \mathbb{E}[dS_t] &= \hat{\mu} S_t dt = \mu S_t dt \\ &+ \lambda \left\{ \int \xi F(d\xi) \right\} S_t dt \end{aligned} \quad (5)$$

where F is the risk-neutral jump distribution. The jump compensator is then given as

$$\mu_J = -\lambda \int \xi F(d\xi) \quad (6)$$

To simplify the presentation, we henceforth assume zero dividends so that $\hat{\mu} = r$, the risk-free rate.

Characteristic Function

Define the forward price $F := S_0 e^{rt}$. If $x_t := \log S_t/F$ is a Lévy process (*see Lévy Processes*), its characteristic function $\phi_T(u) := \mathbb{E}[e^{iux_T}]$ has the Lévy–Khintchine representation

$$\begin{aligned} \phi_T(u) &= \exp \left\{ i u (\mu_J - \sigma^2/2) T - u^2 \sigma^2/2 T \right. \\ &\quad \left. + T \int [e^{i u \xi} - 1] \nu(\xi) d\xi \right\} \end{aligned} \quad (7)$$

Typical assumptions for the distribution of jump sizes are as follows: normal as in the original paper by Merton [5] and double exponential as in [3] (*see Kou Model*). In the Merton model, the Lévy density $\nu(\cdot)$ is given as

$$\nu(\xi) = \frac{\lambda}{\sqrt{2\pi} \delta} \exp \left\{ -\frac{(\xi - \alpha)^2}{2\delta^2} \right\} \quad (8)$$

where α is the mean of the log-jump size $\log J$ and δ the standard deviation of jumps. This leads to the explicit characteristic function

$$\begin{aligned} \phi_T(u) &= \exp \left\{ i u \omega T - \frac{1}{2} u^2 \sigma^2 T \right. \\ &\quad \left. + \lambda T (e^{i u \alpha - u^2 \delta^2/2} - 1) \right\} \end{aligned} \quad (9)$$

with

$$\omega = -\frac{1}{2} \sigma^2 - \lambda (e^{\alpha + \delta^2/2} - 1) \quad (10)$$

In the double-exponential case (see **Kou Model**)

$$\nu(\xi) = \lambda \left\{ p \alpha_+ e^{-\alpha_+ \xi} \mathbf{1}_{\xi \geq 0} + (1-p) \alpha_- e^{-\alpha_- |\xi|} \mathbf{1}_{\xi < 0} \right\} \quad (11)$$

where α_+ and α_- are the expected positive and negative jump sizes, respectively, and p is the relative probability of a positive jump. This gives the explicit characteristic function:

$$\phi_T(u) = \exp \left\{ i u \omega T - \frac{1}{2} u^2 \sigma^2 T + \lambda T \times \left(\frac{p}{\alpha_+ - i u} - \frac{1-p}{\alpha_- + i u} \right) \right\} \quad (12)$$

with

$$\omega = -\frac{1}{2} \sigma^2 - \lambda \left(\frac{p}{\alpha_+ + 1} - \frac{1-p}{\alpha_- - 1} \right) \quad (13)$$

Pricing of European Options

Given a characteristic function, European call options can be priced using Fourier methods (see **Fourier Methods in Options Pricing**), as in [4]:

$$C(S, K, T) = e^{-rT} \left\{ F - \sqrt{FK} \frac{1}{\pi} \int_0^\infty \frac{du}{u^2 + \frac{1}{4}} \times \operatorname{Re} \left[e^{-iuk} \phi_T(u - i/2) \right] \right\} \quad (14)$$

where the log-strike $k := \log(K/F)$.

Valuation Equation

Assuming the process (1) and a constant risk-free rate r and further supposing that the market is complete, the value $V(S, t)$ of a European-style option satisfies

$$\frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + r S \frac{\partial V}{\partial S} - r V + \lambda \int F(d\xi) \left\{ V(S e^\xi, t) - V(S, t) - (\xi - 1) S \frac{\partial V}{\partial S} \right\} = 0 \quad (15)$$

where for ease of notation, V denotes $V(S, t)$. Equation (15) is a partial integro-differential equation (PIDE) (see **Partial Integro-differential Equations (PIDEs)**), which can be solved using finite-difference methods [1].

A Valuation Formula for European Options

Merton [5] derived an exact solution of the valuation equation (15) for a European-style call option with strike K and time to expiration T , which has the form of an infinite sum of Black–Scholes-like terms:

$$C(S, K, T) = \sum_{n=0}^{\infty} \frac{e^{-\lambda T} (\lambda T)^n}{n!} \int F_n(d\xi) \times C_{BS}(S e^{\xi} e^{\mu_J T}, K, r, \sigma, T) \quad (16)$$

where F_n is the distribution of the sum of n -independent jumps and $C_{BS}(\cdot)$ denotes the Black–Scholes solution, which is given as

$$C_{BS}(S, K, r, \sigma, T) = S N(d_1) - K e^{-rT} N(d_2) \quad (17)$$

with

$$d_1 = \frac{\log(S/K) + rT + \frac{\sigma \sqrt{T}}{2}}{\sigma \sqrt{T}} \quad d_2 = \frac{\log(S/K) + rT - \frac{\sigma \sqrt{T}}{2}}{\sigma \sqrt{T}} \quad (18)$$

Jump to Ruin

In the case where $e^{Y_i} = 0$ with probability 1, $\mu_J = \lambda$ and equation (16) simplifies to

$$C(S, K, T) = e^{-\lambda T} C_{BS}(S e^{\lambda T}, K, r, \sigma, T) \quad (19)$$

which is the Black–Scholes formula with a shifted interest rate $r \rightarrow r + \lambda$. This special case of the JD model where the stock price jumps to zero (or ruin) whenever there is a jump is the simplest possible model of default. Equation (19) for the option price in the jump-to-ruin model may also be derived from a Black–Scholes style replication argument using stock and bonds of the issuer of the stock; upon default of the issuer, both stock and bonds jump to zero. The

cost of funding stock with bonds of the issuer is $r + \lambda$ in this picture, which explains the simple form (19) of the solution.

Local Volatility

There is a particularly simple expression for Dupire local volatility in the jump-to-ruin model. It is given by Gatheral [2]:

$$\sigma_{\text{loc}}^2(K, T; S) = \sigma^2 + 2\lambda\sigma\sqrt{T} \frac{N(d_2)}{N'(d_2)} \quad (20)$$

with

$$d_2 = \frac{\log(S/K) + \lambda T}{\sigma\sqrt{T}} - \frac{\sigma\sqrt{T}}{2} \quad (21)$$

As $K \rightarrow \infty$, $d_2 \rightarrow -\infty$ and the correction term vanishes, and as $K \rightarrow 0$, the correction term explodes. In addition, as the *hazard rate* λ increases, so does d_2 , increasing the local volatility for low strikes K relative to high strikes.

Normally Distributed Jumps

Merton [5] also shows that if jumps are normally distributed with $Y_i \sim N(\alpha, \delta)$, equation (16) again simplifies considerably to give

$$C(S, K, T) = \sum_{n=0}^{\infty} \frac{e^{-\lambda' T} (\lambda' T)^n}{n!} C_{\text{BS}}(S, K, r_n, \sigma_n, T) \quad (22)$$

with

$$\lambda' = \lambda e^{\alpha + \delta^2/2} \quad (23)$$

$$\sigma_n^2 T = \sigma^2 T + n \delta^2 \quad (24)$$

$$r_n T = (r + \mu_J) T + n (\alpha + \delta^2/2) \quad (25)$$

Each term $C_{\text{BS}}(S, K, r_n, \sigma_n, T)$ in equation (22) is the value of the option conditional on there being exactly n jumps during its life.

Implied Volatility Smile

If there were no jumps in this model, the implied volatility smile would be flat. Jumps in the JD stock price process induce an implied volatility smile whose short time limit (see, e.g., [2]) is given as

$$K \frac{\partial}{\partial K} \sigma_{\text{BS}}^2(K, T) \rightarrow -2\mu_J \text{ as } T \rightarrow 0 \quad (26)$$

The greater the μ_J , because jumps are either more frequent or more negatively skewed, the more negative is the implied volatility skew.

Time-changed Lévy Process

If L is a Lévy process (*see Lévy Processes*) and $(T_t)_{t \geq 0}$ is a positive increasing process, $X_t = L(T_t)$ is called a *time-changed Lévy process* with time change $(T_t)_{t \geq 0}$. When the time change is independent from L , many properties of X can be derived from those of L .

Many **Lévy processes** have appeared as time-changed Brownian motions (*see Time Change*), so one might ask why one should time change them yet again. In this regard, we note that Lévy processes are by construction processes of independent identically distributed increments and hence all distributional parameters such as variances, skewness, kurtosis, and possibly correlations are constant. Yet all these and possibly more entities are stochastic in actual economies, and this randomness may be important for particular questions of interest. These considerations led in the first instance to the construction of processes displaying stochastic volatility with the local innovations of a Lévy process. Analytical tractability of characteristic functions motivated models with exponential affine characteristic functions (*see Affine Models*) and through the work of Duffie *et al.* [4] it became well known that this would be the case if the infinitesimal generator of the resulting Markov process was linear in state variables. The recipe for constructing these models was, therefore, clear.

A number of models in this direction were presented by Carr *et al.* [2]. Three Lévy processes were selected for being time changed and they were the normal inverse Gaussian (NIG) (*see Normal Inverse Gaussian Model*), the variance gamma (VG) (*see Variance-gamma Model*), and the CGMY model (*see Tempered Stable Process*). The first two were already known to be time changes of Brownian motion with drift. Cont and Tankov [3, Prop. 4.1] show that the CGMY also has such a representation. Characteristic exponents $\psi(u; \cdot)$ are critical to the development of the exponential affine representations (*see Affine Models*) involved, which are given here by the logarithm of the characteristic functions taken at unit time. For these three models, the characteristic exponents are given as (subscript indicates

the model name)

$$\begin{aligned} \psi_{\text{NIG}}(u; \sigma, \nu, \theta) \\ = \sigma \left(\frac{\nu}{\theta} - \sqrt{\frac{\nu^2}{\theta^2} - 2 \frac{\theta i u}{\sigma^2} + u^2} \right), \sigma, \nu > 0, \theta \in \mathbb{R} \end{aligned} \quad (1)$$

$$\begin{aligned} \psi_{\text{VG}}(u; \sigma, \nu, \theta) \\ = \frac{1}{\nu} \log \left(1 - i u \theta \nu - \frac{\sigma^2 \nu}{2} u^2 \right), \sigma, \theta, \nu \in \mathbb{R} \end{aligned} \quad (2)$$

$$\begin{aligned} \psi_{\text{CGMY}}(u; C, G, M, Y) \\ = C \Gamma(-Y) ((M - i u)^Y - M^Y + (G + i u)^Y \\ - G^Y), C, G, M > 0, 0 < Y < 2. \end{aligned} \quad (3)$$

The details of the associated Lévy processes are given, which would assist in various applications. The NIG and VG processes can be written as Brownian motion with drift θ and volatility σ time changed by an inverse Gaussian process and a gamma process, respectively. The inverse Gaussian process T_t^ν is the time taken by an independent Brownian motion with drift ν to reach the level t , while the gamma process G_t^ν is an increasing process with independent identically distributed increments where the increments over unit time have a gamma distribution with unit mean and volatility ν . Both the NIG and VG are pure jump processes with Lévy measures $k_{\text{NIG}}(x) dx$, $k_{\text{VG}}(x) dx$ defined as

$$k_{\text{NIG}}(x) = \sqrt{\frac{2}{\pi}} \sigma \alpha^2 \frac{e^{\beta x} K_1(|x|)}{|x|} \quad (4)$$

$$\beta = \frac{\theta}{\sigma^2}, \quad \alpha^2 = \frac{\nu^2}{\sigma^2} + \frac{\theta^2}{\sigma^4} \quad (5)$$

$$k_{\text{VG}}(x) = \frac{C}{|x|} \exp\left(\frac{G-M}{2}x\right) \exp\left(-\frac{G+M}{2}|x|\right) \quad (6)$$

$$\begin{aligned} C = \frac{1}{\nu}; G = \left(\sqrt{\frac{\theta^2 \nu^2}{4} + \frac{\sigma^2 \nu}{2}} - \frac{\theta \nu}{2} \right)^{-1}, \\ M = \left(\sqrt{\frac{\theta^2 \nu^2}{4} + \frac{\sigma^2 \nu}{2}} + \frac{\theta \nu}{2} \right)^{-1} \end{aligned} \quad (7)$$

where $K_\alpha(x)$ is the Bessel K function.

The CGMY process was defined in terms of its Lévy measure $k_{\text{CGMY}}(x) dx$ with

$$k_{\text{CGMY}}(x) = \frac{C}{|x|^{1+Y}} \exp\left(\frac{G-M}{2}x\right) \times \exp\left(-\frac{G+M}{2}|x|\right) \quad (8)$$

It was shown in [3, Proposition 4.1] (see also [6]) that the CGMY process can be represented as Brownian motion with drift $(G-M)/2$ time changed by a shaved stable $\frac{Y}{2}$ subordinator with shaving function

$$f(y) = e^{-\frac{(B^2 - A^2)y}{2}} E \left[e^{-\frac{B^2 y}{2} \frac{\gamma_{Y/2}}{\gamma_{1/2}}} \right],$$

$$A = \frac{G-M}{2}, \quad B = \frac{G+M}{2} \quad (9)$$

where $\gamma_{Y/2}, \gamma_{1/2}$ are independent gamma variates.

One may explicitly evaluate in terms of Hermite functions:

$$E \left[e^{-\frac{B^2 y}{2} \frac{\gamma_{Y/2}}{\gamma_{1/2}}} \right] = \frac{\Gamma(Y)}{\Gamma\left(\frac{Y}{2}\right) 2^{\frac{Y}{2}-1}} h_{-Y}(B\sqrt{y}) \quad (10)$$

where

$$h_\nu(z) = \frac{1}{\Gamma(-\nu)} \int_0^\infty e^{-y^2/2 - yz} y^{-\nu-1} dy \quad (\nu < 0) \quad (11)$$

A Continuous Time Change

We can introduce stochastic volatility along with a clustering of volatility by time changing these Lévy processes by the integral of the square root process $y(t)$, where

$$dy = \kappa(\eta - y) dt + \lambda\sqrt{y} dW \quad (12)$$

for an independent Brownian motion $(W(t), t > 0)$. For a candidate Lévy process $X(t)$, we consider as a model for the uncertainty driving the stock the composite process

$$Z(t) = X(Y(t)) \quad (13)$$

where

$$Y(t) = \int_0^t y(u) du \quad (14)$$

The characteristic function for the composite process is easily derived from the characteristic function of $Y(t)$ as

$$E[e^{iuY(t)}] = \phi(u, t, y(0), \kappa, \eta, \lambda) = A(t, u) \exp(B(t, u)y(0)) \quad (15)$$

$$A(t, u) = \frac{\exp\left(\frac{\kappa^2 \eta t}{\lambda^2}\right)}{\left(\cosh\left(\frac{\gamma t}{2}\right) + \frac{\kappa}{\gamma} \sinh\left(\frac{\gamma t}{2}\right)\right) \frac{2\kappa\eta}{\lambda^2}} \quad (16)$$

$$B(t, u) = \frac{2iu}{\kappa + \gamma \coth\left(\frac{\gamma t}{2}\right)} \quad (17)$$

$$\gamma = \sqrt{\kappa^2 - 2\lambda^2 iu} \quad (18)$$

It follows that

$$E[\exp(iuZ(t))] = \phi(-i\psi_X(u), t, y(0), \kappa, \eta, \lambda) \quad (19)$$

The Stock Price Model

There are two approaches to model the stock price $S(t)$. The first approach takes the exponential of the composite process corrected to get the correct forward price, whereby we define

$$S_1(t) = S(0) \frac{\exp(Z(t))}{E[\exp(Z(t))]} \quad (20)$$

In this case, the stock price has the right forward and the resulting option prices are free of static arbitrage. However, there may be the possibility of dynamic arbitrage in the model and this is an issue if the model is being used continuously to quote on options with constant parameters through time. To exclude dynamic arbitrage in the model, one could form a martingale model for the forward stock price by modeling it as the stochastic exponential of the martingale:

$$n(t) = Z(t) - \int_0^t \int_{-\infty}^\infty xy(t)k_X(x) dx ds \quad (21)$$

In the second approach, one writes the stock price process $S_2(t)$ as

$$S_2(t) = S(0) \exp((r - q)t) \exp(Z(t) - Y(t)\psi_X(-i)) \quad (22)$$

For the first approach, the log characteristic function for the logarithm of the stock price is given as

$$\begin{aligned} E[\exp(iu \log S_1(t))] \\ = \exp(iu(\log(S(0) + (r - q)t))) \\ \times \frac{\phi(-i\psi_X(u), t, y(0); \kappa, \eta, \lambda)}{\phi(-i\psi_X(-i), t, y(0); \kappa, \eta, \lambda)^{iu}} \end{aligned} \quad (23)$$

The second approach leads to the following characteristic function:

$$\begin{aligned} E[\exp(iu \log S_2(t))] \\ = \exp(iu(\log(S(0) + (r - q)t))) \\ \times \phi(-i\psi_X(u) - u\psi_X(-i), t, y(0); \kappa, \eta, \lambda) \end{aligned} \quad (24)$$

The models of the first approach are termed *NIGSA*, *VGSA*, and *CGMYSA* for NIG, VG, and CGMY with a stochastic arrival rate of jumps adapted to the level of the process $y(t)$. The models of the second approach are martingale models and are termed *NIGSAM*, *VGSA*, and *CGMYSAM*, respectively. It is observed in calibrations that the first approach generally fits the option price data better.

Some Discontinuous Time Changes

One can replace the continuous stochastic process for the arrival rate of jump activity $y(t)$ by a discontinuous process that now only has upward jumps. We call this process $y^J(t)$ for discontinuous jump arrival rates. Given a background driving Lévy process (BDLP) $U(t)$ with only positive jumps, we define

$$dy^J(t) = -\kappa y^J(t) dt + dU(t) \quad (25)$$

The composite process now permits some direct dependence between arrival rate jumps and the underlying uncertainty:

$$Z^J(t) = X(Y^J(t)) + \rho U(t) \quad (26)$$

$$Y^J(t) = \int_0^t y^J(s) ds \quad (27)$$

We suppose that the background driving Lévy process has the following characteristic function:

$$E[\exp(iuU(t))] = \exp(t\psi_U(u)) \quad (28)$$

The characteristic function of the composite process $Z^J(t)$ may be developed in terms of the joint characteristic function of $Y^J(t)$, $U(t)$ as

$$\Phi_t(a, b) = E[\exp(iaY^J(t) + ibU(t))] \quad (29)$$

We may show that

$$E[\exp(iuZ^J(t))] = \Phi_t(-i\psi_X(u), u\rho) \quad (30)$$

We have that

$$\begin{aligned} \Phi_t(a, b) = \exp\left(iaY(0)\frac{1 - e^{-\kappa t}}{\kappa}\right) \\ \times \exp\left(\int_L^U \frac{\psi_U(v)}{a + \kappa b - \kappa v} dv\right) \end{aligned} \quad (31)$$

$$L = b \quad (32)$$

$$U = b + a \frac{1 - e^{-\kappa t}}{\kappa} \quad (33)$$

The characteristic functions for the logarithm of the stock price for the exponential model are now

$$\begin{aligned} E[\exp(iu \log(S_1^J(t)))] \\ = \exp(iu(\log(S(0) + (r - q)t))) \\ \times \Phi_t(-i\psi_X(u), \rho u) \\ \times \exp(-iu \log(\Phi_t(-i\psi_X(-i), -i\rho))) \end{aligned} \quad (34)$$

For the stochastic exponential, the result is given as

$$\begin{aligned} E[\exp(iu \log(S_2^J(t)))] \\ = \exp(iu(\log(S(0)) + (r - q)t - \psi_U(-i\rho)t)) \\ \times \Phi_t(-i\psi_X(u) - u\psi_X(-i), \rho u) \end{aligned} \quad (35)$$

Some explicit examples for $\psi_U(u)$, for which we may obtain exact expressions for $\Phi_t(a, b)$, remain to be determined.

Examples for $\psi_U(u)$ and $\Phi_t(a, b)$

Three explicit models for ψ_U were developed. These are SG for stationary gamma, IG for inverse Gaussian, and SIG for stationary inverse Gaussian.

The SG Case

In this case, the Lévy density for jumps in the process $U(t)$ is

$$k_U(x) = \frac{\lambda}{\zeta} e^{-x/\zeta} \quad (36)$$

The log characteristic function of the BDLP is

$$\psi_U(u) = \frac{i u \lambda}{1/\zeta - i u} \quad (37)$$

The IG Case

The Laplace transform for inverse Gaussian (*see Normal Inverse Gaussian Model*) time with drift ν for the Brownian motion is

$$E \left[\exp(-\lambda T_1^\nu) \right] = \exp \left(\nu - \sqrt{\nu^2 + 2\lambda} \right) \quad (38)$$

and the log characteristic function is

$$\psi_U(u) = \nu - \sqrt{\nu^2 - 2iu} \quad (39)$$

The SIG Case

For this case, Barndorff-Nielsen and Shephard [1] show that the Lévy density is

$$k_U(x) = \frac{1}{2\sqrt{2\pi}} x^{-3/2} (1 + \nu^2 x) \exp \left(-\frac{\nu^2 x}{2} \right) \quad (40)$$

The log characteristic function is

$$\psi_U(u) = \frac{i u}{\sqrt{\nu^2 - 2iu}} \quad (41)$$

For these three cases, the construction of $\Phi_t(a, b)$ is completed on determining the integral

$$\int_L^U \frac{\psi_Z(v)}{a + \kappa b - \kappa v} dv = \Psi(U, a, b) - \Psi(L, a, b) \quad (42)$$

and we have analytic expressions for $\Psi(x, a, b)$ in the SG, IG, and SIG cases that are as follows:

$$\begin{aligned} \Psi_{SG}(x, a, b; \kappa, \lambda, \zeta) \\ = \log \left[\left(x + \frac{i}{\zeta} \right)^{\frac{\lambda}{\kappa - i\zeta(a + \kappa b)}} \right. \\ \left. \times (a + \kappa b - \kappa x)^{\frac{\lambda(a + \kappa b)\zeta}{\kappa((a + \kappa b)\zeta + i\kappa)}} \right] \quad (43) \end{aligned}$$

$$\begin{aligned} \Psi_{IG}(x, a, b; \kappa, \nu) \\ = \frac{2\sqrt{\nu^2 - 2ix}}{\kappa} + \frac{2\sqrt{\nu^2 \kappa - 2i(a + \kappa b)}}{\kappa^{3/2}} \\ \times \operatorname{arctanh} \left[\frac{\sqrt{\kappa} \sqrt{\nu^2 - 2ix}}{\sqrt{\nu^2 \kappa - 2i(a + \kappa b)}} \right] \\ - \frac{\nu \log(a + \kappa b - \kappa x)}{\kappa} \quad (44) \end{aligned}$$

$$\begin{aligned} \Psi_{SIG}(x, a, b; \kappa, \nu) \\ = \frac{\sqrt{\nu^2 - 2ix}}{\kappa} - \frac{2i(a + \kappa b)}{\kappa^{3/2} \sqrt{\nu^2 \kappa - 2i(a + \kappa b)}} \\ \times \operatorname{arctanh} \left[\frac{\sqrt{\kappa} \sqrt{\nu^2 - 2ix}}{\sqrt{\nu^2 \kappa - 2i(a + \kappa b)}} \right] \quad (45) \end{aligned}$$

Correlation in VGSA or VGCSA

We consider the introduction of correlation in VGSA along the following lines. We define the correlated uncertainty as

$$Z^C(t) = X(Y(t)) + \rho y(t) \quad (46)$$

The characteristic function now follows from the joint characteristic function of $Y(t)$, $y(t)$:

$$E \left[e^{iuZ^C(t)} \right] = E \left[e^{Y(t)\psi_X(u) + iu\rho y(t)} \right] \quad (47)$$

Let

$$\Phi_t^C(a, b, x) = E \left[\exp(iaY(t) + iby(t)) | y(0) = x \right] \quad (48)$$

We have

$$\phi_{Z^C}(u) = \Phi_t^C(-i\psi_X(u), \rho u) \quad (49)$$

We recall the solution for $\Phi_t(a, b, x)$ from [5, 7] as

$$\begin{aligned} \Phi_t^C(a, b, x) &= A^C(t, a, b) \exp(B^C(t, a, b)x) \\ A^C(t, a, b) &= \end{aligned} \quad (50)$$

$$\begin{aligned} &= \frac{\exp \left(\frac{\kappa^2 \eta t}{\lambda^2} \right)}{\left[\cosh \left(\frac{\gamma t}{2} \right) + \frac{(\kappa - ib\lambda^2)}{\gamma} \sinh \left(\frac{\gamma t}{2} \right) \right]^{\frac{2\kappa\eta}{\lambda^2}}} \quad (51) \end{aligned}$$

$$B^C(t, a, b) = \frac{ib \left[\gamma \cosh\left(\frac{\gamma t}{2}\right) - \kappa \sinh\left(\frac{\gamma t}{2}\right) \right] + 2ia \sinh\left(\frac{\gamma t}{2}\right)}{\gamma \cosh\left(\frac{\gamma t}{2}\right) + (\kappa - ib\lambda^2) \sinh\left(\frac{\gamma t}{2}\right)} \quad (52)$$

$$\gamma = \sqrt{\kappa^2 - 2\lambda^2 ia} \quad (53)$$

We get the characteristic function for the model VGCSA, where the letter C denotes correlated stochastic arrival by exponentiation as

$$\begin{aligned} E[\exp(iu \log(S_1^C(t)))] \\ = \exp(iu(\log(S(0)) + (r - q)t)) \\ \times \Phi_t^C(-i\psi_X(u), \rho u) \\ \times \exp(-iu \log(\Phi_t^C(-i\psi_X(-i), -i\rho))) \quad (54) \end{aligned}$$

Exciting the Jumps by the Level of Activity that Is Also a Heston Type of Correlated Volatility

In this class of models, we introduce stochastic volatility and allow jump arrival rates to respond to the volatility on each side with separate sensitivities. This will give rise to stochastic skewness as well as to volatility. The model for the logarithm of the stock price $H(t) = \log(S(t))$ is now as follows:

$$\begin{aligned} H(t) = H(0) + (r - q)t - \int_0^t \frac{y(u)}{2} du \\ - (c_p t + s_p Y(t)) \int_0^\infty (e^x - 1 - x) k_p(x) dx \\ - (c_n t + s_n Y(t)) \int_{-\infty}^0 (e^x - 1 - x) k_n(x) dx \\ + x * (\mu - \nu) + \int_0^t \sqrt{y(u)} dW_S(u) \quad (55) \end{aligned}$$

$$Y(t) = \int_0^t y(u) du \quad (56)$$

$$dy = \kappa(\eta - y) dt + \lambda \sqrt{y} dW_y(t) \quad (57)$$

$$dW_y dW_S = \rho dt \quad (58)$$

$$\begin{aligned} \nu(dx, dt) = (c_p + s_p y(t)) k_p(x) \mathbf{1}_{x>0} dx \\ + (c_n + s_n y(t)) k_n(x) \mathbf{1}_{x<0} dx \quad (59) \end{aligned}$$

The growth rate of the stock price is at the risk neutral level of $(r - q)$. The coefficients c_p, c_n are the Lévy jump response components. The sensitivities of jumps to volatility are captured by the two slope coefficients s_p, s_n for the positive and the negative sides. The logarithm of the stock price is a continuous martingale with stochastic volatility plus a compensated jump martingale that has jumps responding to volatility with log price drift set to fix the stock drift at $r - q$.

The joint characteristic function of the log of the stock price, the level of the terminal variance, and the remaining integrated variance is

$$\begin{aligned} \Psi(t, H(t), y(t)) \\ = E_t \left[\exp(iaH(T) + iby(T) + ic \int_t^T y(u) du) \right] \quad (60) \end{aligned}$$

We have a closed form for Ψ in this model given as

$$\Psi(t, H(t), y(t)) = A(\tau) \exp(iaH(t) + \gamma(\tau)y(t)) \quad (61)$$

$$A(\tau) = \exp \left(\left(ia(r - q) + c_p u_p + c_n u_n + (\kappa - \lambda \rho ia) \frac{\kappa \eta}{\lambda^2} \right) \tau \right) \left(\frac{\cosh(D)}{\cosh\left(D - \frac{\tau}{2} \xi\right)} \right)^{\frac{2\kappa \eta}{\lambda^2}} \quad (62)$$

$$\gamma(\tau) = \frac{\kappa - \lambda \rho i a}{\lambda^2} + \frac{\xi}{\lambda^2} \tanh\left(D - \frac{\xi}{2} \tau\right) \quad (63)$$

$$\xi = \sqrt{(\kappa - \lambda \rho i a)^2 + \lambda^2 [a^2 + i(a - 2c) - 2(s_p u_p + s_n u_n)]} \quad (64)$$

$$u_p = \int_0^\infty (e^x - 1 - i a x) k_p(x) dx - i a \int_0^\infty (e^x - 1 - x) k_p(x) dx \quad (65)$$

$$u_n = \int_{-\infty}^0 (e^x - 1 - i a x) k_n(x) dx - \int_{-\infty}^0 (e^x - 1 - x) k_n(x) dx \quad (66)$$

$$D = \tanh^{-1}\left(\frac{i b \lambda^2}{\xi} - \frac{\kappa - \lambda \rho i a}{\xi}\right) \quad (67)$$

On setting $b = c = 0$, we obtain the characteristic function of the log of the final stock price and this yields the models: SVADNE, SVAVG, and SVAC-CGMY.

We note that for DNE

$$u_p = (1 - i a) \frac{1}{\beta_p - 1} \quad (68)$$

$$u_n = -(1 - i a) \frac{1}{\beta_n + 1} \quad (69)$$

The corresponding calculations for VG in the CGM parameterization are

$$u_p = \log\left(\frac{M}{M - 1}\right) \quad (70)$$

$$u_n = \log\left(\frac{G}{G + 1}\right) \quad (71)$$

For CCGMY, we have the following result:

$$u_p = \Gamma(-y_p) ((M - 1)^{y_p} - M^{y_p}) \quad (72)$$

$$u_n = \Gamma(-y_n) ((G + 1)^{y_n} - G^{y_n}) \quad (73)$$

Kou Model

It is well known that empirically asset return distributions have heavier tails (*see* **Heavy Tails**) than those of normal distributions, in contrast to the classical Black–Scholes model (*see* **Black–Scholes Formula**). Jump-diffusion models are among the most popular alternative models proposed to address this issue, and they are especially useful to price options with short maturities (*see* **Exponential Lévy Models**). However, analytical tractability is one of the challenges faced by many alternative models. More precisely, although many alternative models can lead to analytical solutions for European call and put options, unlike the Black–Scholes model, it is difficult to do so for path-dependent options such as lookback (*see* **Lookback Options**), barrier (*see* **Barrier Options**), and American options, which are treated using numerical methods (*see* **Partial Integro-differential Equations (PIDEs)**). For example, the convergence rates of binomial trees and Monte Carlo simulation for path-dependent options are typically much slower than those for call and put options; *see* Boyle *et al.* [3].

The double exponential jump-diffusion model is a jump-diffusion model in which the jump size distribution follows a two-sided exponential distribution. It was introduced to further extend the analytical tractability of models with jumps.

In jump-diffusion models under the physical probability measure P , the asset price, $S(t)$, is modeled as

$$\frac{dS(t)}{S(t-)} = \mu dt + \sigma dW(t) + d\left(\sum_{i=1}^{N(t)} (V_i - 1)\right) \quad (1)$$

where $W(t)$ is a standard Brownian motion, $N(t)$ is a Poisson process with rate λ , and $\{V_i\}$ is a sequence of independent identically distributed (i.i.d.) nonnegative random variables. All the sources of randomness, $N(t)$, $W(t)$, and V 's, are assumed to be independent. Solving the stochastic differential equation (1) gives the dynamics of the asset price:

$$S(t) = S(0) \exp \left\{ \left(\mu - \frac{1}{2} \sigma^2 \right) t + \sigma W(t) \right\} \prod_{i=1}^{N(t)} V_i \quad (2)$$

In the Merton model [28], $Y = \log(V)$ has a normal distribution. In the double exponential jump-diffusion model [23] $Y = \log(V)$ has an asymmetric double exponential distribution with the density

$$f_Y(y) = p \cdot \eta_1 e^{-\eta_1 y} 1_{\{y \geq 0\}} + q \cdot \eta_2 e^{\eta_2 y} 1_{\{y < 0\}}, \quad \eta_1 > 1, \eta_2 > 0 \quad (3)$$

where $p, q \geq 0$, $p + q = 1$, represent the probabilities of upward and downward jumps. The requirement $\eta_1 > 1$ is needed to ensure that $E(V) < \infty$ and $E(S(t)) < \infty$; it essentially means that the average upward jump cannot exceed 100%, which is quite reasonable [2].

As pointed out in [23], the jump part of the double exponential jump-diffusion model can be interpreted as the market response to outside developments; and the heavier tail and higher peak (in comparison to the standard normal distribution) of the double exponential distribution attempt to model market overreaction and underreaction, respectively. Ramezani and Zeng [29] independently proposed the double exponential jump-diffusion model from an econometric viewpoint as a way of improving the empirical fit of Merton's normal jump-diffusion model to stock price data.

Such models lead to incomplete markets in which the replication of an option payoff is impossible. The monograph by Cont and Tankov [10] discusses hedging issues for jump-diffusion models and resulting pricing measures. Alternatively, one can use the rational expectations in [27] and [32] to choose a risk-neutral measure to price derivative as in [23].

The double exponential jump-diffusion model belongs to the class of exponential Lévy models (*see* **Exponential Lévy Models**). There is a large literature on Lévy processes in finance, including several excellent books, for example, the books by Cont and Tankov [10] and Kijima [22].

Analytical Tractability

The main advantage of the double exponential jump-diffusion model is that it offers a rare case where we can derive the analytical solution of the joint distribution of the first passage time and $X(t) = \log(S(t)/S(0))$, thereby making it possible to price path-dependent options such as lookback, barrier, and perpetual American options. An intuitive explanation for this follows.

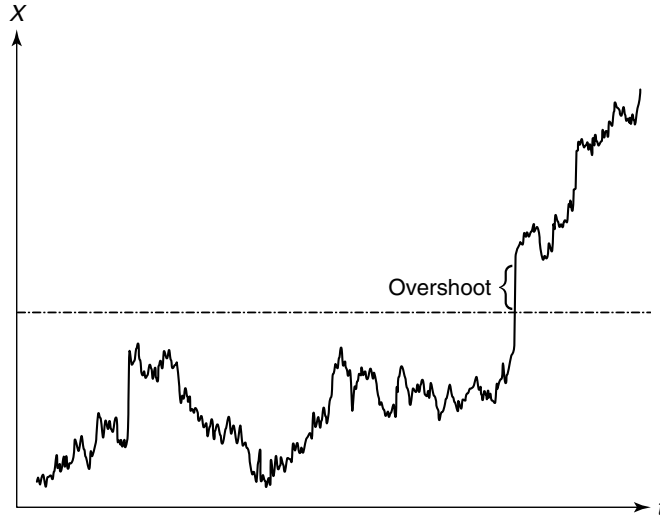

Figure 1 A simulated sample path with the overshoot problem

To price lookback, barrier, and perpetual American options, it is pivotal to study the first passage times τ_b when the process crosses a flat boundary with a level b . Without loss of generality, assume that $b > 0$. When a jump-diffusion process crosses the boundary, sometimes it hits the boundary exactly and sometimes it incurs an “overshoot”, $X_{\tau_b} - b$, over the boundary as shown in Figure 1. The overshoot presents several problems if one wants to compute the distribution of the first passage time analytically. First, one needs the exact distribution of the overshoot, $X_{\tau_b} - b$; particularly, $P(X_{\tau_b} - b = 0)$ and $P(X_{\tau_b} - b > x)$, $x > 0$. Second, one needs to know the dependence structure between the overshoot, $X_{\tau_b} - b$, and the first passage time τ_b .

These difficulties may be resolved under the assumption that the jump size Y has a double exponential distribution. Mathematically, this is because the exponential function has some very nice properties, such as the product of exponential functions is still an exponential function, and the derivatives of exponential functions are still exponential function. These nice properties enable us to solve related ordinary integro-differential equations (OIDE) explicitly, leading to analytical solutions for the marginal and joint distributions of the first passage times, and ultimately, analytical tractability for pricing lookback, barrier, and perpetual American options. More precisely, the infinitesimal generator of the return

process $X(t)$ is given by

$$\begin{aligned} \mathcal{L}u(x) = & \frac{1}{2}\sigma^2 u''(x) + \tilde{\mu}u'(x) \\ & + \lambda \int_{-\infty}^{\infty} [u(x+y) - u(x)] f_Y(y) dy \end{aligned} \quad (4)$$

for all twice continuously differentiable functions $u(x)$. When studying the first passage time, we encounter an OIDE with discontinuous regions as follows:

$$\begin{cases} (\mathcal{L}u)(x) = \alpha u(x), & x < x_0 \\ u(x) = g(x), & x \geq x_0 \end{cases} \quad (5)$$

where $\alpha > 0$ and $g(x)$ is a given function. Many times x_0 is a fixed number, but in the case of American options, x_0 is a parameter that needs to be determined by solving a free boundary problem. Note that $u(x)$ solves the OIDE not for all $x \in \mathbb{R}$ but only for $x < x_0$. However, $u(x)$ does involve the information on $x > x_0$, as the integral inside the generator (4) depends on the function $g(x)$, thereby making itself more complicated. This OIDE can be solved explicitly under the double exponential jump-diffusion model, thereby leading to an analytical solution of the joint distribution of the first passage time τ_b and X_{τ_b} ; see [25, 26], and [24].

In addition to pricing options related to the first passage times, the double exponential jump-diffusion models have been studied in many papers. What is detailed below is only a snapshot of some interesting results.

1. In terms of computational issues, see [11] and [12] for numerical methods *via* solving partial integro-differential equations (*see* **Partial Integro-differential Equations (PIDEs)**); Feng and Linetsky [17] and Feng *et al.* [16] showed how to price path-dependent options numerically *via* extrapolation and variational methods.
2. In terms of applications, see the references in [18] for applications in fixed income derivatives and term structure models, and the references in [9] for applications in credit risk and credit derivatives.
3. Double-barrier options (with both upper and lower barriers) are studied in [30] and [4].
4. Statistical inference and econometric analysis for Lévy processes are discussed in [31].

Volatility Clustering Effect

In addition to the leptokurtic feature, returns distributions also have an interesting dependent structure, called the *volatility clustering effect*; see [14]. More precisely, the volatility of returns (which are related to the squared returns) are correlated, but asset returns themselves have almost no autocorrelation. In other words, a large movement in asset prices, either upward or downward, tends to generate large movements in the future asset prices, although the direction of the movements is unpredictable.

In particular, any model for stock returns with independent increments (such as Lévy processes) cannot incorporate the volatility clustering effect. However, one can combine jump-diffusion processes with other processes [1, 13] or consider time-changed Brownian motion and Lévy processes (*see* **Time Change**) to incorporate the volatility clustering effect. More precisely, if $\tau(t)$ contains a diffusion component (i.e., not a subordinator), then $W(\tau(t))$ and $X(\tau(t))$ may have dependent increments and no longer be Lévy processes; see [6, 7], and [8].

Hyper-Exponential Jumps

Although the main empirical motivation for using Lévy processes in finance comes from the fact that asset return distributions tend to have tails heavier than those of normal distribution, it is not clear how heavy the tail distributions are, as some people favor power-type distributions and others exponential-type distributions, although, as pointed out in [23, p. 1090], the power-type right tails cannot be used in models with continuous compounding as they lead to infinite expectation for the asset price. We stress that, quite surprisingly, it is very difficult to distinguish power-type tails from exponential-type tails and from empirical data unless one has extremely large sample size perhaps in the order of tens of thousands or even hundreds of thousands [19]. Therefore, it is very difficult to choose a good model based on the limited empirical data alone.

A good intuition may be obtained by simply looking at the quantiles for both standardized Laplace (with a symmetric density $f(x) = \frac{1}{2}e^{-x}I_{[x>0]} + \frac{1}{2}e^xI_{[x<0]}$) and standardized t distributions with mean 0 and variance 1. The right quantiles for the Laplace and normalized t densities with degrees of freedom (DOF) from 3 to 7 are given in Table 1.

This table shows that the Laplace distributions may have higher tail probabilities than t distributions, even if asymptotically the Laplace distributions should have lighter tails than t distributions. For example, regardless of the sample size, the Laplace distribution may appear to be heavier tailed than a t -distribution with DOF 6 or 7, up to the 99.9th percentile. To distinguish the distributions it is necessary to use quantiles with very low p values and correspondingly large sample sizes for statistical inference. If the true quantiles have to be estimated from data, then the problem is even worse, as the sample standard deviations need to be considered, resulting in

Table 1 The right quantiles of the Laplace and normalized t -distributions

Prob.	Laplace	t_7	t_6	t_5	t_4	t_3
1%	2.77	2.53	2.57	2.61	2.65	2.62
0.1%	4.39	4.04	4.25	4.57	5.07	5.90
0.01%	6.02	5.97	6.55	7.50	9.22	12.82
0.001%	7.65	8.54	9.82	12.04	16.50	27.67

sample sizes typically in the tens of thousands or even hundreds of thousands necessary to distinguish power-type tails from exponential-type tails. For further discussion, see [20], in which is also discussed the implication in terms of risk measured.

The difficulty in distinguishing tail behavior motivated Cai and Kou [5] to extend the double exponential jump-diffusion model to a hyperexponential jump-diffusion model, in which the jump size $\{Y_i := \log(V_i) : i = 1, 2, \dots\}$ is a sequence of i.i.d. hyperexponential random variables with density

$$f_Y(x) = \sum_{i=1}^m p_i \eta_i e^{-\eta_i x} I_{\{x \geq 0\}} + \sum_{j=1}^n q_j \theta_j e^{\theta_j x} I_{\{x < 0\}} \quad (6)$$

where $p_i > 0$ and $\eta_i > 1$ for all $i = 1, \dots, m$, $q_j > 0$ and $\theta_j > 0$ for all $j = 1, \dots, n$, and $\sum_{i=1}^m p_i + \sum_{j=1}^n q_j = 1$. Here the condition that $\eta_i > 1$, for all $i = 1, \dots, m$, is imposed to ensure that the stock price S_t has a finite expectation.

The hyperexponential distribution is general enough to provide a link between various heavy-tail distributions, no matter which ones we prefer. In particular, any completely monotone distribution, for example, with a density $f(x)$ satisfying the condition that all derivatives of $f(x)$ exist and $(-1)^n f^{(n)}(x) \geq 0$ for all x and $n \geq 1$, can be approximated by hyperexponential distributions as closely as possible in the sense of weak convergence. Many distributions with tails heavier than those of the normal distribution are completely monotone. Here are some examples of completely monotone distributions frequently used in finance:

1. *Gamma distribution.* The density of Gamma (α, β) is $x^{\alpha-1} e^{-\beta x}$, where $\alpha, \beta > 0$. When $\alpha < 1$, the distribution is completely monotone.
2. *Weibull distribution.* The cumulative distribution function of Weibull (c, d) is given by $1 - e^{-(x/d)^c}$, where $c, d > 0$. When $c < 2$, it has heavier tails than the normal distribution.
3. *Pareto distribution.* The distribution of Pareto (a, b) is given by $1 - (1 + bx)^{-a}$, where $a, b > 0$.
4. *Pareto mixture of exponential distribution (PME).* The density of PME (a, b) is given by $\int_0^{+\infty} f_{a,b}(y) y^{-1} e^{-x/y} dy$, where $f_{a,b}$ is the density of the Pareto (a, b) .

In summary, many heavy-tail distributions used in finance can be approximated arbitrarily closely

by the hyperexponential distribution. Feldmann and Whitt [15] develop a numerical algorithm to approximate completely monotone distributions by the hyperexponential distribution.

Cai and Kou [5] show that the hyperexponential jump-diffusion model can lead to analytical solutions for popular path-dependent options, such as lookback, barrier, and perpetual American options. These analytical solutions are made possible mainly because we solve several high-order integro-differential equations related to first passage time problems and optimal stopping problems explicitly. Solving the high-order integro-differential equations is the main technical contribution of [5], which is achieved by discovering a connection between integro-differential equations and homogeneous ordinary differential equations in the case of the hyperexponential jump-diffusion generator.

Multivariate Version

A significant drawback of most of the Levy processes discussed in the literature is that they are one dimensional, whereas many options traded in markets have several underlying assets. To overcome this, Huang and Kou [21] introduced a multivariate jump-diffusion model in which, under the physical measure P , the following stochastic differential equation is proposed to model the asset prices $S(t)$:

$$\frac{dS(t)}{S(t-)} = \mu dt + \sigma dW(t) + d \left(\sum_{i=1}^{N(t)} (V_i - 1) \right) \quad (7)$$

where $W(t)$ is an n -dimensional standard Brownian motion, $\sigma \in R^{n \times n}$ with the covariance matrix $\Sigma = \sigma \sigma^T$. The rate of the Poisson process $N(t)$ process is $\lambda = \lambda_c + \sum_{k=1}^n \lambda_k$; in other words, there are two types of jumps, common jumps for all assets with jump rate λ_c and individual jumps with rate λ_k , $1 \leq k \leq n$, only for the k th asset.

The logarithms of the common jumps have an m -dimensional asymmetric Laplace distribution $\mathcal{AL}_n(m_c, J_c)$, where $m_c = (m_{1,c}, \dots, m_{n,c})' \in R^n$ and $J_c \in R^{n \times n}$ is positive definite. For the individual jumps of the k th asset, the logarithms of the jump sizes follow a one-dimensional asymmetric Laplace distribution, $\mathcal{AL}_1(m_k, v_k^2)$. In summary,

$$Y = \log(V) \sim \begin{cases} \mathcal{AL}_n(m_c, J_c), & \text{with prob. } \lambda_c/\lambda \\ \underbrace{(0, \dots, 0, \mathcal{AL}_1(m_k, v_k^2))}_{k-1}, \underbrace{0, \dots, 0}_{n-k}, & \text{with prob. } \lambda_k/\lambda, \quad 1 \leq k \leq n \end{cases} \quad (8)$$

The sources of randomness, $N(t)$, $W(t)$ are assumed to be independent of the jump sizes V_i . Jumps at different times are assumed to be independent. Note that in the univariate case, the above model degenerates to the double exponential jump-diffusion model [23] but with $p\eta_1 = q\eta_2$.

In the special case of a two-dimensional model, the two-dimensional jump-diffusion return process $(X_1(t), X_2(t))$, with $X_i(t) = \log(S_i(t)/S(0))$, is given by

$$\begin{aligned} X_1(t) &= \mu_1 t + \sigma_1 W_1(t) + \sum_{i=1}^{N(t)} Y_i^{(1)} \\ X_2(t) &= \mu_2 t + \sigma_2 \left[\rho W_1(t) + \sqrt{1 - \rho^2} W_2(t) \right] \\ &\quad + \sum_{i=1}^{N(t)} Y_i^{(2)} \end{aligned} \quad (9)$$

Here all the parameters are risk-neutral parameters; $W_1(t)$ and $W_2(t)$ are two independent standard Brownian motions; and $N(t)$ is a Poisson process with rate $\lambda = \lambda_c + \lambda_1 + \lambda_2$. The distribution of the logarithm of the jump sizes Y_i is given by

$$\begin{aligned} Y_i &= (Y_i^{(1)}, Y_i^{(2)})' \\ &\sim \begin{cases} \mathcal{AL}_2(m_c, J_c), & \text{with prob. } \lambda_c/\lambda \\ (\mathcal{AL}_1(m_1, v_1^2), 0)', & \text{with prob. } \lambda_1/\lambda \\ (0, \mathcal{AL}_1(m_2, v_2^2))', & \text{with prob. } \lambda_2/\lambda \end{cases} \end{aligned} \quad (10)$$

where the parameters for the common jumps are

$$m_c = \begin{pmatrix} m_{1,c} \\ m_{2,c} \end{pmatrix} \quad \text{and} \quad J_c = \begin{pmatrix} v_{1,c}^2 & cv_{1,c}v_{2,c} \\ cv_{1,c}v_{2,c} & v_{2,c}^2 \end{pmatrix} \quad (11)$$

The infinitesimal generator of $\{X_1(t), X_2(t)\}$ is given by

$$\begin{aligned} \mathcal{L}u &= \mu_1 \frac{\partial u}{\partial x_1} + \mu_2 \frac{\partial u}{\partial x_2} \\ &\quad + \frac{1}{2} \sigma_1^2 \frac{\partial^2 u}{\partial x_1^2} + \frac{1}{2} \sigma_2^2 \frac{\partial^2 u}{\partial x_2^2} + \rho \sigma_1 \sigma_2 \frac{\partial^2 u}{\partial x_1 \partial x_2} \\ &\quad + \lambda_c \int_{y_2=-\infty}^{\infty} \int_{y_1=-\infty}^{\infty} [u(x_1+y_1, x_2+y_2) - u(x_1, x_2)] \\ &\quad \times f_{(Y^{(1)}, Y^{(2)})}^c(y_1, y_2) dy_1 dy_2 \\ &\quad + \lambda_1 \int_{y_1=-\infty}^{\infty} [u(x_1+y_1, x_2) - u(x_1, x_2)] f_{Y^{(1)}}(y_1) dy_1 \\ &\quad + \lambda_2 \int_{y_2=-\infty}^{\infty} [u(x_1, x_2+y_2) - u(x_1, x_2)] \\ &\quad \times f_{Y^{(2)}}(y_2) dy_2 \end{aligned} \quad (12)$$

for all continuous twice differentiable function $u(x_1, x_2)$, where $f_{(Y^{(1)}, Y^{(2)})}^c(y_1, y_2)$ is the joint density of correlated common jumps $\mathcal{AL}_2(m_c, J_c)$, and $f_{Y^{(i)}}(y_i)$ is the individual jump density of $\mathcal{AL}_1(m_i, J_i)$, $i = 1, 2$.

One difficulty in studying the generator is that the joint density of the asymmetric Laplace distribution has no analytical expression. Therefore, the calculation related to the joint density and generator becomes complicated. See [21] for change of measures from a physical measure to a risk-neutral measure, analytical solutions for the first passage times, and pricing formulae for barrier and exchange options.

Exponential Lévy Models

Exponential Lévy models generalize the classical Black and Scholes model by allowing the stock prices to jump while preserving the independence and stationarity of returns. There are ample reasons for introducing jumps in financial modeling. First, asset prices exhibit jumps, and the associated risks cannot be handled within continuous-path models. Second, the well-documented phenomenon of *implied volatility smile* in option markets shows that the risk-neutral returns are non-Gaussian and leptokurtic, all the more so for short maturities, a clear indication of the presence of jumps. In continuous-path models, the law of returns for shorter maturities becomes closer to the Gaussian law, whereas in reality and in models with jumps, returns actually become less Gaussian as the horizon becomes shorter. Finally, jump processes correspond to genuinely incomplete markets, whereas all continuous-path models are either complete or can be made so with a small number of additional assets. This fundamental incompleteness makes it possible to carry out a rigorous analysis of the hedging errors in discontinuous models and find ways to improve the hedging performance using additional instruments such as liquid European options.

Lévy Processes

Lévy processes (*see Fundamental Theorem of Asset Pricing*) [1, 3, 17] are stochastic processes with stationary and independent increments. The only Lévy process with continuous trajectories is the Brownian motion with drift; all others have paths with discontinuities in finite or (countably) infinite number. The simplest example of a Lévy process is the Poisson process (*see Poisson Process*): the increasing piecewise constant process with jumps of size 1 only and exponential waiting times between jumps. If (τ_i) is a sequence of independent exponential random variables with intensity λ and $T_k := \sum_{i=1}^k \tau_i$, then the process

$$Z_t := \sum_i 1_{T_i \leq t} \quad (1)$$

is called a *Poisson process* with intensity λ . A piecewise constant Lévy process with arbitrary jump sizes

is called *compound Poisson* and can be written as

$$X_t = \sum_{k=1}^{Z_t} Y_k \quad (2)$$

where Z is a Poisson process and (Y_i) is an i.i.d. sequence of random variables. In general, the number of jumps of a Lévy process in a given interval need not be finite, and the process can be represented as a sum of a Brownian motion with drift and a limit of processes of the form in equation (2):

$$X_t = \gamma t + B_t + N_t + \lim_{\varepsilon \downarrow 0} M_t^\varepsilon \quad (3)$$

where B is a d -dimensional Brownian motion, $\gamma \in \mathbb{R}^d$, N is a compound Poisson process that includes the jumps of X with $|\Delta X_t| > 1$, and M_t^ε is a compensated compound Poisson process (compound Poisson minus its expectation) that includes the jumps of X with $\varepsilon < |\Delta X_t| \leq 1$. The law of a Lévy process is completely identified by its characteristic triplet—the positive definite matrix A (unit covariance of B), the vector γ (drift), and the measure ν on $\mathbb{R}^d$, called the *Lévy measure*, which determines the intensity of jumps of different sizes. $\nu(A)$ is the expected number of jumps on the time interval $[0, 1]$, whose sizes fall in A . The Lévy measure satisfies the integrability condition

$$\int_{\mathbb{R}^d} 1 \wedge \|x\|^2 \nu(dx) < \infty \quad (4)$$

and $\nu(\mathbb{R}) < \infty$ if the process has finite jump intensity. The law of X_t at all times t is determined by the triplet and, in particular, the Lévy–Khintchine formula gives the characteristic function $E[e^{iuX_t}] = \exp[t\psi(u)]$ with

$$\begin{aligned} \psi(u) = & i \langle \gamma, u \rangle + \frac{1}{2} \langle Au, u \rangle + \int_{\mathbb{R}^d} (e^{i \langle u, x \rangle} - 1 \\ & - i \langle u, x \rangle 1_{\|x\| \leq 1}) \nu(dx) \end{aligned} \quad (5)$$

Conversely, any infinitely divisible law (*see Infinite Divisibility*) has a Lévy–Khintchine representation as above, so modeling with Lévy processes allows to pick any infinitely divisible distribution for the law (say, at time $t = 1$) of the process.

Exponential Lévy Models

The Black–Scholes model

$$\frac{dS_t}{S_t} = \mu dt + \sigma dW_t \quad (6)$$

can be equivalently rewritten in the exponential form $S_t = S_0 e^{(\mu - \sigma^2/2)t + \sigma W_t}$. This gives us two possibilities to construct an exponential Lévy model starting from a (one-dimensional) Lévy process X , using the stochastic differential equation

$$\frac{dS_t}{S_{t-}} = dX_t \quad (7)$$

or using the ordinary exponential $S_t = S_0 e^{X_t}$. The solution to equation (7) with initial condition $S_0 = 1$ is called the *stochastic exponential* of X . It can become negative if the process X has a big negative jump: $\Delta X_s < -1$ for $s \leq t$. However, if X does not have jumps of size smaller than -1 , then its stochastic exponential is positive, and the stochastic and the ordinary exponential yield the same class of positive processes. Given this result and the fact that ordinary exponentials are more tractable (in particular, we have the Lévy–Khintchine representation), they are more often used for modeling financial time series than the stochastic ones. In the rest of this article, we focus on the exponential Lévy model

$$S_t = S_0 e^{rt + X_t} \quad (8)$$

where X is a one-dimensional Lévy process with characteristic triplet (σ^2, ν, γ) and r denotes the interest rate.

Examples

Exponential Lévy models fall into two categories. In the first category, called *jump-diffusion* models, the “normal” evolution of prices is given by a diffusion process, punctuated by jumps at random intervals. Here the jumps represent rare events—crashes and large drawdowns. Such an evolution can be represented by a Lévy process with a nonzero Gaussian component and a jump part with finitely many jumps:

$$X_t = \gamma t + \sigma W_t + \sum_{i=1}^{N_t} Y_i \quad (9)$$

In the *Merton model* (see **Jump-diffusion Models**) [16], which is the first model of this type, suggested in the literature, jumps in the log price X are assumed to have a Gaussian distribution: $Y_i \sim N(\mu, \delta^2)$. In the risk-neutral version (i.e., with the choice of drift such that e^X becomes a martingale), the characteristic exponent of the log stock price takes the following form:

$$\begin{aligned} \psi(u) = & -\frac{\sigma^2 u^2}{2} + \lambda \{e^{-\delta^2 u^2/2 + i\mu u} - 1\} \\ & - iu \left(\frac{\sigma^2}{2} + \lambda(e^{\delta^2/2 + \mu} - 1) \right) \end{aligned} \quad (10)$$

In the *Kou model* (see **Kou Model**) [13], jump sizes are distributed according to an asymmetric Laplace law with a density of the form

$$\nu_0(x) = [p\lambda_+ e^{-\lambda_+ x} 1_{x>0} + (1-p)\lambda_- e^{-\lambda_- |x|} 1_{x<0}] \quad (11)$$

with $\lambda_+ > 0$, $\lambda_- > 0$ governing the decay of the tails for the distribution of positive and negative jump sizes and $p \in [0, 1]$ representing the probability of an upward jump. The probability distribution of returns in this model has semiheavy (exponential) tails.

The second category consists of models with an infinite number of jumps in every interval, which we call *infinite activity* or *infinite intensity* models. In these models, one does not need to introduce a Brownian component since the dynamics of jumps is already rich enough to generate nontrivial small time behavior [4].

There are several ways to define a parametric Lévy process with infinite jump intensity. The first approach is to obtain a Lévy process by subordinating a Brownian motion with an independent increasing Lévy process (called *subordinator*). Two examples of models from this class are the variance gamma process and the normal inverse Gaussian process. The variance gamma process (see **Variance-gamma Model**) [5, 15] is obtained by time changing a Brownian motion with a gamma subordinator and has the characteristic exponent of the form

$$\psi(u) = -\frac{1}{\kappa} \log \left(1 + \frac{u^2 \sigma^2 \kappa}{2} - i\theta \kappa u \right) \quad (12)$$

The density of the Lévy measure of the variance gamma process is given by

$$\nu(x) = \frac{c}{|x|} e^{-\lambda_- |x|} 1_{x < 0} + \frac{c}{x} e^{-\lambda_+ x} 1_{x > 0} \quad (13)$$

where $c = 1/\kappa$, $\lambda_+ = \frac{\sqrt{\theta^2 + 2\sigma^2/\kappa}}{\sigma^2} - \frac{\theta}{\sigma^2}$ and $\lambda_- = \frac{\sqrt{\theta^2 + 2\sigma^2/\kappa}}{\sigma^2} + \frac{\theta}{\sigma^2}$.

The normal inverse Gaussian process (see **Normal Inverse Gaussian Model**) [2] is the result of time changing a Brownian motion with the inverse Gaussian subordinator and has the characteristic exponent

$$\psi(u) = \frac{1}{\kappa} - \frac{1}{\kappa} \sqrt{1 + u^2 \sigma^2 \kappa - 2i\theta u \kappa} \quad (14)$$

The second approach is to specify the Lévy measure directly. The main example of this category is the tempered stable process (see **Tempered Stable Process**), introduced by Koponen [12] and also known under the name of *CGMY model* [4]. This process has a Lévy measure with density of the form

$$\nu(x) = \frac{c_-}{|x|^{1+\alpha_-}} e^{-\lambda_- |x|} 1_{x < 0} + \frac{c_+}{x^{1+\alpha_+}} e^{-\lambda_+ x} 1_{x > 0} \quad (15)$$

with $\alpha_+ < 2$ and $\alpha_- < 2$.

The third approach is to specify the density of increments of the process at a given time scale, say Δ , by taking an arbitrary infinitely divisible distribution. Generalized hyperbolic processes (see **Generalized Hyperbolic Models**) [10] can be constructed in this way. In this approach, it is easy to simulate the increments of the process at the same time scale and to estimate parameters of the distribution if data are sampled with the same period Δ , but, unless this distribution belongs to some parametric class closed under convolution, we do not know the law of the increments at other time scales.

Market Incompleteness and Option Pricing

The exponential Lévy models correspond, in general, to arbitrage-free incomplete markets, meaning that options cannot be replicated exactly and,

consequently, their price is not uniquely determined by the law of the underlying. This is good news: this means that the pricing model can be adjusted to take into account both the historical dynamics of the underlying and the market-quoted prices of European call and put options, a procedure known as *model calibration* (see **Model Calibration**). Once the risk-neutral measure Q is calibrated, one can price an exotic option with payoff H_T at time T by taking the discounted expectation

$$P_0 = e^{-rT} E^Q[H_T] \quad (16)$$

Fourier Transform Methods for Option Pricing and Model Calibration

In exponential Lévy models, and in all models where the characteristic function of the log stock price $\Phi_t(u) = E[e^{iuX_t}]$ is known explicitly, Fourier inversion provides a very efficient algorithm for pricing European options. This method was introduced in [5] and later improved and generalized in [14].

Consider a financial model of the form $S_t = S_0 e^{rt + X_t}$, where X is stochastic process whose characteristic function is known explicitly. To compute the price of a call option,

$$C(k) = S_0 E[(e^{X_T} - e^k)^+] \quad (17)$$

where $k = \log(K/S_0) - rT$ is the log forward moneyness, we would like to express its Fourier transform in terms of the characteristic function of X_T and then find the prices for a range of strikes by Fourier inversion. However, the Fourier transform of $C(k)$ is not well defined because this function is not integrable, so we subtract the Black–Scholes call price with nonzero volatility Σ to obtain a function that is both integrable and smooth:

$$z_T(k) = C(k) - C_{BS}^\Sigma(k) \quad (18)$$

If X is a stochastic process such that $E[e^{X_T}] = 1$ and $E[e^{(1+\alpha)X_T}] < \infty$ for some $\alpha > 0$, then the Fourier transform of $z_T(k)$ is given by

$$\zeta_T(v) = S_0 \frac{\Phi_T(v-i) - \Phi_T^\Sigma(v-i)}{iv(1+iv)} \quad (19)$$

where $\Phi_T^\Sigma(v) = \exp(-\frac{\Sigma^2 T}{2}(v^2 + iv))$ is the characteristic function of log stock price in the Black–

Scholes model with volatility Σ . The exact value of Σ is not very important, and one can take, for example, $\Sigma = 0.2$ for practical calculations.

Option prices are computed by evaluating numerically the inverse Fourier transform of ζ_T :

$$z_T(k) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} e^{-ivk} \zeta_T(v) dv \quad (20)$$

This integral can be efficiently computed for a range of strikes using the fast Fourier transform algorithm.

The Fourier-based fast deterministic algorithms for European option pricing can be used to calibrate exponential Lévy models to market-quoted option prices by penalized least squares as in [7]. Exponential Lévy models perform well for calibrating market option prices for a range of strikes and a single maturity, but fail to calibrate the entire implied volatility surface containing many maturities. This is due to the fact that the law of a Lévy process is completely determined by its distribution at a given date, so that if we know option prices for many strikes and a single maturity, we can readily reconstruct the law of the process at all dates, which may be incompatible with the other observations we may have. In particular, the implied volatility smile in exponential Lévy model flattens too fast for long-dated options (see Figure 1). Usually, a jump component can be included in a model to calibrate the short-maturity prices, and a stochastic volatility component is used to calibrate the skew at longer maturities.

PIDE Methods for Exotic Options

For contracts with barriers or American-style exercise, partial integro-differential equation (PIDE) methods provide an efficient alternative to Monte Carlo simulation. In diffusion models, the price of an option with payoff $h(S_T)$ at time T solves the Black–Scholes partial differential equation (PDE)

$$\begin{aligned} \frac{\partial P}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 P}{\partial S^2} &= rP - rS \frac{\partial P}{\partial S} \\ P(T, S) &= h(S) \end{aligned} \quad (21)$$

In an exponential Lévy model, there is a similar equation for the option price

$$P(t, S) = e^{-r(T-t)} E^Q[h(S_T) | S_t = S] \quad (22)$$

but due to the presence of jumps, an integral term appears in addition to the partial derivatives (see **Partial Integro-differential Equations (PIDEs)**):

$$\begin{aligned} \frac{\partial P}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 P}{\partial S^2} - rP + rS \frac{\partial P}{\partial S} \\ + \int_{\mathbb{R}} v(dz) \left\{ P(t, Se^z) - P(t, S) \right. \\ \left. - S(e^z - 1) \frac{\partial P}{\partial S}(t, S) \right\} = 0, \quad P(T, S) = h(S) \end{aligned} \quad (23)$$

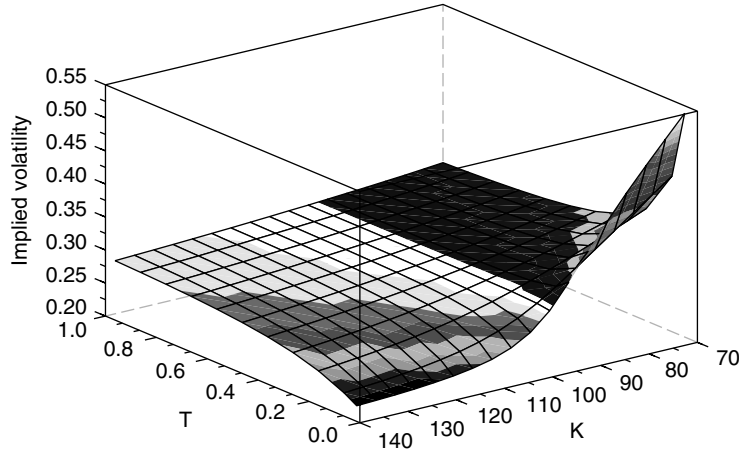

Figure 1 Implied volatility surface in the Kou model with diffusion volatility $\sigma = 0.2$ and only negative jumps with intensity $\lambda = 10$ and average size $\frac{1}{\lambda_-} = 0.05$

Different path-dependent characteristics of the payoff are translated into the boundary conditions of the equation: for example, for a down-and-out option with barrier B , we would impose $P(t, S) = 0$ for $S \leq B$ and all t . This equation and its numerical solution using finite differences is discussed in detail in [9] (see **Partial Integro-differential Equations (PIDEs)**).

Hedging

In the Black–Scholes model, delta hedging is known to completely eliminate the risk of an option position. In the presence of jumps, delta hedging is no longer optimal: to hedge a jump of a given size, one should use the sensitivity to fluctuations of this particular size rather than the sensitivity to infinitesimal movements. Since the jump size is not known in advance, the risk associated with jumps cannot be hedged away completely. The model given by equation (8) therefore corresponds to an incomplete market except for the following two cases:

- no jumps in the stock price ($\nu \equiv 0$, the Black–Scholes case) and
- no diffusion component ($\sigma = 0$) and only one possible jump size ($\nu = \delta_{z_0}(z)$). In this case, the optimal hedging strategy is

$$\phi_t = \frac{P(S_t e^{z_0}) - P(S_t)}{S_t(e^{z_0} - 1)} \quad (24)$$

In all other cases, the hedging becomes an approximation problem: instead of *replicating* an option, one tries to *minimize* the residual hedging error. Many authors (see, e.g. [8, 11]) studied the quadratic hedging, where the optimal strategy is obtained by minimizing the expected squared hedging error. A particularly simple situation is when this error is computed under the martingale probability. The optimal hedge is then a weighted sum of the sensitivity of option price to infinitesimal stock movements, and the average sensitivity to jumps:

$$\begin{aligned} & \phi^*(t, S_t) \\ &= \frac{\sigma^2 \frac{\partial P}{\partial S} + \frac{1}{S_t} \int \nu(dz)(e^z - 1)(P(t, S_t e^z) - P(t, S_t))}{\sigma^2 + \int (e^z - 1)^2 \nu(dz)} \end{aligned} \quad (25)$$

For jump diffusions, if jumps are small, the Taylor decomposition of this formula gives

$$\begin{aligned} \phi_t &\approx \frac{\partial P}{\partial S} + \frac{S_t}{2\Sigma^2} \frac{\partial^2 P}{\partial S^2} \int \nu(dz)(e^z - 1)^3 \\ \Sigma^2 &= \sigma^2 + \int (e^z - 1)^2 \nu(dz) \end{aligned} \quad (26)$$

Therefore, the optimal strategy can be seen as a small and typically negative (since the jumps are mostly negative) correction to delta hedging. For pure-jump processes such as variance gamma, $(\partial^2 P / \partial S^2)$ may not be defined and the correction may be big.

Numerical studies of the performance of hedging strategies in the presence of jumps show that

- If the jumps are small, delta hedging works well and its performance is close to optimal.
- In the presence of a strong jump component, the optimal strategy is superior to delta hedging both in terms of hedge stability and residual error.
- If jumps are strong, the residual hedging error can be further reduced by adding options to the hedging portfolio.

To eliminate the remaining hedging error, a possible solution is to use liquid options as hedging instruments. Optimal quadratic hedge ratios in the case when the hedging portfolio may contain options can be found in [8].

Uncertain Volatility Model

Black–Scholes and Realized Volatility

What happens when a trader uses the Black–Scholes ((BS) in the sequel) formula to dynamically hedge a call option at a given constant volatility while the realized volatility is not constant?

It is not difficult to show that the answer is the following: if the realized volatility is lower than the managing volatility, the corresponding profit and loss (P&L) will be nonnegative. Indeed, a simple, yet, clever application of Itô's formula shows us that the instantaneous P&L of being short a delta-hedged option reads

$$P\&L_t = \frac{1}{2} \Gamma S_t^2 \left[\sigma_t^2 dt - \left(\frac{dS_t}{S_t} \right)^2 \right] \quad (1)$$

where Γ is the gamma of the option (the second derivative with respect to the underlying, which is positive for a call option), and σ_t the spot volatility, for example, the volatility at which the option was sold and $\left(\frac{dS_t}{S_t} \right)^2$ represents the realized variance over the period $[t, t + dt]$. Note that this holds without any assumption on the realized volatility, which will certainly turn out to be nonconstant. This result is fundamental in practice: it allows traders to work with neither exact knowledge of the behavior of the volatility nor a more complex toolbox than the plain BS formula; an upper bound of the realized volatility is enough to grant a profit (conversely, a lower bound for option buyers). This way of handling the realized volatility with the BS formula is of historical importance in the option market. El Karoui, Jeanblanc, and Shreve have formalized it masterfully in [5].

Superhedging and the Uncertain Volatility Model (UVM)

The UVM Framework

Assume that you perform the previous strategy. You are certainly not alone in the market, and you wish you have the lowest possible selling price compatible with your risk aversion. In practice, on the derivatives desk (this is a big difference with the insurance

world where the risk is distributed among a large enough number of buyers), the risk aversion is total, meaning that your managing policy will aim at yielding a nonnegative P&L whatever the realized path. This approach is what is called the superhedging strategy (or superstrategy) approach to derivative pricing. Of course, the larger the set of the underlying scenarios (or paths) for which you want to have the superhedging property (*see Superhedging*), the higher the initial selling price. The first set that comes to mind is the set of paths associated with an unknown volatility, say between two boundary values $\sigma_{\min}$ and $\sigma_{\max}$. In other words, we look for the cheapest price at which we can sell and manage an option without any assumption on the volatility except that it lies in the $[\sigma_{\min}, \sigma_{\max}]$ range. This framework is the uncertain volatility model (UVM) introduced by Avellaneda *et al.* [2].

If you take a call option (or more generally a European option with convex payoff), the BS price at volatility $\sigma_{\max}$ is a good candidate. Indeed, it yields a superhedging strategy by result (1). And should the realized volatility be constantly $\sigma_{\max}$, then your P&L will be 0. It is easy to conclude from this that the BS $\sigma_{\max}$ price is the UVM selling price for an option with a convex payoff.

Now very often traders use strategies (butterflies, callspreads, etc.) which are not convex any longer. It is not at all easy to find a superstrategy in such cases. There is one exception; if you hedge at the selling time and do not rebalance your hedge before maturity, the cheapest price associated to such a strategy will be the value at the initial underlying value of the concave envelope of the payoff function. It is easy to see that this value corresponds to the total uncertainty case, or to the $[0, \infty]$ case in the UVM model. For a call option it will be the value of the underlying.

Black–Scholes–Barenblatt Equation

There come into play the seminal work [2] and independently [7]: Going back to equation (1), we are looking for a model with the property that the managing volatility is $\sigma_{\min}$ when the gamma is nonnegative, and $\sigma_{\max}$ in the converse situation. Should such a model exist, it will yield an optimal solution to the superhedging problem.

An easy way to approximate the optimal solution is to consider a tree (a trinomial tree, for instance) where the dependence upon the volatility lies in

the node probabilities and not in the tree grid. In the classical backward pricing scheme one can then choose the managing volatility according to the local convexity (since it is a trinomial tree, each node has three offshoot and so a convexity information) of the immediately forward price. Of course, it is not the convexity of the current price since we are calculating it, but the related error of replacing the current convexity by the forward one will certainly go to zero when the time step goes to zero.

The related continuous-time object is the Black–Scholes partial differential equation (PDE) where the second-order term is replaced by the following non-linear one

$$\frac{1}{2} S_t^2 (\sigma_{\max}^2 \Gamma^+ - \sigma_{\min}^2 \Gamma^-)$$

where, as usual, x^+ and x^- denote the positive and negative parts. This PDE has been named *Black–Scholes–Barenblatt* since it looks like the Barenblatt PDE occurring in porosity theory. More precisely, in case of no arbitrage, assume that the stock price dynamics satisfy $dS_t = S_t (r dt + \sigma_t dW_t)$, where W_t is a standard Brownian motion and r is the risk-free interest rate. This is valid under the class $\mathcal{P}$ of all the probability measures such that $\sigma_{\min} \leq \sigma_t \leq \sigma_{\max}$. Let Π_t denote the value of a derivative at time t written on S_t with maturity T and final payoff $\Phi(S_T)$; then at any time $0 \leq t \leq T$, we must have $W^-(t, S_t) \leq \Pi_t \leq W^+(t, S_t)$ where

$$\begin{aligned} W^-(t, S_t) &= \inf_{P \in \mathcal{P}} \mathbb{E}_t^P [e^{-r(T-t)} \Phi(S_T)] \\ W^+(t, S_t) &= \sup_{P \in \mathcal{P}} \mathbb{E}_t^P [e^{-r(T-t)} \Phi(S_T)] \end{aligned} \quad (2)$$

The two bounds satisfy the following nonlinear PDE, called the *Black–Scholes–Barenblatt equation* (which reduces to the classical BS one in the case $\sigma_{\min} = \sigma_t = \sigma_{\max}$):

$$\begin{aligned} \frac{\partial W^\pm}{\partial t} + r \left(\frac{\partial W^\pm}{\partial S} S - W^\pm \right) \\ + \frac{1}{2} \Sigma \left(\frac{\partial^2 W^\pm}{\partial S^2} \right) S^2 \frac{\partial^2 W^\pm}{\partial S^2} = 0 \end{aligned} \quad (3)$$

with the terminal condition

$$W^\pm(S, T) = \Phi(S_T) \quad (4)$$

where

$$\Sigma \left(\frac{\partial^2 W^+}{\partial S^2} \right) = \begin{cases} \sigma_{\max}^2 & \text{if } \frac{\partial^2 W^+}{\partial S^2} \geq 0 \\ \sigma_{\min}^2 & \text{if } \frac{\partial^2 W^+}{\partial S^2} < 0 \end{cases} \quad (5)$$

and

$$\Sigma \left(\frac{\partial^2 W^-}{\partial S^2} \right) = \begin{cases} \sigma_{\max}^2 & \text{if } \frac{\partial^2 W^-}{\partial S^2} \leq 0 \\ \sigma_{\min}^2 & \text{if } \frac{\partial^2 W^-}{\partial S^2} > 0 \end{cases} \quad (6)$$

Observe that in case Φ is convex, the BS price at volatility $\sigma_{\max}$ is convex for any time t , so that it solves the Black–Scholes–Barenblatt equation. Conversely, if Φ is concave, so is its BS price at volatility $\sigma_{\max}$ for any time t , which yields the unique solution to the Black–Scholes–Barenblatt equation.

Superstrategies and Stochastic Control

Note that this PDE is also a classical Hamilton–Jacobi–Bellman equation occurring in stochastic control theory. Indeed a related object of interest is the supremum of the risk-neutral prices over all the dynamics of volatility that satisfy the range property:

$$\sup_{P \in \mathcal{P}} \mathbb{E}^P f$$

where $\mathcal{P}$ is the set of risk-neutral probabilities, each of which corresponds to a volatility process with value at each time in $[\sigma_{\min}, \sigma_{\max}]$. In fact, such an object is not that easy to define in the classical probabilistic modeling framework, since two different volatility processes will typically yield mutually singular probability measures on the set of possible paths. A convenient framework is the stochastic control framework. In such a framework, the managing volatility being interpreted as a control, one tries to optimize a given expectation—the risk-neutral price in this case. It turns out that stochastic optimal control will yield the optimal superstrategy price.

Nevertheless, the connection between the superstrategy problem and stochastic control is not that obvious, and these need to be spelled out carefully in this respect. Recall that the stochastic control problem is the maximization of an expectation over a set of processes, whereas the superstrategy problem is

the almost sure domination of the option payoff at maturity by a hedging strategy.

Note that even in the UVM case, there are still plenty of open questions. In fact, a neat formulation of the superhedging problem is not a piece of cake. The issue is avoided in [2], handled partially in [7], and more formally in [8], where the model uncertainty is specified as a set of martingale probabilities on the canonical space, and also in [6]. Once this is done, a natural theoretical problem, given such a “model set”, is to find out a formula for the cheapest superhedging price. The supremum of the risk-neutral prices over all the probabilities of the set will in general be strictly smaller than the cheapest price, even if they match in the UVM setting. The precise property of the “model set” that makes this equality remains to be clarified. Some partial results in this direction, with progresses towards a general theorem, are available in [4], where the case of path-dependent payoffs in the UVM framework is also solved.

Lagrangian UVM

In practice, the UVM approach is easy to implement for standard options by using the tree scheme described above, for example. It can be extended in the same way for path-dependent options. Nevertheless, when the price pops up, the usual reaction of the trader or risk officer is that the price is too high, especially too high to explain the observed market price.

The fact that the price is high is a direct consequence of the total aversion approach in the superstrategy formulation, and also of the fact that the price corresponds to the worst-case scenario where the gamma changes signs exactly when the volatility switches regimes. This is a highly unlikely situation. To lower the price and fit in the traditional setting where one wants to fit the observed market price of liquid European calls and puts (so-called vanillas), Avellaneda, Levy, and Paras propose a constrained extension of the UVM model where the price of the complex products of the trader is handled within the UVM framework with the additional constraint of fitting the vanilla prices. By duality, this reduces to computing the UVM price for a portfolio parameterized by a Lagrangian multiplier and then minimizing the dual value function over the Lagrangian parameter. Mathematically speaking, let us consider an asset S_t and a payoff $\Phi(S_T)$. m European options with

payoffs $F_1(S_{T_1}), \dots, F_m(S_{T_m})$ with maybe different strikes and maturities are available for hedging; let $f_1, \dots, f_m$ be their respective market prices at the time of the valuation $t \leq \min(T, T_1, \dots, T_m)$. Consider now an agent who buys quantities $\lambda_1, \dots, \lambda_m$ of each option. His total cost of hedging then reads

$$\begin{aligned} \Pi(t, S_t, \lambda_1, \dots, \lambda_m) \\ = \sup_{P \in \mathcal{P}} \left\{ e^{-r(T-t)} \Phi(S_T) - \sum_{i=1}^m \lambda_i e^{-r(T_i-t)} F_i(S_{T_i}) \right\} \\ + \sum_{i=1}^m \lambda_i f_i \end{aligned} \quad (7)$$

where the supremum (sup) is calculated within the UVM framework as presented above, and we must specify a range $\Lambda_i^+ \leq \lambda_i \leq \Lambda_i^-$ ($\Lambda_i^\pm$ represent the quantities available on the market). The optimal hedge Π is then defined as the solution to the problem

$$\Pi^*(t, S_t) = \inf_{\lambda_1, \dots, \lambda_m} \Pi(t, S_t, \lambda_1, \dots, \lambda_m) \quad (8)$$

In fact, the first-order conditions read $\frac{\partial \Pi}{\partial \lambda_i} = \sum_{i=1}^m f_i - \mathbb{E}^{P^*}(e^{-r(T_i-t)} F_i(S_{T_i})) = 0$, where P^* realizes the sup above. These conditions exactly fit the model to observed market prices. The convexity of $\Pi(t, S_t, \lambda_1, \dots, \lambda_m)$ with respect to λ_i ensures that if a minimum exists, then it is unique.

This approach is very attractive from a theoretical point of view, but it is much harder to implement. The consistency of observed vanilla prices is a crucial step that is rarely met in practice. Even if numerous robust algorithms exist to handle the dual problem, their implementation is quite tricky. In fact, this constrained formulation implies a calibration property of the model, and the design of a stable and robust calibration algorithm is one of the greatest challenges in the field of financial derivatives.

The Curse of Nonlinearity

Another issue for a practitioner is the inherent nonlinearity of the UVM formulation. Most traditional models like BS, Heston, or Lévy-based models are linear models. The fact that an option price should depend on the whole portfolio of the trader is a no-brainer for risk officers, but this nonlinearity is a challenge for the modularity and the flexibility of

pricing systems. This is very often a no-go feature in practice.

The complexity of evaluating a portfolio in the UVM framework is real, as studied thoroughly by Avellaneda and Buff in [1]. Following [1], let us consider a portfolio with n options with payoffs $f_1, \dots, f_n$ and maturities $t_1, \dots, t_n$. The computational problem becomes tricky when the portfolio consists of barrier options. Indeed, this means that, at any time step, the portfolio we are trying to value might be different (in case the stock price has reached the barrier of any option) from the one at the previous time step. Because of the nonlinearity, a PDE specific to this portfolio has to be solved in this case. Avellaneda and Buff [1] addressed this very issue: a naive implementation would require solving the $2^n - 1$ nonlinear PDEs, each representing a subportfolio. They provide an algorithm to build the minimal number N_n of subportfolios (i.e., of nonlinear PDEs to solve) and show the following:

- If the initial portfolio consists of barrier (single or double) and vanilla options, then $N_n \leq \frac{n(n+1)}{2}$
- If the initial portfolio only consists of single barrier options (n_u up-and-out ones and $n_d = n - n_u$ down-and-out ones), then $N_n = n_d + n_u + n_d n_u$. This assumes that all the barriers are different. If some are identical, then the number of required computations decreases.

Numerically speaking, the finite-difference pricing is done on a lattice, matching almost exactly all the barriers. Nevertheless in [3], an optimal construction of the lattice to solve the PDEs is provided.

Implied Volatility: Market Models

The market model approach for implied volatility consists in taking implied volatilities as the quantities one wishes to model. In many options exchanges and over-the-counter markets, implied volatility is the way an option is quoted and hence plays the role of a price.

The market model approach for implied volatilities is inspired by the corresponding market model approach for interest rates, the so-called Heath–Jarrow–Morton (HJM) approach to interest rate modeling (*see Heath–Jarrow–Morton Approach*). In interest rate modeling, it is simple to characterize the dynamics of the entire family of instantaneous forward rates in such a way that the corresponding family of bond prices is arbitrage free. It is also simple to give examples of such dynamics and to price interest rate sensitive contingent claims in such models.

Correspondingly, the market model approach to implied volatility seeks to characterize the dynamics of the entire implied volatility surface in such a way that the corresponding family of option prices is arbitrage free. It also seeks simple examples of such dynamics and ideally practical means of computing prices of exotic options on the underlying in such models.

Despite numerous attempts and recent progress in this area, it is fair to say that this approach has unfortunately not delivered the same elegant and useful results as the HJM approach has in interest rate modeling. The market approach to implied volatility can be traced back to the works [11, 12, 20].

As in the HJM approach, the no-arbitrage condition for implied volatilities takes the form of a drift restriction. In other words, the drift must be constrained for option prices to be local martingales under the pricing measure.

Drift Restriction

To continue the discussion, we need the following definitions. Let $(\mathbf{W}_t)_{t \geq 0}$ be an n -dimensional Wiener process that models the uncertainty in the economy. We shall use boldface letters for vectors, $\cdot$ for the

usual scalar product, and $|\cdot|$ for the Euclidean norm. We assume that the probability measure is risk neutral, that is, discounted price processes are local martingales. We assume for simplicity that interest rates and dividends are zero.

The traded asset on which options are written is denoted by S_t and its volatility vector by σ_t , that is,

$$\frac{dS_t}{S_t} = \sigma_t \cdot d\mathbf{W}_t \quad (1)$$

The no-arbitrage constraint for the implied volatility $\Sigma_t(T, K)$ for the option with strike K and maturity T implies the following drift restriction in their dynamics

$$\begin{aligned} \Sigma_t(T, K) &= \Sigma_0(T, K) - \int_0^t \left[\frac{|\sigma_s - \ln(S_s/K) \xi_s|^2 - \Sigma_s^2}{2\Sigma_s(T-s)} \right. \\ &\quad \left. + \frac{1}{2} \Sigma_s \sigma_s \cdot \xi_s - \frac{1}{8} \Sigma_s^3 (T-s) |\xi_s|^2 \right] (T, K) ds \\ &\quad + \int_0^t \Sigma_s(T, K) \xi_s(T, K) \cdot d\mathbf{W}_s \end{aligned} \quad (2)$$

where $\xi_t(T, K)$ is the implied volatility's volatility vector. The corresponding call option price dynamics is

$$\begin{aligned} C_t(T, K) &= C_0(T, K) + \int_0^t S_s (\Phi(d_1) \sigma_s \\ &\quad + \Sigma_s \sqrt{T-s} \varphi(d_1) \xi_s)(T, K) \cdot d\mathbf{W}_s \end{aligned} \quad (3)$$

where, as usual, $d_1 = (\ln(S_t/K)/\Sigma_t(T, K)\sqrt{T-t}) + \frac{1}{2} \Sigma_t(T, K)\sqrt{T-t}$ and Φ and φ denote, respectively, the cumulative distribution and density probability function of a standard Gaussian random variable.

The above equation (2) is the equivalent of the HJM equation for implied volatilities. However, unlike the HJM equation, the drift does not solely involve the volatility vector ξ_t but also depends on S_t and σ_t .

The Spot Volatility Specification

Equation (2) has interesting properties. In particular, when we consider the infinite system of equation (2)

for a fixed K and all $T > t$, it alone specifies the spot volatility σ_t . This phenomenon is directly related to the convergence of option prices to the option payoff at expiry. Equivalently, the solution to equation (2) should not blow up too fast near expiry. It is called *no-bubble restriction* in [17], whereas [5] calls it the *feedback condition* and traces it back to [8]. It is also called the *volatility specification* in [19] and [6]. It reads

$$\Sigma_t(t, K) = \left| \sigma_t - \ln \left(\frac{S_t}{K} \right) \xi_t(t, K) \right| \quad (4)$$

For a proof under proper assumptions, see [13].

The case where we let $K = S_t$ in equation (4) says $\Sigma_t(t, S_t) = |\sigma_t|$. In other words, the current value of the spot volatility can be exactly recovered from the implied volatility smile. This very much parallels the fact that the instantaneous forward rate with infinitely small tenor is the short rate in the HJM approach to interest rates.

It is shown in [14] that the relation $\Sigma_t(t, S_t) = |\sigma_t|$ holds in great generality even when jumps in the spot and/or its volatility are present. It turns out to be a consequence of the central limit theorem for martingales.

Equation (4) has an interesting connection to the work of Berestycki *et al.* [3]. In a time homogeneous stochastic volatility model, [3] shows that the implied volatility in the short maturity limit can be expressed using the geodesic distance associated with the generator of the bivariate diffusion (x_t, y_t) , where x_t is the log-moneyness and y_t is the spot volatility ($|\sigma_t|$ in our notation). Keeping their notation, we denote by $d(x, y)$ the signed geodesic distance from (x, y) to $(0, y)$, and obtain

$$\Sigma_t(t, K) = \frac{\ln(S_t/K)}{d(\ln(S_t/K), |\sigma_t|)} \quad (5)$$

By comparing equations (4) and (5), it becomes clear that the geodesic distance associated with the generator of the stochastic volatility model and the implied volatility's volatility vector are strongly related.

The Case of a Single Strike

We first deal with the problem studied by [1, 4, 16, 17, 19] where only a single option is considered. The goal is to set up conditions under which the infinite system of equation (2) for a fixed K and

all $T > t$ together with equation (1) admits a unique solution. The best results were obtained by [4] and [19]. Without loss of generality, one can assume that equation (1) is driven by the first Wiener process only and that $\sigma_t = (\sigma_t, 0, \dots, 0)$. Assume that ξ_t has the functional form,

$$\xi_t(T, K) = \frac{1}{2} \int_t^T \frac{X_t(u, K)}{X_t(T, K)} \mathbf{V}_t(u, K) du \quad (6)$$

where $X_t(T, K) = \frac{\partial}{\partial T}(\Sigma_t(T, K)^2(T - t))$ is the square of the *forward implied volatility* and where $\mathbf{V}$ has the form

$$\mathbf{V}_t(T, K) = \mathbf{V}(t, T, K, \Sigma_t(T, K), \Sigma_t(t, K), S_t) \quad (7)$$

for a deterministic function $\mathbf{V}$ satisfying technical positivity, growth, and Lipschitz conditions [19]. Assume also that the spot volatility has the functional form $\sigma_t = \sigma(t, K, \Sigma_t(t, K), S_t)$, where the deterministic function σ is determined by equation (4). Then, the infinite system of equation (2) for a fixed K and all $T > t$ together with equation (1) admits a unique solution.

The Case of Several Strikes

The infinite system of equation (2) for all K and all $T > t$ together with equation (1) is more complicated and conditions on ξ_t under which it admits a unique solution are still poorly understood. One advantage of dealing with all strikes K at once is that one can remove the dependence on S in equation (2) by changing the parameterization of the surface from K to moneyness K/S_t . The dynamics of the implied volatility surface in these coordinates are obtained by applying the Itô–Wentzell formula as in [5]. One of the difficulties of the multistrike case is that the solution to the infinite system in equation (2) must satisfy some shape restrictions at each time t . These are consequences of the well-known static arbitrage restrictions that we now recall.

Static Arbitrage Restrictions

Static arbitrage relations lead to constraints on the shape of the implied volatility surface. The fact that calendar spreads have positive values leads to

$$\frac{\partial \Sigma_t}{\partial T} + \frac{\Sigma_t}{2(T - t)} \geq 0 \quad (8)$$

The fact that call values are a decreasing function of the strike leads to

$$\frac{-\Phi(-d_1)}{\varphi(d_1)\sqrt{T-t}} \leq K \frac{\partial \Sigma_t}{\partial K} \leq \frac{\Phi(d_2)}{\varphi(d_2)\sqrt{T-t}} \quad (9)$$

Finally, the fact that butterfly spreads have positive values, or that calls are convex functions of the strike leads to

$$\begin{aligned} & \left(1 - \frac{\ln(K/S_t)}{\Sigma_t} K \frac{\partial \Sigma_t}{\partial K}\right)^2 - \frac{(T-t)^2}{4} \Sigma_t^2 \left(K \frac{\partial \Sigma_t}{\partial K}\right)^2 \\ & + (T-t) \Sigma_t \left(K \frac{\partial \Sigma_t}{\partial K} + K^2 \frac{\partial^2 \Sigma_t}{\partial K^2}\right) \geq 0 \end{aligned} \quad (10)$$

where $d_2 = d_1 - \Sigma_t(T, K)\sqrt{T-t}$. These restrictions must hold at each time t and at each point (T, K) of the implied volatility surface.

Deterministic Models

Practitioners [10] have proposed two simple models for implied volatility surfaces movements: the sticky strike model and the sticky delta model. The sticky strike model supposes that between date s and $t \geq s$, the implied volatility surface evolves as

$$\Sigma_t(T, K) = \Sigma_s(T, K) \quad (11)$$

whereas the sticky delta model supposes that

$$\Sigma_t(T, K) = \Sigma_s\left(T, \frac{S_s}{S_t} K\right) \quad (12)$$

In a sticky strike model, an option with a given strike has constant implied volatility. This contrasts with a sticky delta model where options with same moneyness have same implied volatilities. In other words, the implied volatility surface moves in perfect sync with the spot. In reality, implied volatilities move in a more complicated fashion but these two extreme cases are useful stylized benchmarks.

The sticky strike and sticky delta models, in fact, imply strong restrictions on the possible spot dynamics. Balland [2] showed that a sticky delta occurs if and only if the underlying asset price is the exponential of a process with independent increments (i.e., a Lévy process, *see Exponential Lévy Models*) under the pricing measure, and that a sticky strike situation occurs in the Black–Scholes model only!

Empirical Models

To overcome the obvious shortcomings of the sticky strike and sticky delta models, Cont and da Fonseca [9] have proposed to write down a model for the future evolution of the surface as an infinite system where each point of the surface is driven by a few common factors. These dynamics allow for easy calibration using principal component analysis [9] and can be useful for risk management and scenarios simulation. It is difficult, however, to check whether such specifications satisfy arbitrage restrictions, which prevents them from being used to price exotic options.

The Spot Volatility Dynamics from the Implied Volatility Surface

In the HJM approach (*see Heath–Jarrow–Morton Approach*) to interest rate modeling, the HJM equation can be used to write down the short rate dynamics starting from the forward rate dynamics. The parallel result in the case of implied volatility was obtained in [13]. The statement is the following: there exists a scalar Wiener process $W^\perp$ adapted to the filtration generated by $(\mathbf{W}_t)_{t \geq 0}$ such that

$$\begin{aligned} |\sigma_t|^2 = & |\sigma_0|^2 + \int_0^t \left[4 |\sigma_s| \frac{\partial \Sigma_s}{\partial T}(s, S_s) + 6 |\sigma_s|^2 \right. \\ & \times \left(S_s \frac{\partial \Sigma_s}{\partial K}(s, S_s) \right)^2 + 2 |\sigma_s|^3 S_s^2 \frac{\partial^2 \Sigma_s}{\partial K^2}(s, S_s) \Big] ds \\ & + \int_0^t 4 |\sigma_s| \frac{\partial \Sigma_s}{\partial K}(s, S_s) dS_s + \int_0^t 2 |\sigma_s|^2 \xi_s^\perp dW_s^\perp \end{aligned} \quad (13)$$

where

$$\begin{aligned} (\xi_t^\perp)^2 = & -\frac{2}{|\sigma_t|} \frac{d}{dt} \left\langle S_t, \frac{\partial \Sigma_t}{\partial K}(t, S_t) \right\rangle \\ & + 2 \left(S_t \frac{\partial \Sigma_t}{\partial K}(t, S_t) \right)^2 - |\sigma_t| S_t \frac{\partial \Sigma_t}{\partial K}(t, S_t) \\ & - 3 |\sigma_t| S_t^2 \frac{\partial^2 \Sigma_t}{\partial K^2}(t, S_t) \end{aligned}$$

Moreover, the two local martingales appearing in the decomposition are orthogonal in the sense that

$$\left\langle \int_0^t 4 |\sigma_s| \frac{\partial \Sigma_s}{\partial K}(s, S_s) dS_s; \int_0^t 2 |\sigma_s|^2 \xi_s^\perp dW_s^\perp \right\rangle = 0 \quad (14)$$

This result actually has a converse, which allows one to get a very precise idea of the implied volatility of a given spot model. It indeed allows to compute the first terms of the Taylor expansion of the implied volatility surface for short maturity and around the money [13].

Other Approaches

Modeling implied volatilities is equivalent to modeling option prices; as seen in equation (3), it is merely a parameterization of the options' volatilities. The difficulties in modeling implied volatilities have led researchers to look for other and possibly more tractable parameterizations. We mention them here, although these approaches depart from the strict study of implied volatilities.

First, following a program started in [7, 10] model option prices by modeling Dupire local volatility as a random field. They are able to find explicit drift conditions as well as some examples of such dynamics. The Dupire local volatility surface also specifies the spot volatility in the short maturity limit but does not have complicated static arbitrage restrictions like equations 8–10.

Another way of parameterizing option prices consists in modeling its intrinsic value, that is, the difference between the option price and the payoff if the option was exercised today. This is the approach taken by [15] in a very general semimartingale framework. Exactly as with implied volatilities, this approach yields a spot specification when options are close to maturity.

Finally, let us mention the recent work [18], where the authors introduce new quantities: the “local implied volatilities” and “price level” to parameterize option prices. These have nicer dynamics and naturally satisfy the static arbitrage conditions. They derive existence results for the infinite system of equations driving these quantities.

Rating Transition Matrices

Rating transition matrices play an important role in credit risk management both as a method for summarizing the empirical behavior of a rating system and as a tool for computing probabilities of rating migrations in, for example, a portfolio of risky loans. Analysis of statistical properties of rating transition matrices is intimately linked with Markov chains. Even if rating processes in general are not Markovian, statistical analysis of rating systems often focuses on assessing a particular deviation from Markovian behavior. Furthermore, the tractability of the Markovian setting can be preserved in some simple extensions.

Discrete-time Markov Chains

Let the rating process $\eta = (\eta_0, \eta_1, \dots)$ be a discrete-time stochastic process taking values in a finite state space $\{1, \dots, K\}$. If the rating process is a Markov chain, the probability of making a particular transition between time t and time $t + 1$ does not depend on the history before time t , and one-step transition probabilities of the form

$$p_{ij}(t; t + 1) = \Pr(\eta_{t+1} = j \mid \eta_t = i) \quad (1)$$

describes the evolution of the chain. If the one-step transition probabilities are independent of time, we call the chain time homogeneous and write

$$p_{ij} = \Pr(\eta_{t+1} = j \mid \eta_t = i) \quad (2)$$

The one-period transition matrix of the chain is then given as

$$P = \begin{pmatrix} p_{11} & \cdots & p_{1K} \\ \vdots & & \vdots \\ p_{K1} & \cdots & p_{KK} \end{pmatrix} \quad (3)$$

where $\sum_{j=1}^K p_{ij} = 1$ for all i .

Consider a sample of N firms whose transitions between different states are observed at discrete dates $t = 0, \dots, T$. Now introduce the following notation:

- $n_{ij}(t)$ = number of firms that went from i at date $t - 1$ to j at date t .
- $N_i(t) = \sum_{j=1}^K n_{ij}(t)$ = number of firm exposures recorded at the beginning of transition periods.
- $N_{ij}(T) = \sum_{t=1}^T n_{ij}(t)$ = total number of transitions observed from i to j over the entire period.

If we do not assume time homogeneity, we can estimate each element of the one-step transition probability matrix using the maximum-likelihood estimator

$$\widehat{p}_{ij}(t - 1; t) = \frac{n_{ij}(t)}{n_i(t - 1)} \quad (4)$$

which simply is the fraction of firms that made the transition divided by the number of firms which could have made the transition.

Assuming time homogeneity, the maximum-likelihood estimator of the transition probabilities matrix is

$$\widehat{p}_{ij} = \frac{N_{ij}(T)}{N_i(T)} \quad (5)$$

for all $i, j \in K$. This estimator is different from the estimator obtained by estimating a sequence of 1-year transition matrices and then computing the average of each element at a time. The latter method will weigh years with few observations as heavily as years with many observations. If the viewpoint is that there is variation in 1-year transition probabilities over time due to, for example, business cycle fluctuations, the averaging can be justified as a way of obtaining an unconditional 1-year default probability over the cycle.

Rating agencies often form a cohort of firms at a particular date, say January 1, 1980, and record transition frequencies over a fixed time horizon, say 5 years. This can be done in a straightforward way using only information on the initial rating and final rating after 5 years, assuming that all companies that are in the cohort, to begin with, stay in the sample. In practice, rating withdrawals occur, that is, firms or debt issues cease to have a rating. According to [4], the vast majority of withdrawals are due to debt maturing, being redeemed or called. It is traditional in the rating literature to view these events as “noninformative” censoring. One way to deal with withdrawals is to eliminate the firms from the sample and in essence use only those firms that do not have their rating withdrawn in the 5-year period. Another way is to estimate a sequence of

- $n_i(t)$ = number of firms in state i at date t .

1-year transition probability matrices using the 1-year estimator and then estimate the 5-year matrix as the product of 1-year matrices. In this case, information of a firm whose rating is withdrawn is used for the years where it is still present in the sample. Both methods rely on the assumption of withdrawals being noninformative.

Continuous-time Markov Chains

When one has access to full rating histories and therefore knows the exact dates of transitions, the continuous-time formulation offers significant advantages in terms of tractability. Recall that the family of transition matrices for a time-homogeneous Markov chain in continuous time on a finite state space can be described by an associated generator matrix, that is, a $K \times K$ matrix Λ , whose elements satisfy

$$\begin{aligned}\lambda_{ij} &\geq 0 \text{ for } i \neq j \\ \lambda_{ii} &= -\sum_{j \neq i} \lambda_{ij}\end{aligned}\quad (6)$$

Let $P(t)$ denote the $K \times K$ matrix of transition probabilities, that is, $p_{ij}(t) = P(\eta_t = j | \eta_0 = i)$. Then

$$P(t) = \exp(\Lambda t) \quad (7)$$

where the right hand side is the matrix exponential of the matrix Λt obtained by multiplying all entries of Λ by t .

In case a row consists of all zeros, the chain is absorbed in that state when it hits it. It is convenient to work with the default states as absorbing states even if firms in practice may recover and leave the default state. If we ask what the probability is that a firm will default before time T then this can be read from the transition matrix $P(T)$ when we have defined default to be an absorbing state. If the state is not absorbing, but P allows the chain to jump back into the nondefault rating categories, then the transition probability matrix for time T will only give the probability of being in default at time T and this (smaller) probability is typically not the one we are interested in for risk management purposes.

Assume that we have observed a collection of firms between time 0 and time T . The maximum-likelihood estimator for the off-diagonal elements of

the generator matrix is given by

$$\hat{\lambda}_{ij} = \frac{N_{ij}(T)}{\int_0^T Y_i(s) ds} \quad (8)$$

where $Y_i(s)$ is the number of firms in rating class i at time s and $N_{ij}(T)$ is the total number of direct transitions over the period from i to j , where $i \neq j$. The denominator counts the number of “firm-years” spent in state i .

Any period a firm spends in a state will be picked up through the denominator. In this sense all information is being used. Note also how (noninformative) censoring is handled automatically: When a firm leaves the sample, it simply stops contributing to the denominator. Also, this method will produce estimates of transition probabilities for “rare transitions”, even if the rare transitions have not been observed in the sample. For more on this, see [9].

Nonhomogeneous Chains

For statistical specifications and applications to pricing, the concept of a nonhomogeneous chain is useful. In complete analogy with the discrete-time case, the definition of the Markov property does not change when we drop the assumption of time homogeneity, but the description of the family of transition matrices requires that we keep track of calendar dates instead of just time lengths.

For each pair of states i, j with $i \neq j$, let A_{ij} be a nondecreasing right-continuous (and with left limits) function, which is zero at time zero. Let

$$A_{ii}(t) = -\sum_{j \neq i} A_{ij}(t) \quad (9)$$

and assume that

$$\Delta A_{ii}(t) \geq -1 \quad (10)$$

Then there exists a Markov process with state space $1, \dots, K$ whose transition matrix is given by

$$\begin{aligned}P(s, t) &= \Pi_{[s, t]}(I + dA) \\ &\equiv \lim_{\max |t_i - t_{i-1}| \rightarrow 0} \Pi_i(I + A(t_i) - A(t_{i-1}))\end{aligned}\quad (11)$$

where $s \leq t_1 \leq t_n \leq t$. One can think of the probabilistic behavior as follows: Given that the chain is in state i at time s the probability that it remains in that state at least until t (assuming that $\Delta A_{ii}(u) > -1$ for $u \leq t$) is given by

$$P(\Delta\eta_u = 0 \text{ for } s < u \leq t | \eta_s = i) \\ = \exp(-(A_{ii}(t) - A_{ii}(s))) \quad (12)$$

We are interested in testing assumptions on the intensity measure when it can be represented through integrated intensities, that is, we assume that there exists integrable functions (or transition intensities) $\lambda_{ij}(\cdot)$ such that

$$A_{ij}(t) = \int_0^t \lambda_{ij}(s) ds \quad (13)$$

for every pair of states i, j with $i \neq j$.

In this case, given that the chain jumps away from i at date t , the probability that it jumps to state j is given by $\frac{\lambda_{ij}(t)}{\sum_{k \neq i} \lambda_{ik}(t)}$.

A homogeneous Markov chain with intensity matrix Λ has $A_{ij}(t) = \lambda_{ij}t$ and in this special case we can write $P(s, t) = \exp(\Lambda(t - s))$.

For a method for estimating the continuous-time transition probabilities nonparametrically using the so-called Aalen–Johansen estimator, see, for example, [2]. The specification of individual transition intensities allows us to use hazard regressions on specific rating transitions. For an example of nonparametric techniques, see [5]. A Cox regression approach can be found in [9].

Empirical Observations

There is a large literature on the statistical properties of the observed rating transitions, mainly for firms rated by Moody's and Standard and Poors. It has been acknowledged for a long time that the observed processes are not time homogeneous and not Markov. This is consistent with stated objectives of rating agencies of trying to avoid rating reversals and seeking to change ratings only when the change in credit quality is seen as enduring—a property sometimes referred to as “rating through the cycle”. This is in contrast to “point-in-time” rating. The distinction between the two approaches is not rigorous, but a rough indication of the difference is that

a primary concern of through-the-cycle rating is the correct ranking of the firm's default probabilities (or expected loss) over a longer time horizon, whereas a point-in-time is more concerned with following actual, shorter-term default probabilities seeking to maintain a constant meaning of riskiness associated with each rating category.

The degree to which transition probabilities depend on the previous rating history, business cycle variables, and the sector or country to which the rated companies belong has been investigated, for example, in papers [1, 9, 10]. A good entry into the literature is in the special journal issue introduced by Cantor [3].

Rating agencies have a system of modifiers that effectively enlarge the state space. For example, Moody's operates with a watchlist and long-term outlooks. Being on a watchlist signals a high likelihood of rating action in a particular direction in the near future, and outlooks signal longer term likely rating directions. Hamilton and Cantor [7] investigate the performance of ratings when the state space is enlarged with these modifiers and conclude that they go a long way in reducing dependence on rating history.

Correlated Transitions

In risk management, the risk of loan portfolios and exposures to different counterparties in derivatives contracts depends critically on the extent to which the credit ratings of different loans and counterparties are correlated.

We finish by briefly outlining two ways of incorporating dependence into rating migrations. For the first approach, see, for example, [6]; we map rating probabilities into thresholds. The idea is easily illustrated through an example. If firm 1 is currently rated i and we know the (say) 1-year transition probabilities $p_{i1}, \dots, p_{iK}$, then we can model the transition to the various categories using a standard Gaussian random variable ϵ_1 and defining thresholds $a_1 > a_2 > \dots > a_{K-1}$ such that

$$p_{iK} = P(\epsilon_1 \leq a_{K-1}) = \Phi(a_{K-1}) \quad (14)$$

$$p_{i,K-1} = P(a_{K-1} \leq \epsilon_1 \leq a_{K-2}) \\ = \Phi(a_{K-2}) - \Phi(a_{K-1}) \quad (15) \\ \vdots$$

$$p_{i1} = P(a_1 \leq \epsilon_1) = 1 - \Phi(a_1) \quad (16)$$

Similarly, for firm 2, we can define thresholds $b_1, \dots, b_{K-1}$ and a standard random normal variable ϵ_2 so that the transition probabilities are matched as earlier. Letting ϵ_1 and ϵ_2 be correlated with correlation coefficient ρ induces correlation into the migration patterns of the two firms. This can be extended to a large collection of firms using a full correlation matrix obtained, for example, by looking at equity return correlations.

A second approach, which makes it possible to link up rating dynamics with continuous-time pricing models, is proposed in [8]. The idea here is to model the “conditional generator” of a Markov process as the product of a constant generator Λ and a strictly positive affine process μ , that is, conditionally on a realization of the process μ , the Markov chain is time non-homogeneous with the transition intensity $\lambda_{ij}(s) = \mu(s)\lambda_{ij}$. This framework allows for closed form computation of transition probabilities in a setting where rating migrations are correlated through dependence on state variables.

Credit Migration Models

It is nowadays widely recognized that portfolio models are an essential tool for a proper and effective management of credit portfolios, be it from the perspective of a corporate bank, a mortgage bank, a consumer finance provider, or a fixed-income asset manager. Traditional credit management was, to a large extent, focused on the stand-alone analysis and monitoring of the credit quality of obligors or counterparties. Frequently, the credit process did also include *ad hoc* exposure-based limit-setting policies that were devised in order to prevent excessive risk concentrations. This approach was scrutinized in the 1990s, when the financial industry started to realize that univariate models for obligor default had to be extended to a portfolio context. It was recognized that credit rating and loss recovery models, although a crucial element in the assessment of credit risk, fail to explain some of the important stylized facts of credit loss distributions, if the stochastic dependence of obligor defaults is neglected. From a statistical point of view, not only the skewness and the relatively heavy upper tails of credit portfolio loss distributions, but also the historically observed variation of default rates and the clustering of bankruptcies in single sectors are clearly inconsistent with stochastic independence of defaults. From an economics point of view, it is plausible that default rates are connected to the intrinsic fluctuations of business cycles; relationships between default rates and the economic environment have indeed been established in numerous empirical studies [5]. All these insights supported the quest for tractable credit portfolio models that reflect these stylized facts.

Apart from an accurate statistical description of credit losses, a portfolio model can serve many more purposes. In contrast to a univariate approach, a credit portfolio framework allows to quantify the diversification effects between credit instruments. This makes it, for example, possible to evaluate the impact on the total risk when securities are added or removed from a portfolio. In the same vein, the risk numbers produced by a portfolio model help to identify possible hedges. Ultimately, the use of a portfolio model facilitates the active management of credit portfolios and the efficient allocation of capital. Less of a pure risk management matter is the use of portfolio models for risk-adjusted pricing

(see **Loan Valuation**) or performance measurement. The total portfolio risk is commonly considered as a capital which the lender should hold in order to buffer large losses. For nontraded assets, such as loans or mortgages, the costs for holding this risk capital are typically transferred to the borrowers by means of a surcharge on interest rates. Calculating these surcharges necessitates that the total portfolio risk capital is broken down to borrower (or instrument) level risk contributions. Only in a portfolio model framework, where the dependence between obligors and the resulting diversification benefits are correctly captured, this risk contribution can be determined in an economically rational and fair fashion. We mention that risk contributions can also be applied in order to determine the *ex post* (historical) risk-adjusted performance of instruments or subportfolios. Credit portfolio models also play an important role in the pricing of credit derivatives or structured products, such as credit default swaps or CDSs. For the correct pricing of many of these credit instruments, it is crucial that the dependence between obligor default times are well modeled.

Overview of Credit Migration-based Models

This article gives a survey on migration-based portfolio models, that is, models that describe the joint evolution of credit ratings. The ancestor of all such models is CreditMetrics^{®a}, which was introduced by the US investment bank J.P. Morgan. In 1997, J.P. Morgan and cosponsors from the financial industry published a comprehensive technical document [13] on CreditMetrics, in an effort to set industry standards and to create more transparency in credit risk management. This publication attracted a lot of attention and proved to stimulate research in credit risk. To this date, the CreditMetrics or derivations thereof have been implemented by a large number of financial institutions. Before we turn to a detailed description of CreditMetrics, it might be worth to mention two related models. CreditPortfolioView by McKinsey & Co is credit-migration-based as well. However, in contrast to CreditMetrics, which assumes temporally constant transition matrices, it is endowed with an estimator of credit migration probabilities based on macroeconomic observables. is dedicated to its discussion.

The second link concerns the longer standing KMV model.^b An outline of the KMV methodology can be extracted from an article by Kealhofer and Bohn [16]. In both CreditMetrics and KMV, the obligor correlation is generated in a similar fashion, that is, with a dependence structure following a Gaussian copula. The main differences concern the number of credit states and the source of probabilities of default (PDs). The KMV model operates on a continuum of states, namely, the so-called expected default frequencies (Moody's KMV EDF^{TMc}), basically estimated PDs, whereas CreditMetrics is restricted to a finite number of credit rating states. For this reason, KMV is strictly spoken not a credit-migration-based model and therefore only touched in this article. As remarked by McNeil *et al.* [19], a discretization of EDF would translate KMV to a model which, apart from parametrization, is structurally equivalent to CreditMetrics. Secondly, while for CreditMetrics rating transition matrices are the required exogenous inputs, the KMV counterparts, EDF of listed companies, are estimated through a proprietary method, which is basically an extension of the celebrated Merton model [20] for firm default. Inputs to the EDF model are historical time-series of equity prices together with company debt information, with which the unobserved asset value processes are reconstructed and a quantity called *distance to default* (DD) is calculated for every firm. This DD is used as a predictor of EDF; the relationship is determined by a nonlinear regression of historical default data against historical DD values. It is beyond the scope of this article to provide more details and so we refer to [2] or [17] for an account of the EDF methodology.

The CreditMetrics Model

CreditMetrics models the distribution of the credit portfolio value at a future time, from which risk measures can be derived. The changes of portfolio value are caused by credit migrations of the underlying instruments. In the following, we describe the rationale of the main building blocks of CreditMetrics.

Timescale

CreditMetrics was conceived as a discrete time model. It has a user-specified time horizon T that is

reached in one step from the analysis time 0; typically the time horizon is 1 year. It is assumed that the portfolio is static, that is, its composition is not altered during the time period $(0, T)$.

Risk Factors and Valuation

In case of CreditMetrics, the basic assumption is that each instrument is tied to one or several obligors. The user furnishes obligors with a rating from a rating system with a finite number of classes and an absorbing default state. The obligor ratings are the main risk drivers. We index the obligors by $i = 1, \dots, n$ and assume a rating system with rating classes $\{1, \dots, K\}$ that are ordered with respect to the credit quality, and a default class 0. At time 0, the obligor i has the (known) initial rating S_i^{init} , which then becomes S_i^{new} at time T . The change from S_i^{init} to S_i^{new} happens in a random fashion, according to the so-called credit migration probabilities. These probabilities are assumed to be identical for obligors in the same rating class and can therefore be represented by a so-called credit migration (or rating transition) matrix $\mathbf{M} = (m_{jk})_{j,k \in \{0, \dots, K\}}$. Clearly,

$$\mathbb{P}(S_i^{\text{new}} = k | S_i^{\text{init}} = j) = m_{jk} \quad (1)$$

The credit migration matrix is an important input to CreditMetrics. In practice, one often uses rating systems supplied by agencies such as Moody's or Standard&Poor's. The model also allows to work in parallel with several rating systems, depending on the obligor. If public ratings are not available, financial institutions can resort to internal ratings; *see Credit Rating; Internal-ratings-based Approach; Credit Scoring*.

To treat specific positions, CreditMetrics must estimate values for the position contingent on the position's obligor being in each possible future rating state. This is equivalent to estimating the loss (or gain) on the position contingent on each possible rating transition. In the case of default, the recovery rate δ_i determines the proportion of the position's principal that is paid back by the obligor.^d

For the nondefault states, the standard implementation of the model is to value positions based on market factors: the risk-free interest rate curve and a spread curve corresponding to the rating state. For this reason, CreditMetrics is commonly referred to as a *mark-to-market model*. Importantly, the mark-to-market approach incorporates a maturity effect into

the model: other things being equal, a downward credit migration will have a greater impact on a long maturity bond than a short one, given the long bond's higher sensitivity (duration) to the spread widening that is assumed to accompany the migration. However, this approach does require relevant spread curves for positions of all possible rating states.

For positions where there is little market information, or where the mark-to-market approach is inconsistent with an institution's accounting scheme, it is possible to utilize policy-driven rather than market-driven valuation. For example, if an institution has a reserves policy whereby loss reserves are determined by credit rating and maturity, then the change in required reserves can serve as a proxy for the loss on a position, contingent on a particular rating move. In this way, the model can still incorporate a maturity effect, even where a mark-to-market approach is not practical.

Risk Factor Dynamics and Obligor Dependence Structure

In the original formulation of CreditMetrics, foreign exchange (FX) rates and interest rate and spread curves are assumed to be deterministic since one focuses on the rating as the main risk driver. In principle, this assumption could be relaxed.

The migration matrix in the CreditMetrics model specifies the rating dynamics of a *single* obligor, but it does not provide any information about the *joint* obligor credit migrations. In order to capture the obligor dependence structure, CreditMetrics borrows ideas from the Merton structural model for firm default, which links default to the obligor asset value falling short of its liabilities. The assumption of CreditMetrics is that the obligor rating transition is caused by changes of the obligor's asset value, or equivalently, the asset value return. The lower this random return, the lower the new rating; if the asset value return drops below a certain threshold, default occurs. Mathematically, this amounts to defining return buckets for each obligor; the thresholds bounding these buckets depend on the initial obligor rating, the transition probabilities, and the return distribution. The rating of an obligor is determined by the bucket its return falls into. Obviously, the bucket probabilities must coincide with the transition probabilities. Models of this type are also called *threshold models*.

More formally, if R_i denotes the asset return of obligor i over $(0, T]$, then the rating at time T is determined by

$$S_i^{\text{new}} = j \iff d_j^{(i)} < R_i \leq d_{j+1}^{(i)} \quad (2)$$

The increasing thresholds $d_j^{(i)}$ are picked such that the resulting migration probabilities coincide with the ones prescribed by the credit migration matrix. Consequently,

$$d_0^{(i)} = -\infty \quad \text{and} \quad d_{K+1}^{(i)} = +\infty$$

$$G_i(d_{j+1}^{(i)}) - G_i(d_j^{(i)}) = \mathbb{P}(S_i^{\text{new}} = j \mid S_i^{\text{init}}) \quad (3)$$

where G_i is the cumulative distribution function of R_i . We illustrate the rating transition mechanism in Figure 1, which shows the return distribution and the thresholds for an obligor with an initial rating 2 in a hypothetical rating system with four nondefault classes.

The dependence between obligor ratings stems from the dependence of the asset returns. CreditMetrics assumes that these returns follow a linear factor model with multivariate normal factors and independent Gaussian innovations. This means that

$$R_i = \alpha_i + \sum_{\ell=1}^p \beta_{i\ell} F_\ell + \sigma_i \epsilon_i \quad (4)$$

where the common factors $\mathbf{F} = (F_1, \dots, F_p)' \sim \mathcal{N}_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ are multivariate Gaussian and the ϵ_i 's are independent and identically distributed (i.i.d.) standard normal variables independent of the factors. The numbers $\beta_{i\ell}$ are also called *factor exposures* or *loadings*, $\sum_{\ell=1}^p \beta_{i\ell} F_\ell$ is the systematic return, σ_i is the volatility of idiosyncratic (or specific) return $\sigma_i \epsilon_i$ of obligor i , and the real parameter α_i is referred to as *alpha*. The dependence between the returns, and consequently the dependence between future ratings, is caused by the exposure of the obligors to the common factors. Usually one normalizes the returns R_i to unit variance; this does not alter the joint distribution of $\mathbf{S}^{\text{new}} = (S_1^{\text{new}}, \dots, S_n^{\text{new}})'$ and leads to adjusted thresholds that are simpler. Not explicitly distinguishing between returns and normalized returns in our notation, equation (4) then reads as

$$R_i = \psi_i(\mathbf{F}) + \sqrt{1 - \text{Var}(\psi_i(\mathbf{F}))} \epsilon_i \sim \mathcal{N}(0, 1) \quad (5)$$

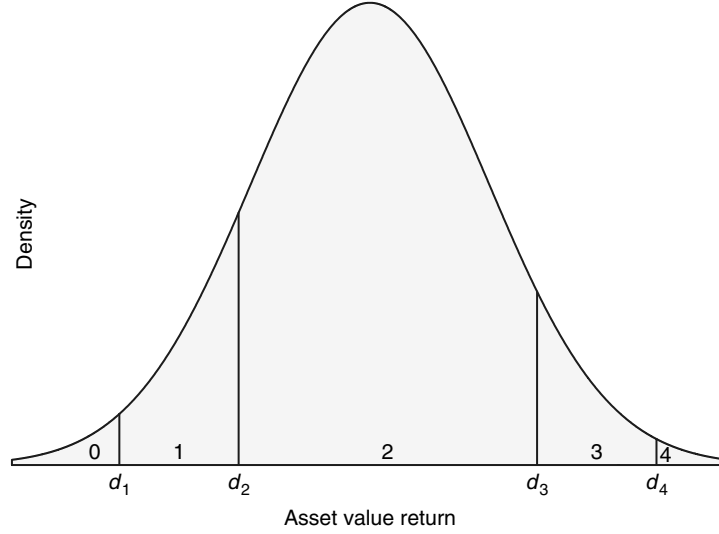

Figure 1 Asset return distribution, thresholds and rating classes

for appropriate affine linear functions ψ_i . The adjusted thresholds are given by

$$d_j^{(i)} = d_j(S_i^{\text{init}}) \quad \text{with} \\ d_j(s) = \Phi^{-1} \left(\sum_{k=0}^{j-1} m_{sk} \right), \quad 0 < j \leq K \quad (6)$$

where Φ is the standard normal distribution function.

As regards the recovery rates δ_i , they are assumed to be independent of each other and of the obligor returns. One stipulates that they are beta-distributed with parameters (a_i, b_i) .

Obligor Dependence Structure from Copulas

As was first recognized by Frey *et al.* [9] (see also [8]), copulas provide an elegant means for describing the obligor dependence structure in credit portfolio models. By virtue of Sklar's theorem, the joint distribution of the random vector $\mathbf{R} = (R_1, \dots, R_n)'$ can be factorized as

$$G(r_1, \dots, r_n) = \mathbb{P}(R_1 \leq r_1, \dots, R_n \leq r_n) \\ = C(G_1(r_1), \dots, G_n(r_n)) \quad (7)$$

where C , the copula associated with $\mathbf{R}$, is the distribution function of a random vector with standard uniform marginal distributions. From standard arguments (*see e.g.*, **Copulas: Estimation; Copulas in Econometrics; or Copulas in Insurance** and references therein),

$$\begin{aligned} \mathbb{P}(S_1^{\text{new}} = s_1, \dots, S_n^{\text{new}} = s_n) \\ &= \mathbb{P}(d_{s_1}^{(1)} < R_1 \leq d_{s_1+1}^{(1)}, \dots, d_{s_n}^{(n)} < R_n \leq d_{s_n+1}^{(n)}) \\ &= \int_{d_{s_1}^{(1)}}^{d_{s_1+1}^{(1)}} \cdots \int_{d_{s_n}^{(n)}}^{d_{s_n+1}^{(n)}} dG(r_1, \dots, r_n) \\ &= \int_{G_1(d_{s_1}^{(1)})}^{G_1(d_{s_1+1}^{(1)})} \cdots \int_{G_n(d_{s_n}^{(n)})}^{G_n(d_{s_n+1}^{(n)})} dC(u_1, \dots, u_n) \end{aligned} \quad (8)$$

Note that the integration limits $G_i(d_{s_i}^{(i)}) = \sum_{k=0}^{s_i-1} m_{s_i^{\text{init}},k}$ do not depend on G_i . This implies that the joint distribution of the ratings vector $\mathbf{S}^{\text{new}}$ is determined by the initial obligor ratings, the credit migration matrix $\mathbf{M}$ and the copula C ; the marginal distributions G_i do not matter.

This result helps to categorize threshold credit portfolio models; models using the same families of copulas can be considered as structurally equivalent. The copula associated with a Gaussian random vector

is called *Gaussian copula* and depends on the correlation matrix only. Since the returns $\mathbf{R}$ are multivariate Gaussian, the original CreditMetrics model [13] is referred to as *having a Gaussian copula*. Replacing the Gaussian copula family by other families gives different models. Frey *et al.* [9] study the CreditMetrics model with Student- t copulas and find that the tail of the loss distribution is considerably fatter as compared with the Gaussian copula with identical correlation parameters.

CreditMetrics as a Mixture Model

We now interpret the CreditMetrics model in a conditional fashion in order to better understand the meaning of the factors $\mathbf{F}$. To this end, we look at the vector of default indicators $\mathbf{D} = (D_1, \dots, D_n)'$, where $D_i = \mathbf{I}_{\{S_i^{\text{new}} = 0\}}$. We denote the default probabilities by $\bar{p}_i = \mathbb{P}(D_i = 1)$. Then conditional on the factors $\mathbf{F}$, the vector $\mathbf{D}$ consists of *independent* Bernoulli random variables with success probabilities

$$\begin{aligned} p_i(\mathbf{F}) &= \mathbb{P}(D_i = 1 \mid \mathbf{F}) \\ &= \Phi \left(\frac{\Phi^{-1}(\bar{p}_i) - \psi_i(\mathbf{F})}{\sqrt{1 - \text{Var}(\psi_i(\mathbf{F}))}} \right) \end{aligned} \quad (9)$$

We deduce that one can simulate $\mathbf{D}$ by first drawing $\mathbf{F}$ from a multivariate Gaussian distribution and then generating independent Bernoulli random variables with success probabilities $p_i(\mathbf{F})$. From this angle, $\mathbf{F}$ represents the state of the economy that determines the obligor default probabilities. The distribution of $\mathbf{D}$, which is obtained from “mixing” the conditional distributions of $\mathbf{D}$ by $\mathbf{F}$, is a so-called Bernoulli mixture:

$$\begin{aligned} &\mathbb{P}(D_1 = d_1, \dots, D_n = d_n) \\ &= \mathbb{E}(\mathbb{P}(D_1 = d_1, \dots, D_n = d_n \mid \mathbf{F})) \\ &= \mathbb{E} \left(\prod_{i=1}^n p_i(\mathbf{F})^{d_i} (1 - p_i(\mathbf{F}))^{1-d_i} \right) \end{aligned} \quad (10)$$

The conditional view offers computational advantages. Finger [6] exploits it for the determination of credit portfolio distributions. Using the Poisson approximation for sums of independent Bernoulli variables, various authors have shown that CreditMetrics is approximated by a Poisson mixture model;

this allows one to make a link to CreditRisk+ (see [3, 8, 11] for details).

Asymptotic Behavior of CreditMetrics

In CreditMetrics, risk measures such as VaR (Value-at-Risk) or ES (expected shortfall) cannot be expressed in terms of simple closed formulas. For their estimation, one has to resort to Monte-Carlo (MC) simulation or other numerical methods (see **Credit Portfolio Simulation**). Although the topic of approximations in credit portfolio models is covered in **Large Pool Approximations; Saddlepoint Approximation**, we provide a brief discussion because the asymptotic results provide important qualitative insights.

Concerning approximation, research has dealt with strong limits of the relative portfolio loss and the tail behavior of the loss distribution when the number of obligors tends to infinity. While the derivation of strong limits consists of straightforward applications of the strong law of large numbers, the analysis of the tail behavior of the loss is more involved. For the tail behavior, we refer to [18] and a recent article by Glasserman *et al.* [10].

We next present the idea of the so-called large pool approximation. To this end, we work in a simplified framework that is adapted to loan portfolios. We assume that recovery rates, spreads, and interest rates are all equal to zero. Every obligor i has an outstanding loan of size e_i . Then the loss in the period $(0, T]$ is given by

$$L_n = \sum_{i=1}^n e_i D_i \quad (11)$$

We define total exposure by $e = \sum_{i=1}^n e_i$ and set $\bar{L}_n = L_n/e$ for the relative loss of the portfolio. We want to verify to which extent the specific risk caused by the obligor-specific returns ϵ_i is diversified away when the number of obligors grows. To this end, we decompose the relative loss into a systematic and an obligor-specific component:

$$\bar{L}_n = \mathbb{E}(\bar{L}_n \mid \mathbf{F}) + \Delta_n \quad (12)$$

It is straightforward to show that obligor-specific variance tends to zero as $n \rightarrow \infty$, provided the

Herfindahl index, which measures exposure concentration, converges to zero:

$$\text{Var}(\Delta_n) \rightarrow 0 \quad \text{if} \quad H_n = \frac{1}{e} \sum_{i=1}^n e_i^2 \rightarrow 0 \quad (13)$$

The stronger property that Δ_n converges almost surely to zero holds true (see e.g. [8] for a proof). This justifies the following approximation for large portfolios with no severe exposure concentration:

$$\bar{L}_n \approx \mathbb{E}(\bar{L}_n | \mathbf{F}) = \frac{1}{e} \sum_{i=1}^n p_i(\mathbf{F}) \quad (14)$$

This means that for n large enough, the relative loss virtually coincides with its systematic component, or in other words, the idiosyncratic risks are diversified away and one is left with systematic risk (caused by $\mathbf{F}$) only. The systematic risk cannot be diversified away other than by hedges that impact $\mathbb{E}(\bar{L}_n | \mathbf{F})$. Despite this positive result, one should be aware that the portfolio R-squared is typically significantly lower than the R-squared in long-only equity portfolios with a similar number of securities. This indicates that in credit portfolios the idiosyncratic risks are comparatively more important than in equity portfolios, or in other words, more securities are necessary to diversify a credit portfolio. This feature is due to the fact that the default correlations $\text{Corr}(D_i, D_{i'})$ are very low (less than 5%) for typical values of asset correlations (10–30%) and default probabilities.^e

The large pool approximation (14) lies at the core of the capital requirement in the Basel II internal ratings-based (IRB) approach. The IRB approach imposes a constant correlation Gaussian one-factor model, that is, $\psi_i(\mathbf{F}) = \sqrt{\rho}\mathbf{F}$ in (5), and $\mathbf{F} \sim \mathcal{N}(0, 1)$ is a latent (unobserved) factor. IRB assumes that the portfolio is infinitely fine-grained, that is, it neglects Δ_n and calculates risk directly from $\mathbb{E}(\bar{L}_n | \mathbf{F})$. Since the latter is the sum of comonotonic^f (or perfectly positive dependent) obligor contributions, portfolio VaR is just the sum of the obligor VaR contributions. For an explanation of the additional multiplicative adjustments for maturities and rules for the choice of ρ_i applied by the IRB approach, we refer to **Internal-ratings-based Approach**, [7, 12].

If the default probabilities in the constant correlation Gaussian one-factor model are constant and

equal to $\bar{p}$, the limit $\mathbb{E}(\bar{L}_n | \mathbf{F})$ is a so-called probit-normal random variable:

$$\bar{L}_n \approx p(\mathbf{F}) = \Phi\left(\frac{\Phi^{-1}(\bar{p}) - \sqrt{\rho}\mathbf{F}}{\sqrt{1-\rho}}\right) \quad (15)$$

This result goes back to [23, 24]. Studying the properties of the probit-normal distribution reveals that the tail behavior of $\bar{L}_n$ is essentially governed by the correlation; the larger the ρ , the thicker the tail of the distribution of $\bar{L}_n$. Along the same lines one can analyze the tails of credit-migration-based models with non-Gaussian copulas, as was done by Lucas *et al.* [18].

Model Estimation

Statistical inference poses a big challenge in CreditMetrics and related models. No estimation method that we know of is truly flawless because assumptions that are difficult to verify are ever involved. As we have seen, the model (2) is fully determined by the credit migration matrix and the matrix of asset correlations. In what follows, we take the existence of a credit migration matrix for granted (*see Rating Transition Matrices*) and restrict our discussion to the estimation of asset correlations. *See also Portfolio Credit Risk: Statistical Methods* for a general discussion of statistical methods for the calibration of credit portfolio models. We distinguish between *direct* and *indirect* approaches. The direct approaches start by estimating the exposures and variances in the factor model (4), typically by regressions against certain predefined factors; the asset correlations are then easily derived. In the indirect approaches, asset correlations are inferred from historical default data.

CreditMetrics uses a direct approach. A major difficulty is that firm asset values cannot be directly observed, even for companies that have publicly traded equity. CreditMetrics circumvents this problem by assuming that asset return correlations are proxied by equity return correlations, or in other words, it regards the R_i 's in equation (4) as equity returns. The CreditMetrics technical document [13] suggests to use MSCI industry and country index returns as explanatory factors. In principle, one could work with any other set of factors. A nice benefit of letting equity returns drive the rating transitions is the

fact that CreditMetrics can be naturally embedded into market risk models of the RiskMetrics^{®g} type because the CreditMetrics risk factors are already part of the RiskMetrics factor universe. This allows the aggregation of credit and market risks in a straightforward fashion.

So far we have explained the case of obligors with publicly traded equity. For private firms, the betas are mostly set by resorting to economic arguments. Often one uses the obligor's country and industry or sector affiliations. Say, a firm has two equally large lines of businesses, which belong to the US Information Technology and US Consumer Discretionary sectors, respectively. Then the betas with respect to the MSCI US Information Technology and MSCI US Consumer Discretionary sector index returns would both be set to 0.5, and all other betas to zero. Another piece to specify is the variance of the idiosyncratic term in equation (4), or equivalently, the R-squared. Here CreditMetrics stipulates that R-squareds obey $R^2 = 1/(1 + A^\gamma \exp(\lambda))$, where A is the book value of the firm's total assets and γ and λ are fixed parameters estimated from a cross-section of traded stocks; we refer to [14] for a critical appraisal of this method. Alternatively, R-squared can be set by the experienced user.

We mention that KMV uses a direct approach as well, but in contrast to CreditMetrics it reconstructs the asset values from the equity price history using the Merton model framework; see [17] for details about this reconstruction and [16] for a description of the structure of the KMV factor model.

The indirect approaches apply statistical inference to time-series of count data of defaults. These methods are constricted by the sparsity of clean data. Since defaults rarely happen and the time-series are short, one creates groups of obligors and assumes that asset correlations in these groups are constant. There exist several studies following an indirect approach. Bluhm *et al.* [1] back out asset correlations in rating classes from standard deviations of historical default rates. De Servigny and Renault [22] infer default correlation from observed joint defaults. Demey *et al.* [4] use maximum-likelihood estimation and reduce the number of parameters by assuming that both asset correlations between and within rating classes are constants. Hamerle and Rösch [15] also apply maximum-likelihood estimation, but advocate the use of lagged macroeconomic variables as additional predictors.

End Notes

^aRiskMetrics and CreditMetrics are registered trademarks of RiskMetrics Group, Inc. and its affiliates.

^bSince the original development of the model, the KMV company was acquired by Moody's, Inc. and is now part of Moody's KMV.

^cMoody's KMV EDF, which we refer to as simply EDF, is a trademark of Moody's KMV. See www.moodyskmv.com.

^dEquivalently, the loss is determined by the loss given default (LGD) specified for the position.

^eThe picture is similar when R-squared is replaced by squared ratios of other risk measures.

^fSee e.g., McNeil *et al.* [19] for formal definition of comonotonicity.

^gSee Mina and Xiaao [21] for an introduction to RiskMetrics.

Structural Default Risk Models

Structural models of default risk for individual firms originate from the seminal work of Merton [25]. Default is linked to the economic fundamentals of the considered firm *via* the assumption that default occurs if the value of the firm's assets, modeled as a geometric Brownian motion, falls below some default threshold (the firm's liabilities) at some future point in time (the maturity of a zero-coupon bond). A significant extension of this methodology was proposed by Black and Cox [7], who continuously test for default. Hence, in their model, the time of default is a first-passage time. Further generalizations address stochastic interest rates, more general assumptions on the default threshold, the definition of the default event, and discontinuous processes as model for the firm's assets [10, 12, 20–22, 34]. On a high level, these innovations aim at making the model-induced term structure of default probabilities flexible enough to allow for a precise fit of the model to observed bond prices and credit default swap (CDS) spreads.

The growing popularity of derivatives on credit portfolios, for example, collateralized debt obligations (CDOs) and n th to default baskets, and advanced demands on risk-management solutions produced a need for portfolio models that simultaneously explain the credit quality of multiple firms. Since corporate defaults in a globalized economy are not independent, a multivariate default model has to explain univariate default probabilities and the dependence among the default events. A natural assumption for a multivariate structural-default model is to introduce dependence by assuming correlated asset values, leading to dependent default events. Zhou [33] motivates this approach by the observation: "The fortunes of individual companies are linked together via industry-specific and/or general economic conditions." The first portfolio model of this class was formulated by Vasicek [31] and can be classified as a multivariate generalization of the work by Merton [25]. This model is discussed in some detail in the section "*The Model of Vasicek*", as it constitutes the basis for most of today's generalizations and is used to assess the regulatory capital for loan portfolios within the Basel II framework.

A major advantage of (multivariate) structural-default models is the appealing economic interpretation of the definition of default. Additionally, comovements of the individual firm-value processes might also be interpreted as being the result of common risk factors. Moreover, modeling the evolution of the firm's values as some multivariate stochastic process naturally implies a dynamic model, which is highly desirable in risk-management and pricing applications. The downside of this class of models is the mathematical challenge of computing the portfolio-loss distribution or even bivariate default correlations. Hence, most of the proposed models rely on simplifying assumptions or can be solved only *via* a Monte Carlo simulation.

Merton-type Models

The Model of Vasicek

In his short memo [31], Vasicek considers a portfolio of n loans with unit nominal and maturity T . Each individual firm-value process is modeled as a geometric Brownian motion defined by the stochastic differential equation:

$$\begin{aligned} dV_t^i &= V_t^i(\gamma^i dt + \sigma^i dW_t^i), \\ V_0^i &> 0, \quad i \in \{1, \dots, n\} \end{aligned} \quad (1)$$

The first simplification, often referred to as *homogeneous portfolio assumption*, is to assume identical default probabilities for all firms. In the current setup, this assumption corresponds to identical parameters $V_0 \equiv V_0^i$, $\sigma \equiv \sigma^i$, and $\gamma \equiv \gamma^i$. Moreover, an identical correlation across all bivariate pairs of Brownian motions W^i and W^j is assumed. Using Itô's formula and replacing the growth rate γ by the risk-free interest rate r , we find

$$V_T^i \stackrel{d}{=} V_0^i \exp((r - 0.5\sigma^2)T + \sigma\sqrt{T}X^i) \quad (2)$$

where $X^i := W_T^i/\sqrt{T}$ follows a standard normal distribution. Given some default threshold $d_T \equiv d_T^i$, one can immediately compute the probability of default at time T , since the distribution of the firm value at time T is known explicitly. Moreover, since default can only happen at maturity, only the distribution of V_T^i is of importance and not the dynamic model leading to it. By scaling the

original default threshold, default can alternatively be expressed in terms of the standard normally distributed variable X^i . More precisely, assuming the default probability of firm i at time T is given by p^i , the default threshold with respect to X^i is $K^i = \Phi^{-1}(p^i)$, where Φ^{-1} is the quantile function of the standard normal distribution.

To incorporate correlation among the companies, one explains X^i by a common market factor M and an idiosyncratic risk factor ϵ^i , that is,

$$X^i \stackrel{d}{=} \sqrt{\rho}M + \sqrt{1-\rho}\epsilon^i, \quad \rho \in (0, 1) \quad (3)$$

where $M, \{\epsilon^i\}_{i=1}^n$ are independent standard normally distributed random variables. Consequently, $\text{Cor}(X^i, X^j) = \rho$ for $i \neq j$, and each X^i is again distributed according to the standard normal law. By conditioning on the common market factor M , the firm's values and default events are independent. The result is the so-called *conditionally independent model*. We denote this conditional default probability by $p^i(M)$ and obtain

$$p^i(m) = \mathbb{P}(X^i < K^i | M = m) = \Phi\left(\frac{K^i - \sqrt{\rho}m}{\sqrt{1-\rho}}\right) \quad (4)$$

Furthermore, all companies are assumed to have identical default probabilities $p \equiv p^i$. Now Ω is defined as the random variable that describes the fraction of defaults in the portfolio up to time t . The distribution of Ω depends on two parameters: the individual default probability p and the correlation ρ . In what follows, this distribution is denoted by $F_{p,\rho}^{(n)}(x) = \mathbb{P}(\Omega \leq x)$. It is crucial that firms are independent given M , since the probability that exactly k firms default can be derived by integrating out the market factor:

$$\mathbb{P}(n\Omega = k) = \int_{-\infty}^{\infty} \mathbb{P}(n\Omega = k | M = m) \times \phi(m) dm \quad (5)$$

$$= \int_{-\infty}^{\infty} \binom{n}{k} p(m)^k (1-p(m))^{n-k} \times \phi(m) dm \quad (6)$$

where ϕ is the density of a standard normal distribution and $k \in \{0, \dots, n\}$. For large portfolios, evaluating the binomial coefficient is numerically critical and

can be avoided by applying the law of large numbers; this approach is called *large portfolio approximation*. The key observation is that $\mathbb{P}(\Omega \leq x | M = m) \rightarrow \mathbf{1}_{\{p(m) \leq x\}}$ for $(n \rightarrow \infty)$. A straightforward calculation, see, for example, [29] for details, establishes

$$F_{p,\rho}^{(n)}(x) \rightarrow F_{p,\rho}^{\infty}(x) := \Phi\left(\frac{\sqrt{1-\rho}\Phi^{-1}(x) - \Phi^{-1}(p)}{\sqrt{\rho}}\right), \quad (n \rightarrow \infty) \quad (7)$$

This approximation is continuous and strictly increasing in x . As it further maps the unit interval onto itself, it is a distribution function, too. It is also worth mentioning that the quality of this approximation is typically good; see [29] for a discussion.

The IRB Approach in Basel II

Vasicek's asymptotic loss distribution or, more precisely, its quantile function

$$K_{p,\rho}(y) := \Phi\left(\frac{\Phi^{-1}(y)\sqrt{\rho} + \Phi^{-1}(p)}{\sqrt{1-\rho}}\right) \quad (8)$$

plays a major role in today's regulatory world. The core of the first pillar of the Basel II accord [4] is the internal rating-based (IRB) approach for calculating capital requirements for loan portfolios. Within this framework, banks classify their loans by asset class and credit quality into homogeneous buckets and use their own internal rating systems to estimate risk characteristics such as loss-given default (LGD), the expected exposure at default (EAD), and the one-year default probability (PD), that is, $PD = p_1$. It is worth mentioning that estimating LGD and PD independently contradicts the empirical observation that recovery rates and default rates are inversely related; see, for example, [2] and [11]. Still, banks are free to choose a certain internal rating system, as long as they can demonstrate its accuracy and meet certain data requirements. In the second step, these credit characteristics are used in the IRB formula to assess the minimum capital requirements for the unexpected loss *via* the factor

$$K_{\text{IRB}} = \text{LGD} \cdot (K_{PD,\rho}(99.9\%) - PD) \cdot MA \quad (9)$$

The risk-weighted assets (RWA) are then obtained by

$$RWA = \frac{K_{IRB} \cdot EAD}{0.08} = 12.5 \cdot K_{IRB} \cdot EAD \quad (10)$$

where 0.08 corresponds to the 8% minimum capital ratio. The very conservative one-year 99.9%-quantile in equation (9) is part of the Basel II accord and might be interpreted as some cushion regarding the underlying simplifications in Vasicek's model. The factor MA is the *maturity adjustment* and calculated *via* (some exceptions apply)

$$MA = \frac{1 + (M - 2.5) \cdot b(PD)}{1 - 1.5 \cdot b(PD)},$$

$$M = \min \left\{ \frac{\sum_t t \cdot CF_t}{\sum_t CF_t}, 5 \right\} \quad (11)$$

and $b(PD) = (0.11852 - 0.05478 \cdot \log PD)^2$, where CF_t denotes the expected cash-flow at time t . M accounts for the fact that loans with longer (shorter) maturity than one year require a higher (lower) capital charge. Finally, the crucial correlation parameter needs to be specified. Basel II uses a convex combination between some lower ρ^l and upper ρ^u correlation whose weights depend on the default probability of the respective loan, that is,

$$\rho = \rho^l a(PD) + \rho^u (1 - a(PD)),$$

$$a(x) = \frac{1 - e^{-50x}}{1 - e^{-50}} \quad (12)$$

For corporate credits, the correlation-adjustment factor

$$SM_{ad}(S) = -0.04 \cdot \left(1 - \frac{\max\{5, S\} - 5}{45} \right) \times \mathbf{1}_{\{S \leq 50\}} \quad (13)$$

is added to ρ for borrowers with reported annual sales $S \leq 50$, measured in millions of Euros. The specific form of $a(x)$ and the adjustment factor $SM_{ad}(S)$ being negative stem from the empirical observation [23] that large firms that bear more systemic risk are more correlated compared to small firms that

are more likely to default due to idiosyncratic reasons. (ρ^l, ρ^u) depend on the type of loan and are specified as (0.12, 0.24) for sovereign, corporate, and bank loans; (0.12, 0.30) for highly volatile commercial real estate loans; $\rho^l = \rho^u = 0.15$ for residential mortgages; $\rho^l = \rho^u = 0.04$ for revolving retail loans such as credit cards; and finally (0.03, 0.16) for other retail exposures, where in this case the weight function $a(x)$ is computed with exponents -35 instead of -50 .

The IRB approach is sometimes criticized for the strong assumptions that are required to derive Vasicek's distribution. However, one should recognize the IRB approach as a compromise that provides a common language for regulators, banks, and investors to communicate and establishes comparable risk estimates across banks. The IRB formula is discussed in depth in [5, 30].

Generalizations Using Other Distributions

It is well known that the model [31] does not yield a satisfactory fit to market quotes of tranches of CDOs. More precisely, an implied correlation smile is present when the model is inverted for the correlation parameter tranche by tranche. Especially tail events with multiple defaults are underrepresented in a Gaussian world, making a precise fit to senior tranches of a CDO impossible. To overcome this shortcoming, a natural assumption is to give up normality in equation (3) and consider other heavier tailed distributions. For the derivation leading to $F_{p,\rho}^\infty$ in equation (7), the stability of the normal distribution under convolutions is essential in equation (3). Hence, natural choices for generalizations are other infinitely divisible distributions, which are connected to Lévy processes; see, for example, [8]. These generalizations add flexibility to the model and can additionally imply a dependence structure with tail dependence, making multiple defaults more likely. Specific models in this spirit include, for example, the NIG model of Kalemánova *et al.* [17], the VG model of Moosbrucker [27], and the BVG model of Baxter [6]. Following [1], we now derive a *large homogeneous portfolio approximation* in a general Lévy framework.

Let $X = \{X_t\}_{t \in [0,1]}$ be a Lévy process (see **Lévy Processes**) with $X_1 \sim H_1$ for some infinitely divisible distribution H_1 . Assume X_1 to be standardized to zero mean and unit variance. Given a correlation

$\rho \in (0, 1)$, define in analogy to equation (3) for independent copies $\{X^i\}_{i=1}^n$ of X the random variables V^i by

$$V^i := X_\rho + X_{1-\rho}^i, \quad i \in \{1, \dots, n\} \quad (14)$$

Here, the common market factor is represented by X_ρ , and the idiosyncratic risk of firm i is captured in $X_{1-\rho}^i$. Using the Lévy properties of X , each V^i is again distributed according to H_1 and $\text{Cor}(V^i, V^j) = \rho$ for $i \neq j$. In what follows, we denote by H_t^{-1} the inverse of the distribution function of X_t . The homogeneous portfolio assumption in the present setup translates to identical univariate default probabilities up to time T , abbreviated as $p \equiv p^i$, identical threshold levels $K_T = H_1^{-1}(p) \equiv K_T^i$, and unit notional of each firm. The probability of exactly k defaults in the portfolio is then again obtained as

$$\mathbb{P}(n\Omega = k) = \int_{-\infty}^{\infty} \mathbb{P}(n\Omega = k | X_\rho = m) dH_\rho(m), \quad k \in \{0, \dots, n\} \quad (15)$$

Similar to Vasicek's model, the conditional distribution of the number of defaults given $X_\rho = m$ is a binomial distribution with n trials and success probability $p(m) = \mathbb{P}(V^i \leq K_T | X_\rho = m) = H_{1-\rho}(K_T - m)$. The large portfolio assumption, that is, letting the number of firms n tend to infinity, then gives

$$F_{p,\rho}^\infty(x) = 1 - H_\rho(H_1^{-1}(p) - H_{1-\rho}^{-1}(x)) \quad (16)$$

as distribution function of the fractional loss in an infinite granular portfolio; see [1] for a complete proof. Let us finally remark that evaluating H_t and H_t^{-1} requires numerical routines for most choices of $X_1 \sim H_1$.

The Model of Willemann

The starting point for Willemann [32] is the univariate jump-diffusion model of Zhou [34]. This model assumes a discontinuous firm-value process of the form

$$\begin{aligned} dV_t &= V_t((\gamma - \lambda v)dt + \sigma dW_t + (\Pi - 1)dN_t), \\ V_0 &> 0 \end{aligned} \quad (17)$$

where N_t is a Poisson process with intensity $\lambda > 0$ and the jumps Π are log-normally distributed with

expected jump size $v = \mathbb{E}[\Pi - 1]$. The advantage of supporting negative jumps on a univariate level is that default events are no longer predictable, which translates to positive short-term credit spreads. Willemann [32] incorporates dependence to the individual firm-value processes by the classical decomposition of each Brownian motion into a market factor and an idiosyncratic component. Moreover, it is assumed that all firm-value processes jump together, that is, all processes are driven by the same Poisson process N_t . Consequently, this construction allows for two layers of correlation: diffusion and jump correlation; the latter being the main innovation of this setup.

The default threshold of firm i is set to $K_t^i = e^{-\phi^i t} K_0^i$ for some positive constants ϕ^i and K_0^i . This declining form is chosen to increase short-term spreads, but might also imply that the fit to individual CDS gets worse with increase in time. To achieve semianalytical results for the portfolio-loss distribution, default is tested on a grid. The advantage of this simplification is that only the distribution of each firm-value process at the grid points is required, instead of functionals as $\inf_{s \in [0, t]} V_s$. Individual default probabilities up to time t can then be computed conditional on the number of jumps up to time t , which is a Poisson-distributed random variable. Since the specific choice of jump-size distribution is compatible to the Brownian motion of the model, this leads to an infinite sum of normally distributed random variables. Moreover, all default events are independent conditional on the market factor and the number of jumps. Hence, the portfolio-loss distribution can be found by integrating out these common factors and using a recursion technique similar to [3, 16]. Willemann [32] demonstrates quite successfully how the model is simultaneously fitted (in seconds) to individual CDS spreads and the tranches of a CDO.

A Remark on Asset and Default Correlation

Modeling asset values as correlated stochastic processes introduces dependence to the resulting default times. Still, this relation is not trivial and deserves some caution, especially when it comes to estimating the model's asset-correlation parameter. We follow [24] in defining the default correlation of two firms (up to time t) as

$$\begin{aligned}\rho_t^D &:= \text{Cor}(\mathbb{1}_{\{\tau^1 \leq t\}}, \mathbb{1}_{\{\tau^2 \leq t\}}) \\ &= \frac{\mathbb{P}(P_t^1, P_t^2) - \mathbb{P}(P_t^1)\mathbb{P}(P_t^2)}{\sqrt{\mathbb{P}(P_t^1)(1 - \mathbb{P}(P_t^1))}\sqrt{\mathbb{P}(P_t^2)(1 - \mathbb{P}(P_t^2))}}\end{aligned}\quad (18)$$

where $P_t^i := \{\tau^i \leq t\}$, $i \in \{1, 2\}$. Most structural-default models share the commonality that evaluating $\mathbb{P}(P_t^1, P_t^2)$, the probability of a joint default of both firms up to time t , is quite difficult; an exception being the case of two companies with Gaussian factors coupled as described in equation (3). This example is, therefore, used to illustrate the nonlinear relation of asset and default correlation. A joint default in this setup corresponds to a simultaneous drop of both factors X^1 and X^2 below their respective default threshold $K^i = \Phi^{-1}(p_t^i)$, $i \in \{1, 2\}$. Since the vector (X^1, X^2) follows a two-dimensional normal distribution with mean vector $(0, 0)$ and the asset-correlation ρ as correlation parameter, we obtain

$$\mathbb{P}(P_t^1, P_t^2) = \Phi_2(K^1, K^2; \rho) \quad (19)$$

which is used to produce Figure 1. This example illustrates that small asset correlations induce only a negligible default correlation.

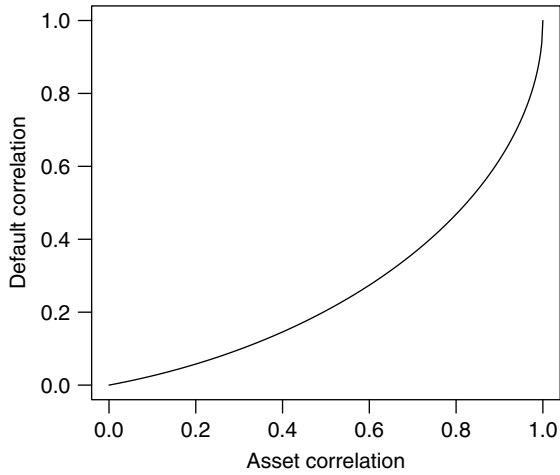

Figure 1 Default correlation ρ_t^D as a function of asset correlation $\rho \in [0, 1]$, with $\mathbb{P}(P_t^1) = \mathbb{P}(P_t^2) = 0.05$ and $t = 1$

Being able to convert default to asset correlations (and *vice versa*) opens the possibility of estimating the model's asset correlation using historical default correlations (and *vice versa*); see, for example, [14]. This approach is relevant since asset values are not directly observable, making an estimation of asset correlations delicate. It is an ongoing debate whether indirectly observed changes in asset values, computed from changes in the respective firm's equity, or observed defaults are the better source of data for the estimation of the model's correlation parameter. In both cases, pointing out the respective limitations is much simpler than providing theoretical evidence for the methodology. Empirically estimating default correlations (based on groups of firms with similar characteristics) requires a large set of observations, since corporate defaults are rare events. This makes the approach vulnerable to structural changes such as new bankruptcy rules. On the other hand, daily equity prices are readily available for most firms. When this latter source of data is used, the difficulty lies in transforming equity to asset returns, see, for example, [9], from which the correlation might be estimated. In addition, one should be aware that equity prices might change for reasons that are not related to credit risk.

First-passage Time Models

The starting point for most multivariate first passage-time models is equation (1). Compared to models in the spirit of the work by Merton [25], the time of default is now defined as suggested in [7], that is,

$$\tau^i := \inf\{t \geq 0 : V_t^i \leq d_t^i\}, \quad i \in \{1, \dots, n\} \quad (20)$$

where d_t^i is the default threshold of firm i at time t . From a modeling perspective, this definition overcomes the unrealistic assumption of default being restricted to maturity. This observation is even more crucial in a portfolio environment when bonds with different maturities are monitored simultaneously. More precisely, a first-passage model naturally induces a dynamic model for the default correlation (since the firm-value processes evolve dynamically over time) and allows the computation of consistent default correlations over any time horizon.

However, the main drawback of this model class is its computational intractability. This stems from

the fact that the joint distribution of the minimum of several firm-value processes is required, which is already a challenging problem for univariate marginals. The following section collects models where analytical results or numerical routines are available to overcome this problem.

The Model of Zhou

Zhou studies [33] a portfolio of two firms whose asset-value processes are modeled as in equation (1) with correlated Brownian motions. The default thresholds are assumed to be exponential, that is, $d_t^i = e^{\lambda^i t} K^i$ for $i \in \{1, 2\}$. The degree of dependence of both firms is measured in terms of their *default correlation* up to time t , that is, as $\text{Cor}(\mathbf{1}_{\{\tau^1 \leq t\}}, \mathbf{1}_{\{\tau^2 \leq t\}})$. The key observation is that results of Rebholz [28] can be applied to give an analytical representation of the default correlation in terms of an infinite sum of indefinite integrals over modified Bessel functions. Sensitivity analysis of the model parameters indicates that the model-induced default correlations for short maturities are close to zero. This observation needs to be considered when portfolio derivatives with short maturities are priced within such a framework.

The Model of Giesecke

Giesecke [13] considers a portfolio of n firms whose value processes evolve according to some vector-valued stochastic process $(V^1, \dots, V^n)$, where default is again defined as in equation (20). The key innovation is to replace the vector of default thresholds by an initially unobservable random vector $(d^1, \dots, d^n)$ whose dependence structure is represented by some copula. It is shown that the model-induced copula of default times is a function of the copula of default thresholds and the copula of the vector of historical lows of the firm-value processes.

On a univariate level, the assumption of an unobservable random threshold overcomes the predictability of individual defaults, which is responsible for vanishing credit spreads for short maturities; see [10] for a related model. Short-term spreads [13] are positive as long as the respective firm-value process is close to its historical low. The consequence of this construction on a portfolio level is also remarkable. Observing a corporate default τ^i reveals the respective default threshold d^i to all investors. This

piece of information allows to update the knowledge on all other default thresholds, leading to *contagious* jumps in credit spreads of the remaining firms. Giesecke [13] also presents an explicit example of two firms with independent value processes modeled as geometric Brownian motions and default thresholds coupled *via* a Clayton copula. While this simplified example illustrates the desired contagion effect of the model, it also highlights the challenge of finding analytic results in a realistic framework.

Models Relying on Monte Carlo Simulations

This section briefly presents two first-passage time models that rely on Monte Carlo simulations for the pricing of CDOs.

The n firm-value processes [15] are defined as in equation (1); the model can therefore be considered as a generalization of Zhou's [33] bivariate model to larger portfolios. The default thresholds are rewritten in terms of the driving Brownian motions. Asset correlation is introduced by n_F risk factors, that is, the Brownian motion of firm i is replaced by

$$dW_t^i := \sum_{j=1}^{n_F} \alpha_{i,j} dF_t^j + \left(1 - \sum_{j=1}^{n_F} \alpha_{i,j}^2\right)^{\frac{1}{2}} dU_t^i, \quad i \in \{1, \dots, n\} \quad (21)$$

where $\alpha_{i,j}$ is the sensitivity of firm i to changes of the risk factor F^j and U^i is the idiosyncratic risk of this firm. All processes F^j and U^i are independent Brownian motions. Hull *et al.* [15] also consider extensions to stochastic correlations, stochastic recovery rates, and stochastic volatilities and compare these in terms of their fitting capability to CDO tranches. An interesting conclusion that also applies to similar first-passage time models is drawn when the model is compared to a copula model. It is argued that the default environment in a copula model is static for the whole life of the model, while the dynamic nature of equation (21) allows to have bad default environments in one year, followed by good environments later. Hence, the use of one or more common risk factors implies a sound economic model for cyclical correlation.

Kiesel and Scherer [18] present another multivariate extension of the work by Zhou [34]. They model the firm-value process of the company i as

the exponential of a jump-diffusion process with two-sided exponentially distributed jumps Y_{ij} , that is,

$$V_t^i = V_0^i \exp(X_t^i),$$

$$X_t^i = \gamma^i t + \sigma^i W_t^i + \sum_{j=1}^{N_t(b^i)} Y_{ij}, \quad V_0^i > 0 \quad (22)$$

where the Brownian motions of different firms are again correlated *via* a factor decomposition. The novelty in their approach is the use of a Poisson process N_t as ticker for jumps in the market that is thinned-out with probability $(1 - b^i)$ to induce jumps in V^i . Consequently, some but not necessarily all firms jump (and possibly default) together. As a result of common jumps, the model allows for default clusters that extend the cyclical correlation induced by common continuous factors. For this choice of jump distribution, the marginals of the model can be calibrated to CDS quotes using the Laplace transform of first-passage times of X^i , which is derived in [19]. The multivariate model is solved *via* a Brownian-bridge Monte Carlo simulation in the spirit of the work by Metwally and Atiya [26].

Conclusion

Structural-default models allow for an appealing interpretation of corporate default: companies operate as long as they have sufficient assets. A clear economic interpretation also holds for the way dependence is introduced to a portfolio of companies: comovements of the firm-value processes might be seen as the result of common risk factors, to which economic interpretations might also apply. This rationale can also be used to empirically estimate the correlation structure of the model from market data. Summarizing, the dependence structure and univariate marginals are simultaneously explained. Moreover, since each company is modeled explicitly, called *bottom-up approach*, it is also possible to price portfolio derivatives and individual risk consistently; a major advantage over *top-down models* that purely focus on the portfolio-loss process. In addition, the current asset level might be mapped to some credit rating, implying a dynamic model of rating changes including default. Finally, the dynamic nature of the modeled firm-value processes translates to a dynamic model for the default correlation and

the portfolio-loss process; a desired property in risk-management solutions and for the pricing of (exotic) credit-portfolio derivatives.

The downside of multivariate structural-default models lies in the difficulty of translating the model to analytical formulas for default correlations and the portfolio-loss distribution. This becomes especially apparent when the simplifying assumption in [31] and its generalizations are reconsidered; the bottom-up nature of structural-default models is entirely given up in order to compute the portfolio-loss distribution in closed form. The price to pay for a more realistic framework typically is a Monte Carlo simulation. However, if such a simulation is efficiently implemented, a realistic dynamic model for a portfolio of credit-risky assets is available.

CreditRisk+

CreditRisk+ is a portfolio credit risk model developed by the bank Credit Suisse, who published the methodology in 1997 [2].

A portfolio credit risk model is a means of estimating the statistical distribution of the aggregate loss from defaults in a portfolio of loans or other credit-risky instruments over a period of time. More generally, changes in credit quality other than default can be considered, but CreditRisk+ in its original form is focused only on default. The most widely used portfolio credit risk models are undoubtedly the so-called structural models, including models based on the Gaussian copula framework (*see Structural Default Risk Models*). CreditRisk+ performs its calculation in a different way to these models, but it is recognized that CreditRisk+ and Gaussian copula models have a similar conceptual basis. A detailed discussion can be found in [4, 7].

Financial institutions use portfolio credit risk models to estimate aggregate credit losses at high percentiles, corresponding to very bad outcomes (often known as the *tail* of the loss distribution). These estimates are then used in setting and allocating economic capital (*see Economic Capital*) and determining portfolio performance measures such as risk-adjusted return on capital (*see Risk-adjusted Return on Capital (RAROC)*).

Portfolio credit risk models have two elements. The first is a set of statistical assumptions about the effect of economic influences on the likelihood of individual borrowers defaulting, and about how much the individual losses might be when they default. The second element is an algorithm for calculating the resulting loss distribution under these assumptions for a specific portfolio. Unlike most portfolio credit risk models, CreditRisk+ calculates the loss distribution using a numerical technique that avoids Monte Carlo simulation. The other distinction of CreditRisk+ is that it was presented as a methodology rather than as a software implementation. Practitioners and institutions have developed their own implementations, leading to a number of significant variants and improvements of the original model. The model has also been used by regulators and central banks: CreditRisk+ played a role in the

early formulation of the Basel accord (see [5]) and has been used by central banks to analyze country-wide panel data on defaults (an example is reported in [1]).

For these reasons, since its introduction in 1997, CreditRisk+ has consistently attracted the interest of practitioners, financial regulators, and academics, who have generated a significant body of literature on the model. An account of CreditRisk+ and its subsequent developments can be found in [6].

The CreditRisk+ Algorithm

The function of CreditRisk+ is to transform data about the creditworthiness of individual borrowers into a portfolio-level assessment of risk. In most portfolio credit risk models, this step requires Monte Carlo simulation (*see Credit Portfolio Simulation*). However, CreditRisk+ avoids simulation by using an efficient numerical algorithm, as outlined below.

The approach confers advantages in terms of speed of computation and enhanced understanding of the drivers of the resulting distribution: many useful statistics, such as the moments of the loss distribution, are given by simple formulae in CreditRisk+, whose relationship to the risk management features of the situation is transparent. On the other hand, owing to its analytic nature, CreditRisk+ is a relatively inflexible portfolio model, and as such has tended to find application where transparency and ease of calculation are more important than flexible parameterization.

To understand the CreditRisk+ calculation, we consider a portfolio containing N loans, where we wish to assess the loss distribution over a one-year time horizon. (The model can be applied to bonds or derivatives counterparties, but the main features of the calculation are the same.) To run CreditRisk+, a number R of economic factors must be chosen. This can be the number of distinct economic influences on the portfolio that are considered to exist (say, the number of geographical regions or industries significantly represented in the portfolio), but it is often assumed in practice that $R = 1$, in which case the model is said to be in “one-factor” mode. CreditRisk+ with one factor gives an assessment of risk that ignores subtle industry or geographic diversification, but can capture the correct overall amount of economic and concentration risk present

in the portfolio, and is sufficient for many purposes. In any event, typically R is much less than N , the number of loans, reflecting the fact that all the significant influences on the portfolio affect many borrowers at once.

For each loan i , where $1 \leq i \leq N$, the model needs the following input data:

1. Long-term average probability of default p_i : This is the probability that the obligor will default over the year, typically estimated from the credit rating (*see Credit Rating*).
2. Loss on default E_i : This is typically estimated as the loan notional less an estimated recovery amount (*see Recovery Rate*).
3. Economic factor loadings: These are given by $\theta_{i,j}$, for $1 \leq j \leq R$, where R is the number of factors introduced above. $\theta_{i,j}$ must be nonnegative numbers satisfying $\sum_{j=1}^R \theta_{i,j} = 1$ for each i .

The factor loadings $\theta_{i,j}$ require some further explanation: they represent the sensitivity of the obligor i to each of the R economic factors assumed to influence the portfolio. In general, determining suitable values for $\theta_{i,j}$ is one of the main difficulties of using CreditRisk+, and analogous difficulties exist for all portfolio models. Note, however, that if R is chosen to be 1 (“one-factor mode” as described above), then we must have $\theta_{i,1} = 1$ for all i , and there is no information requirement. This reflects the fact that one-factor mode ignores the subtle industry or geographic diversification effects in the portfolio, but is, nevertheless, a popular mode of use of the model due to the simpler parameter requirements.

To understand how CreditRisk+ processes this data, let $X_1, \dots, X_R$ be random variables, each with mean $E(X_j) = 1$. The variable X_j represents the economic influence of sector j over the year. In common with most portfolio credit risk models, CreditRisk+ does not incorporate economic prediction. Instead, uncertainty about the economy is reflected by representing economic factors as random variables in this way. CreditRisk+ then assumes that the realized probability of default P_i for loan i is given by the following critical relationship:

$$P_i = p_i(\theta_{i,1}X_1 + \dots + \theta_{i,R}X_R) \quad (1)$$

The realized default probability P_i depends not only on the long-term average probability of default

p_i but also on the random variables $X_1, \dots, X_R$. Note that because $E(X_j) = 1$ and $\sum_{j=1}^R \theta_{i,j} = 1$, we have

$$E(P_i) = p_i(\theta_{i,1} + \dots + \theta_{i,R}) = p_i \quad (2)$$

so that the long-term average default probability (or equivalently, the average of the default probabilities across all states of the economy) is p_i as required. In a particular year, however, P_i will differ from its long-term average. If the borrower i is sensitive to a factor j , (i.e., $\theta_{i,j} > 0$), and if a large value is drawn for X_j , then this represents a poor economy with a negative impact on the obligor i , and we will tend to have $P_i > p_i$, meaning that the obligor i is more likely to default in this particular year than on average. Because the same will be true of other obligors i' with $\theta_{i',j} > 0$, the economic influence represented by factor j can affect a large number of obligors at once. This mechanism incorporates systematic risk, which affects many obligors at once and so cannot be diversified away. The same mechanism in various forms is present in all commonly used portfolio credit risk models.

Two technical assumptions are now made in CreditRisk+:

1. The random variables X_j , $1 \leq j \leq R$, are independent, and each has a Gamma distribution with mean 1 and variance β_j .
2. For each loan i , $1 \leq i \leq N$, the loss given default E_i is a positive integer.

The first assumption is made to facilitate the CreditRisk+ numerical algorithm. In other credit risk models, notably the Gaussian copula models, the variables that play the role of the X_j are assumed to be normally distributed. Although these assumptions seem very different, in fact for many applications they have little effect on the final risk estimate. Assumption (1) can, however, lead to difficulties in parameterizing CreditRisk+.

The second assumption, known as *bucketing* of exposures, also requires some further explanation. Without this assumption, E_i could be any positive amounts, all expressed in units of a common reference currency. An insight of CreditRisk+ is that the precise values of E_i are not critical: E_i can be rounded to whole numbers without significantly affecting the aggregate risk assessment (a simple way of estimating the resulting error is given in Section A4.2 of [2]). The amount of rounding depends on

how E_i are expressed before rounding; for example, it is common to express E_i in millions, so that a loss on default of say 24.35, meaning 24.35 million units of the reference currency, would be rounded to 25.

After bucketing of exposures, the aggregate loss from the portfolio must itself be a whole number (in the example above, this would mean a whole number of millions of the reference currency). The loss distribution can therefore be summarized in terms of its *probability generating function*

$$G(z) = \sum_{n=0}^{\infty} A_n z^n \quad (3)$$

where A_n denotes the probability that the aggregate loss is exactly n . To obtain the loss distribution, we need the numerical value of A_n , for $n = 0$ (corresponding to no loss), $1, 2, \dots$ up to a desired point. For CreditRisk+, with the inputs described above, it can be shown that the probability generating function (3) is given explicitly as

$$G(z) = \prod_{j=1}^R \left(1 - \beta_j \left(\sum_{i=1}^N \theta_{i,j} p_i (z^{E_i} - 1) \right) \right)^{-1/\beta_j} \quad (4)$$

For the derivation of this equation, see, for example [2], Section A9 or [6], Chapter 2. The derivation involves a further approximation, known as the *Poisson approximation*, which can roughly be described as assuming that the default probabilities p_i are small enough that their squares can be neglected. CreditRisk+ then uses an approach related to the so-called Panjer algorithm, which was developed originally for use in actuarial aggregate claim estimation. This relies on the fact that there exist polynomials $P(z)$ and $Q(z)$, whose coefficients can be computed explicitly from the input data *via* equation (4), and which satisfy

$$P(z) \frac{dG(z)}{dz} = Q(z)G(z) \quad (5)$$

Equating the coefficients of z^n on each side of this identity, for each $n \geq 0$, leads finally to a simple *recurrence relationship* between A_n in equation (3). The recurrence relationship expresses the value of A_n for each n , in terms of the earlier coefficients $A_0, \dots, A_{n-1}$. The calculation is started

by calculating A_0 , which is the probability of no loss, by setting $z = 0$ in equation (4) to give the explicit formula

$$A_0 = G(0) = \prod_{j=1}^R \left(1 + \beta_j \left(\sum_{i=1}^N \theta_{i,j} p_i \right) \right)^{-1/\beta_j} \quad (6)$$

and the recurrence relation then allows efficient calculation of A_n up to any desired level. For a complete treatment of this algorithm, see, for example, [6], Chapter 2.

Later Developments of CreditRisk+

Many enhancements to CreditRisk+ have been proposed by various authors (see the introduction to [6] for a discussion of some of the drawbacks of the original model). Developments have fallen into the following broad themes:

1. alternative calculation algorithms, such as saddlepoint approximation, Fourier inversion, and the method of Giese [3];
2. improved capital allocation methods, notably the method of Haaf and Tasche;
3. inclusion of additional risks, such as migration risk and uncertain recovery rates;
4. improved methods for determining inputs, particularly the economic factor loadings $\theta_{i,j}$;
5. application to novel situations such as default probability estimation [8]; and
6. asymptotic formulae, notably the application of the “granularity adjustment” [5].

The reader is also referred to [6] for details on many of these developments.

Large Pool Approximations

The loss distribution of a large credit portfolio can be valued by Monte Carlo methods. This is perhaps the most common approach used by practitioners today. The problem is that Monte Carlo methods are computationally intensive usually taking a significant amount of time to achieve the required accuracy. Therefore, although such methods may lend themselves to pricing and structuring of credit derivatives, they are not appropriate for risk management where simulation and stress testing are required. In fact, nesting a second level of simulation, for pricing, within the risk management simulation represents a performance challenge.

Analytical approximations of losses of large portfolios represent an efficient alternative to Monte Carlo simulation. The following methods can be applied for approximation of a large portfolio's loss distribution: the law of large numbers (LLN), the central limit theorem (CLT), and large deviation theory.

The analytical methods for approximation of credit portfolio losses are usually applied in an additive scheme: the portfolio losses due to default, $\mathcal{L}$, over some fixed time horizon (single step) are represented as

$$\mathcal{L} = \sum_{k=1}^K L_k \quad (1)$$

where L_k is the loss of the k th name in the portfolio and K is the number of names. Application of limit theorems for stochastic process becomes quite natural as K increases. The main technical difficulties are related to dependency of default events and losses of the counterparties.

The analytical methods for portfolio losses are applied in the conditional independence framework pioneered in [14] (see also [7, 9]), based on the assumption that there is a random vector, X , such that conditional on the values of X , the default events are independent. Usually, X is interpreted as a vector of credit drivers describing the state of the economy or a sector of the economy, at the end of the time horizon [3, 5, 8, 12]. In multistep models, X can be a random process describing the dynamics of the credit drivers [7]. In this case, computation of conditional default and migration probabilities requires efficient

numerical quadratures for multidimensional integrals [7]. The multistep portfolio modeling is applied when it is necessary to incorporate the effect of stochastic portfolio exposure, as in the integrated market and credit risk framework in [7].

The notation $\mathbb{P}_x$ denotes the regular conditional probability measure, conditional on $X = x$; $\mathbb{E}_x$ is the corresponding conditional expectation operator.

A general approach to approximate the distribution of the random variable $\mathcal{L}$ can be described as follows:

1. Choose a sufficiently rich family of distributions, F_θ , such that $\theta \mapsto F_\theta$ is a Borel measurable mapping of a vector of parameters θ .
2. Fix a value of the variable, $X = x$ and compute parameters, $\theta(x)$, of the approximating family of distributions, $F_{\theta(x)}(\ell)$, such that the conditional distribution, $\mathbb{P}_x(\mathcal{L} \leq \ell) = \mathbb{P}(\mathcal{L} \leq \ell | X = x)$, is approximated by $F_{\theta(x)}(\ell)$. (It is assumed that $x \mapsto \theta(x)$ is Borel measurable, so that $x \mapsto F_{\theta(x)}(\ell)$ is also measurable, for each ℓ .)
3. Find the unconditional approximating distribution by integration over the distribution, G_X , of the variable X :

$$F^*(\ell) = \int F_{\theta(x)}(\ell) dG_X(x) \quad (2)$$

Law of Large Numbers: Vasicek Approximation

The first key result was obtained in [14, 13] for homogeneous portfolios. The K random variables, L_k , can be expressed as $L_k = N \cdot I_k$, where I_k is the indicator of default of the k th name and N is the constant loss given default. The random variables I_k are identically distributed and their sum, $\nu = \sum_{k=1}^K I_k$, is the number of names in default. The portfolio losses $\mathcal{L} = N\nu$.

The variable, X , in the Vasicek model is latent and has a standard normal distribution, $\Phi(x)$. Conditional on $X = x$, the default events are independent and ν has a binomial distribution with parameter $p(x) = \mathbb{P}(I_k = 1 | X = x)$ so that

$$\int_{-\infty}^{\infty} p(x) d\Phi(x) = \pi_* \quad (3)$$

where π_* is the common unconditional probability of default. The unconditional distribution of ν is then a

generalized binomial distribution and

$$\begin{aligned}\mathbb{P}(\mathcal{L} = mN) &= \mathbb{P}(v = m) \\ &= \binom{K}{m} \int_{-\infty}^{\infty} p^m(x) q^{K-m}(x) d\Phi(x), \\ m &= 0, 1, \dots, K\end{aligned}\quad (4)$$

where $q(x) = 1 - p(x)$.

The following specification^a of the conditional default probability is widely used in the literature [6, 14], and so on.

$$p(x) = \Phi\left(\frac{H - \beta x}{\sigma}\right) \quad \beta^2 + \sigma^2 = 1 \quad (5)$$

where $H = \Phi^{-1}(\pi_*)$, and β is a parameter that determines the correlation between default events.

Consider the ratio $v_K = v/K$ determining the portfolio losses. If $\beta = 0$, then $p(x) \equiv \pi_*$ and

$$\lim_{K \rightarrow \infty} v_K = \pi_* \quad \text{almost surely} \quad (6)$$

in accordance with the strong law of large numbers. If $\beta \neq 0$ the limit in equation (6) is in distribution, to a random variable with the same distribution as $\xi = p(X)$. Thus, one obtains

$$\lim_{K \rightarrow \infty} \mathbb{P}(v_K \leq \ell) = \Phi\left(\frac{\sigma \Phi^{-1}(\ell) - H}{\beta}\right), \quad 0 \leq \ell \leq 1 \quad (7)$$

It follows from equation (7) that the quantile approximation, ℓ_q^* , corresponding to the probability q , is

$$\ell_q^* = N \Phi\left(\frac{\beta \Phi^{-1}(q) + H}{\sigma}\right) \quad (8)$$

In terms of the general approach, one has $\theta = \mu$ with $F_\theta(\ell) = \mathbb{1}_{[\mu, \infty)}(\ell)$ and $\theta(x) \equiv \mu(x) = KNp(x)$.

Central Limit Theorem

The heterogeneous case is treated at the outset, as it is no more difficult than the homogeneous case, which is described as a special case at the end. Once again, X is univariate and latent. Denote by N_k , the loss

given default of the k th name in the portfolio, and by $p_k(x)$, the conditional default probability of the k th name. Then the conditional mean, $\mu(x)$, and the conditional variance, $\sigma^2(x)$, of the portfolio losses are

$$\begin{aligned}\mu(x) &= \sum_{k=1}^K N_k p_k(x), \\ \sigma^2(x) &= \sum_{k=1}^K N_k^2 p_k(x) \cdot (1 - p_k(x))\end{aligned} \quad (9)$$

Under mild conditions on the notionals, N_k (which are vacuous in the homogeneous case), the conditional distribution of the portfolio losses satisfies

$$\mathbb{P}_x\left(\frac{\mathcal{L} - \mu(x)}{\sigma(x)} \leq \ell\right) \rightarrow \Phi(\ell) \quad \text{as } K \rightarrow \infty \quad (10)$$

Let a probability, q , $0 < q < 1$, be fixed and consider the equation

$$q = \mathbb{P}(\mathcal{L} \leq \ell_q) \quad (11)$$

for the quantile of the distribution of the random variable $\mathcal{L}$. One has

$$\begin{aligned}\mathbb{P}(\mathcal{L} \leq \ell_q) &= \int_{-\infty}^{\infty} \mathbb{P}_x(\mathcal{L} \leq \ell_q) d\Phi(x) \\ &\doteq \int_{-\infty}^{\infty} \Phi\left(\frac{\ell_q - \mu(x)}{\sigma(x)}\right) d\Phi(x)\end{aligned} \quad (12)$$

Therefore the quantile approximation, ℓ_q^* , is the solution of the equation

$$q = \int_{-\infty}^{\infty} \Phi\left(\frac{\ell_q^* - \mu(x)}{\sigma(x)}\right) d\Phi(x) \quad (13)$$

In terms of the general approach, one has $\theta = (\mu, \sigma)$ with $F_\theta(\ell) = \Phi\left(\frac{\ell - \mu}{\sigma}\right)$ and $\theta(x) = (\mu(x), \sigma(x))$.

In the case of a homogeneous portfolio, considered in [14, 13] one has the simplifications

$$\mu(x) = KNp(x) \quad \sigma^2(x) = KN^2(p(x) - p^2(x)) \quad (14)$$

The normal approximation is just the classical central limit theorem (CLT). The equation for the quantile approximation simplifies to

$$q = \int_{-\infty}^{\infty} \Phi \left(\frac{\ell_q^*/N - Kp(x)}{\sqrt{Kp(x)(1-p(x))}} \right) d\Phi(x) \quad (15)$$

Generalized Poisson Approximation

Consider a homogeneous portfolio, for which the number, K , of obligors is moderately large but not very large. If also the conditional mean number of default events in the portfolio, $K \cdot p(x)$, takes moderate values, the conditional distribution of v might be better approximated by a Poisson distribution

$$\mathbb{P}_x(v = m) = \exp(-\lambda(x)) \frac{\lambda^m(x)}{m!}, \quad m = 0, 1, 2, \dots \quad (16)$$

than by a normal distribution, where $\lambda(x) = Kp(x)$. In this case, the (unconditional) portfolio losses can be approximated by the generalized Poisson distribution: for moderately large K ,

$$\mathbb{P}(\mathcal{L} = mN) = \int e^{-\lambda(x)} \frac{\lambda^m(x)}{m!} dG_X(x), \quad m = 0, 1, 2, \dots \quad (17)$$

In terms of the general approach, one has F_θ being the Poisson distribution function with mean θ and $\theta(x) = \lambda(x)$.

In particular, for the quantile approximation, one obtains

$$q = \int \sum_{m=0}^{\ell_q^*/N} e^{-\lambda(x)} \frac{\lambda^m(x)}{m!} dG_X(x) \quad (18)$$

Compound Poisson Approximation

In order to extend the result of the previous section to heterogeneous portfolios, one needs to consider compound Poisson distributed random variables. The compound Poisson distribution is a well known approximation in insurance models [11]. In risk management of credit derivatives, the approach

was used in [2] and [6] for synthetic collateralized debt obligation (CDO) pricing. The same approach is applicable for approximation of portfolio losses.

In the case of a heterogeneous portfolio, it is not sufficient to approximate the distribution of the number of losses suffered. One must keep track of who defaults or at least the sizes of the individual potential losses because, given only the number of defaults, one cannot infer the losses incurred. To see how this added complexity is handled and how the compound Poisson distribution arises quite naturally, the simplest heterogeneous case is analyzed first; namely, when there are only two distinct recovery-adjusted notional values among the obligors in the portfolio.

Denote by $N_{(1)}$ and $N_{(2)}$, the two distinct values of the recovery-adjusted notionals in the pool. The portfolio then divides into two groups: one with obligors having the common recovery-adjusted notional equaling $N_{(1)}$; the other having common recovery-adjusted notional equaling $N_{(2)}$. Denote the number of defaults in each of the two groups, by v_1 and v_2 , respectively. Conditionally, their distributions are independent and can be approximated by a Poisson distribution with conditional mean $\lambda_i(x) = \sum_{k: N_k = N_{(i)}} p_k(x)$, $i = 1, 2$, provided both group sizes are moderately large. (This assumption on the group sizes, is only being made in the context of this example.) The total number of defaults in the portfolio, $v = v_1 + v_2$, is conditionally Poisson with conditional mean $\lambda(x) = \lambda_1(x) + \lambda_2(x)$. The total portfolio loss is the sum of the losses of the first and second groups:

$$\mathcal{L} = v_1 N_{(1)} + v_2 N_{(2)} \quad (19)$$

As a positive linear combination of conditionally independent Poisson random variables, $\mathcal{L}$ is conditionally a compound Poisson random variable with the same distribution as that of

$$\tilde{\mathcal{L}} := \sum_{j=1}^v \mathcal{N}^{(j)} \quad (20)$$

where $\mathcal{N}^{(j)}$ is a conditionally independent and identically distributed (i.i.d.) sequence of random variables, each taking two values, $N_{(1)}$ and $N_{(2)}$, with corresponding conditional probabilities $\frac{\lambda_1(x)}{\lambda(x)}$ and $\frac{\lambda_2(x)}{\lambda(x)}$ and conditionally independent of v . (This is an elementary

calculation using the conditional characteristic functions of $\mathcal{L}$ and $\tilde{\mathcal{L}}$.) More formally, the conditional distribution of $\mathcal{N}^{(j)}$ is

$$f(N; x) \equiv \mathbb{P}_x(\mathcal{N}^{(j)} = N) = \begin{cases} \frac{\lambda_1(x)}{\lambda(x)}, & N = N_{(1)} \\ \frac{\lambda_2(x)}{\lambda(x)}, & N = N_{(2)} \end{cases} \quad (21)$$

In the general case where the recovery-adjusted notionals take more than two values, the conditional distribution of the random variable, $\mathcal{N}^{(j)}$, is

$$f(N; x) = \sum_{k: N_k = N} p_k(x) / \lambda(x) \quad (22)$$

where $\lambda(x) = \sum_{k=1}^K p_k(x)$ and N represents a possible individual loss.

In the special case where p_k does not depend on k , f is simply the relative frequency of the notional values and does not depend on x :

$$f(N) = [\#k \in \{1, 2, \dots, K\} : N_k = N] / K \quad (23)$$

In general, the function $f(N; x)$ is a probability mass function with respect to N , which approximates the conditional probability that the portfolio loss is of size N , given that there has been only one default.

More generally, it can be shown that

$$\mathbb{P}_x(\mathcal{L} = N | v = m) \approx f^{*m}(N; x) \quad (24)$$

where f^{*m} denotes the m -fold convolution of f with itself, as a probability mass function (for notational convenience, $f^{*1} \equiv f$ and $f^{*0}(N; x) = 1$ if and only if $N = 0$). Given that there have been exactly m defaults, the pool loss amounts to a sum of m notional amounts but, as one does not know who defaulted, in the heterogeneous case there is still some randomness left; that randomness is captured (approximately) by f^{*m} .

Assuming that a monetary unit has been chosen and that all recovery-adjusted notionals are expressed as integers—that is, integer multiples of the monetary unit—one has the following result [6]:

Theorem 1 *In the limiting case of a large portfolio (K large), the following approximate equality holds in distribution under $\mathbb{P}_x$ (i.e., conditional on $X = x$):*

for fixed $i = 1, 2, \dots, n$,

$$\mathcal{L} \stackrel{\mathcal{D}}{\approx} \sum_{m=1}^v \mathcal{N}^{(m)} \quad (25)$$

where $(\mathcal{N}^{(m)})_{m=1}^K$ is an i.i.d. sequence of random variables with common probability mass function f and independent of v , the number of defaults in the pool, which is approximately Poisson distributed under $\mathbb{P}_x$

$$v \stackrel{\mathcal{D}}{\approx} \text{Pois}(\lambda(x)) \quad (26)$$

More precisely,

$$\begin{aligned} \max_N \left| \mathbb{P}_x(\mathcal{L} = N) - \mathbb{P}_x\left(\sum_{m=1}^v \mathcal{N}^{(m)} = N\right) \right| \\ = \mathcal{O}\left(\sum_{k=1}^K (p_k(x))^2\right) \end{aligned} \quad (27)$$

For the unconditional loss distribution,

$$\mathbb{P}(\mathcal{L} \leq \ell) = \int \sum_{N \leq \ell} \sum_{m=0}^{\infty} f^{*m}(N; x) \frac{e^{-\lambda(x)} \lambda^m(x)}{m!} dG_X(x) \quad (28)$$

In terms of the general approach, one has F_θ being the compound Poisson distribution function with parameter $\theta = (\theta_1, \theta_2, \dots, \theta_K) \in [0, 1]^K$ and $\theta(x) = (p_1(x), p_2(x), \dots, p_K(x))$; F_θ is defined as

$$F_\theta = \sum_{N \leq \ell} \sum_{m=0}^{\infty} f^{*m}(N) \frac{e^{-\lambda} \lambda^m}{m!} \quad (29)$$

where $\lambda := \sum_{k=1}^K \theta_k$, $f(N) := \lambda^{-1} \sum_{k: N_k = N} \theta_k$. In practice, the convolutions, would be calculated recursively using the fast Fourier transform.

Large Deviations

Approximations based on large deviation theory usually lead to exponential approximations of the tail of the conditional portfolio loss distribution. These approximations are derived using the saddlepoint

method for the characteristic function of the portfolio losses,

$$\begin{aligned}\Psi_{\mathcal{L}}(s) &= \mathbb{E}[\exp(is\mathcal{L})] \\ &= \int \prod_{k=1}^K (1 - p_k(x) + p_k(x)e^{isN_k}) dG_X(x)\end{aligned}\quad (30)$$

The technical details can be found in [1] (*see also Saddlepoint Approximation*).

Other Methods

There are some methods of approximation that deal only with quantiles of the loss distribution directly, focusing on quantiles with high quantile probability, which is the case of interest for credit risk. The large deviation approximations are examples of such methods.

Another one of these methods is due to Pykhtin [12] who, building on the work of Martin and Wilde [10], adapted the tools of an earlier investigation [4] in market-risk sensitivity to position sizes, to the credit risk setting. Note that this method is a direct, analytical approximation to the quantile of the *unconditional* loss distribution using an approximate model, unlike the other semianalytic methods described so far, which calculate the quantile by making analytical approximations to the conditional loss distribution (conditional on a systemic credit scenario). It is also worth noting that the result is in closed form, a qualitative description of which is given here.

Pykhtin's approach can be described at a high level as follows. It consists of a three-stage series of approximations:

1. A single-factor model, which is an approximation based on an LLN type of loss function; that is, it is a Vasicek type of model.
 - a) The single factor is built as a weighted sum of the portfolio's counterparties' credit drivers.
 - b) The weights are chosen to maximize the single factor's correlation with the drivers.
 - c) The weights use the counterparties' loss characteristics such as default probabilities and losses given default.
2. An analytic adjustment (approximation) to a full multifactor model that is still based on an LLN type of loss function. This adjustment is called a *multifactor* adjustment.
3. An analytic adjustment, bridging the LLN-type loss function of the second stage to the usual Merton-type one with full specific risk. This adjustment is called a *granularity* adjustment.

The reason behind the terminology for the two adjustments, is that for a single-factor model, the multifactor adjustment vanishes, whereas for an infinitely granular portfolio (i.e., a very large, homogeneous one), the granularity adjustment vanishes.

The approximations, in both the second and third stages, are based on a single formula for quantile approximation, due originally to Gouriéroux *et al.* [4]. The formula is a second-order Taylor expansion, for the quantile, in a small parameter that is used to express the full loss model as a perturbation of the single-factor model. The first-order Taylor coefficient is the difference between the single-factor (conditional) loss and the conditional expected loss of the full model, conditional on the single factor. The single factor is constructed so that the first-order Taylor term vanishes.

The second-order Taylor coefficient is related to the conditional variance of the full loss, conditional on the single factor. The well-known conditional variance decomposition from statistics is used to split the Taylor coefficient into two terms, which are the approximations in the second and third stages.

The end result for the entire adjustment to the single-factor quantile, is expressed as a sum of four quadratic forms in the recovery-adjusted exposures, with coefficients involving the bivariate and univariate normal cumulative distribution functions, evaluated in terms of the input statistical parameters of the model. The result is thus in closed form. The reader is referred to [12] for the quantitative details of the construction, the formulae for the terms in the quantile approximation, and a study of the scope of applicability of the method.

End Notes

^aThis specification is a partial case of the famous Gaussian copula model [9].

Saddlepoint Approximation

The classical method known variously as the *saddlepoint approximation*, the *method of steepest descents*, the *method of stationary phase*, or the *Laplace method*, applies to contour integrals that can be written in the form

$$I(s) = \int_{\mathcal{C}} e^{sf(\zeta)} d\zeta \quad (1)$$

where f , an analytic function, has a real part that goes to minus infinity at both ends of the contour $\mathcal{C}$. The fundamental idea is that the value of the integral when $s > 0$ is large should be dominated by contributions from the neighborhoods of points where the real part of f has a saddlepoint. Early use was made of the method by Debye to produce asymptotics of Bessel functions, as reviewed in, for example, [8]. Daniels [3] wrote a definitive work on the saddlepoint approximation in statistics. Later, these ideas evolved into the theory of large deviations, initiated by Varadhan in [7], which seeks to determine rigorous asymptotics for the probability of rare events.

If we write $\zeta = x + iy$, elementary complex analysis implies that the surface over the (x, y) plane with graph $\Re f$ has zero mean curvature, so any critical point ζ^* (a point where $f' = 0$) will be a saddlepoint of the modulus $|e^{sf(\zeta)}|$. The level curves of $\Re f$ and $\Im f$ form families of orthogonal trajectories: the curves of steepest descent of $\Re f$ are the level curves of $\Im f$, and *vice versa*. Thus the curve of steepest descent of the function $\Re f$ through ζ^* is also a curve on which $\Im f$ is constant. In other words, it is a curve of “stationary phase”. On such a curve, the modulus of $e^{sf(\zeta)}$ will have a sharp maximum at ζ^* . If the contour $\mathcal{C}$ can be deformed to follow the curve of steepest descent through a unique critical point ζ^* , and the modulus of $e^{sf(\zeta)}$ is negligible elsewhere, the dominant contribution to the integral for large s can be computed by a local computation in the neighborhood of ζ^* . In more complex applications, several critical points may need to be accounted for.

The tangent line to the steepest descent curve at ζ^* can be parameterized by $w \in \mathbb{R}$ by the equation

$$(sf^{(2)}(\zeta^*))^{1/2}(\zeta - \zeta^*) = iw \quad (2)$$

(care is needed here to select the correct sign of the complex square root), and on this line, the Taylor expansion of f about ζ^* implies

$$f(z) = f(\zeta^*) + \sum_{n \geq 2} \frac{1}{n!} f^{(n)}(\zeta^*) \left(\frac{iw}{s(f^{(2)}(\zeta^*))^{1/2}} \right)^n \quad (3)$$

One can write the integrand in the form

$$\begin{aligned} e^{sf(z)} &\sim e^{sf(\zeta^*) - w^2/2} \left[1 - is^{-1/2} \frac{f^{(3)}(\zeta^*)}{3!(f^{(2)}(\zeta^*))^{3/2}} w^3 \right. \\ &\quad \left. + s^{-1} \left(\frac{f^{(4)}(\zeta^*)}{4!(f^{(2)}(\zeta^*))^2} w^4 \right. \right. \\ &\quad \left. \left. - \frac{(f^{(3)}(\zeta^*))^2}{2!(3!)^2(f^{(2)}(\zeta^*))^3} w^6 \right) + \dots \right] \quad (4) \end{aligned}$$

Now approximating the integral over $\mathcal{C}$ by the integral over the tangent line parameterized by w leads to a series of Gaussian integrals, each of which can be computed explicitly. The terms with an odd power of w all vanish, leading to the result

$$\begin{aligned} I(s) &\sim i \left(\frac{2\pi}{sf^{(2)}(\zeta^*)} \right)^{1/2} e^{sf(\zeta^*)} \\ &\quad \times \left[1 + s^{-1} \left(\frac{3f^{(4)}(\zeta^*)}{4!(f^{(2)}(\zeta^*))^2} \right. \right. \\ &\quad \left. \left. - \frac{5 \cdot 3 \cdot (f^{(3)}(\zeta^*))^2}{2!(3!)^2(f^{(2)}(\zeta^*))^3} \right) + \dots \right] \quad (5) \end{aligned}$$

Daniels’ Application to Statistics

Daniels [3] presented an asymptotic expansion for the probability density function (pdf) $f_n(x)$ of the mean $\bar{X}_n$ of n i.i.d. copies of a continuous random variable X with cumulative probability function $F(x)$ and pdf $f(x) = F'(x)$. Assuming that the moment generating function

$$M(\tau) = e^{\Psi(\tau)} = \int_{-\infty}^{\infty} e^{\tau x} f(x) dx \quad (6)$$

is finite for τ in an open interval $(-c_1, c_2)$ containing the origin, the Fourier inversion theorem implies that

$$f_n(x) = \frac{n}{2\pi i} \int_{\alpha - i\infty}^{\alpha + i\infty} e^{n(\Psi(\tau) - \tau x)} d\tau \quad (7)$$

for any real $\alpha \in (-c_1, c_2)$. This integral is now amenable to a saddlepoint treatment as follows.

For each x in the support of f , one can show that the saddlepoint condition

$$\Psi'(\tau) - x = 0 \quad (8)$$

has a unique real solution $\tau^* = \tau^*(x)$. One now evaluates the integral given by equation (7) with $\alpha = \tau^*$, and uses Taylor expansion and the substitution $w = -i\sqrt{n\Psi''(\tau^*)}(\tau - \tau^*)$ to write

$$\begin{aligned} f_n(x) &\sim \frac{\sqrt{n}}{2\pi\sqrt{\Psi''(\tau^*)}} \int_{-\infty}^{\infty} e^{n(\Psi(\tau^*) - \tau^*x) - w^2/2} \\ &\times \left[1 + in^{-1/2}(\Psi''(\tau^*))^{-3/2}\Psi^{(3)}(\tau^*)w^3/3! \right. \\ &\left. + n^{-1}(\Psi''(\tau^*))^{-2}\Psi^{(4)}(\tau^*)w^4/4! + \dots \right] dw \end{aligned} \quad (9)$$

Each term in this expansion is a Gaussian integral that can be evaluated in closed form. The odd terms all vanish, leaving an expansion in powers of n^{-1} :

$$\begin{aligned} f_n(x) &\sim g_n(x) \left[1 + n^{-1} \left(\frac{\Psi^{(4)}(\tau^*)}{8(\Psi''(\tau^*))^2} \right. \right. \\ &\left. \left. - \frac{5(\Psi^{(3)}(\tau^*))^2}{24(\Psi''(\tau^*))^3} \right) + O(n^{-2}) \right] \end{aligned} \quad (10)$$

where the leading term (called the *saddlepoint approximation*) is given by

$$g_n(x) = \left(\frac{n}{2\pi\Psi''(\tau^*)} \right)^{1/2} e^{n(\Psi(\tau^*) - \tau^*x)} \quad (11)$$

The function $I(x) = \sup_{\tau} \tau x - \Psi(\tau) = \tau^*x - \Psi(\tau^*)$ that appears in this expression is the Legendre transform of the cumulant generating function Ψ , and is known as the *rate function* or *Cramér function* of the random variable X . The *large deviation principle*

$$\lim_{n \rightarrow \infty} \frac{1}{n} \log P(\bar{X}_n > x) = -I(x) \quad \text{for } x > E[X] \quad (12)$$

holds for very general X . Another observation is that the Edgeworth expansion of statistics comes out in a similar way, but takes 0 instead of τ^* as the center of the Taylor expansion.

One can show, using a lemma due to Watson [8], that equation (10) is an *asymptotic expansion*,

which means roughly that when truncated at any order of n^{-1} , the remainder is of the same magnitude as the first omitted term. A more precise statement of the magnitude of the remainder is difficult to establish: the lack of a general error analysis is an acknowledged deficiency of the saddlepoint method.

Applications to Portfolio Credit Risk

The problem of portfolio credit risk measures and the problem of evaluating arbitrage-free pricing of *collateralized debt obligations* (CDOs) both boil down to computation of the probability distribution of the portfolio loss at a set of times, and can be amenable to a saddlepoint treatment. To illustrate this fact, we consider a simple portfolio of credit risky instruments (e.g., corporate loans or credit default swaps), and investigate the properties of the losses caused by default of the obligors. Let $(\Omega, \mathcal{F}, \mathcal{F}_t, P)$ be a filtered probability space that contains all of the random elements: P may be either the physical or the risk-neutral probability measure. The portfolio is defined by the following basic quantities:

- M reference obligors with notional amounts N_j , $j = 1, 2, \dots, M$;
- the default time τ_j of the j th credit, an $\mathcal{F}_t$ stopping time;
- the fractional recovery R_j after default of the j th obligor;
- the loss $l_j = (1 - R_j)N_j/N$ caused by default of the j th obligor as a fraction of the total notional $N = \sum_j N_j$;
- the cumulative portfolio loss $L(t) = \sum_j l_j I(\tau_j \leq t)$ up to time t as a fraction of the total notional.

For simplicity, we make the following assumptions:

1. The discount factor is $v(t) = e^{-rt}$ for a constant interest rate $r \geq 0$.
2. The fractional recovery values R_j and hence l_j are deterministic constants.
3. There is a sub σ -algebra $\mathcal{H} \subset \mathcal{F}$ generated by a d -dimensional random variable Y , the “condition”, such that the default times τ_j are mutually conditionally independent under $\mathcal{H}$. The marginal distribution of Y is denoted by P_Y and has pdf $\rho_Y(y)$, $y \in \mathbb{R}^d$.

The most important consequence of these assumptions is that, conditioned on $\mathcal{H}$, the fractional loss $L(t)$ is a sum of independent (but not identical) Bernoulli random variables. For fixed values of the time t and conditioning random variable Y , we note that $\hat{L} := L(t)|_Y \sim \sum_j l_j X_j$ where $X_j \sim \text{Bern}(p_j(t, y))$, $p_j = \text{Prob}(\tau_j \leq t | Y = y)$. The following functions are associated with the random variable $\hat{L}$:

1. the pdf $\rho(x) := F^{(-1)}(x)$ (in our simple example, it is a sum of delta functions supported on the interval $[0, 1]$);
2. the cumulative distribution function (CDF) $F^{(0)}(x) = E[I(\hat{L} \leq x)]$;
3. the higher conditional moment functions $F^{(m)}(x) = (m!)^{-1} E[(x - \hat{L})^+{}^m]$, $m = 1, 2, \dots$;
4. the cumulant generating function (CGF) $\Psi(u) = \log(E[e^{u\hat{L}}])$.

When we need to make explicit the dependence on t, y we write $F^{(m)}(x|t, y)$. The unconditional versions of these functions are given by

$$F^{(m)}(x|t) = E[F^{(m)}(x|t, Y)] = \int_{\mathbb{R}} F^{(m)}(x|t, y) \times \rho_Y(dy), \quad m = -1, 0, \dots \quad (13)$$

According to these definitions, for all $m = 0, 1, \dots$ we have the integration formula

$$F^{(m)}(x) = \int_0^x F^{(m-1)}(z) dz \quad (14)$$

Credit Risk Measures

In risk management, the key quantities that determine the economic capital requirement for such a credit risky portfolio are the *Value at Risk* (VaR) and *Conditional Value at Risk* (CVaR) for a fixed time horizon T and a fixed confidence level $\alpha < 1$. These are defined as follows:

$$\text{VaR}_\alpha(L_T) = \inf\{x | F^{(0)}(x|T) > \alpha\} \quad (15)$$

$$\begin{aligned} \text{CVaR}_\alpha(L_T) &= \frac{E[(L_T - x)^+]}{1 - \alpha} \\ &= \frac{F^{(1)}(x|T) + E[L_T] - x}{1 - \alpha} \end{aligned} \quad (16)$$

Here, we need to take P to be the physical measure.

CDO Pricing

CDOs are portfolio credit swaps that can be schematically decomposed into two types of basic contingent claims whose cash flows depend on the portfolio loss L_t . These cash flows are analogous to insurance and premium payments paid periodically (typically, quarterly) on dates t_k , $k = 1, \dots, K$, to cover default losses within a “tranche” that occurred during that period.

The writer (the *insurer*) of one unit of a default leg for a tranche with attachment levels $0 \leq a < b \leq 1$ pays the holder (the *buyer of insurance*) at each date t_k all default losses within the interval $[a, b]$ that occurred over $[t_{k-1}, t_k]$. The time 0 arbitrage price of such a contract is

$$W_{a,b} = \sum_k e^{-rt_k} E[(b - L_{t_k})^+ - (b - L_{t_{k-1}})^+ - (a - L_{t_k})^+ + (a - L_{t_{k-1}})^+] \quad (17)$$

where E is now the expectation with respect to some risk-neutral measure. The writer of one unit of a premium leg for a tranche with attachment levels $a < b$ (the insured) pays the holder (the insurer) on each date t_k an amount jointly proportional to the year fraction $t_k - t_{k-1}$ and the amount remaining in the tranche. We ignore a possible “accrual term” that account for defaults between payment dates. The time 0 arbitrage price of such a contract is

$$V_{a,b} = \sum_k e^{-rt_k} (t_k - t_{k-1}) E[(b - L_{t_k})^+ - (a - L_{t_k})^+] \quad (18)$$

The *CDO rate* $s_{a,b}$ for this contract at time 0 is the number of units of the premium leg that has the same value as one unit of the default leg, that is, $s_{a,b} = W_{a,b}/V_{a,b}$.

Saddlepoint Approximations for $F^{(m)}$

We see that the credit risk management problem and the CDO pricing problem both boil down to finding an efficient method to compute $E[F^{(m)}(x|t, y)]$ for $m = 0, 1$ and a large but finite set of values (x, t, y) . For the conditional loss $\hat{L} = L_t|Y = y$, the CGF is

explicit

$$\Psi(u) = \sum_{j=1}^M \log[1 - p_j + p_j e^{u l_j}] \quad (19)$$

We suppose that the conditional default probabilities $p_j = p_j(t, y)$ are known. A number of different strategies can be used to compute this distribution accurately:

1. In the fully homogeneous case when $p_j = p, l_j = l$, the distribution is binomial.
2. When $l_j = l$, but p_j are variable (the homogeneous notional case), these probabilities can be computed highly efficiently by a recursive algorithm in [1, 5].
3. When both l_j, p_j are variable, it has been noted in [2, 4, 6, 9] that a saddlepoint treatment of these problems offer superior performance over a naive Edgeworth expansion.

We now consider the fully nonhomogeneous case and begin by using the Laplace inversion theorem to write

$$\rho(x) = F^{(-1)}(x) = \frac{1}{2\pi} \int_{\alpha-i\infty}^{\alpha+i\infty} e^{\Psi(\tau)-\tau x} d\tau \quad (20)$$

Since ρ is a sum of delta functions, this formula must be understood in the distributional sense, and holds for any real α . When $\alpha < 0$,

$$\begin{aligned} F^{(0)}(x) &= \frac{1}{2\pi} \int_{\alpha-i\infty}^{\alpha+i\infty} e^{\Psi(\tau)} \frac{1 - e^{-\tau x}}{\tau} d\tau \\ &= -\frac{1}{2\pi} \int_{\alpha-i\infty}^{\alpha+i\infty} \tau^{-1} e^{\Psi(\tau)-\tau x} d\tau \end{aligned} \quad (21)$$

In the last step in this argument, one term is zero because $e^{\Psi(\tau)}$ is analytic and decays rapidly as $\Re \tau \rightarrow -\infty$. Similarly, for $m = 1, 2, \dots$ one can show that

$$F^{(m)}(x) = (-1)^{m+1} \frac{1}{2\pi} \int_{\alpha-i\infty}^{\alpha+i\infty} \tau^{-m-1} e^{\Psi(\tau)-\tau x} d\tau \quad (22)$$

provided $\alpha < 0$. It is also useful to consider the functions

$$G^{(m)}(x) := (-1)^{m+1} \frac{1}{2\pi} \int_{\alpha-i\infty}^{\alpha+i\infty} \tau^{-m-1} e^{\Psi(\tau)-\tau x} d\tau \quad (23)$$

defined when $\alpha > 0$. One can show by evaluating the residue at $\tau = 0$ that

$$F^{(0)}(x) = G^{(m)}(x) - 1 \quad (24)$$

$$F^{(1)}(x) = G^{(1)}(x) - E[L] + x \quad (25)$$

with similar formulas relating $F^{(m)}$ and $G^{(m)}$ for $m = 2, 3, \dots$

Since the conditional portfolio loss is a sum of similar, but not identical, independent random variables, we can follow the argument of Daniels to produce an expansion for the functions $F^{(m)}$. Some extra features are involved: the cumulant generating function is not N times something, but rather a sum of N (easily computed) terms; we must deal with the factor τ^{-m-1} ; we must deal with the fact that critical points of the exponent in these integrals may be on the positive or negative real axis and there is a pole at $\tau = 0$. To treat the most general case, we move the factor τ^{-m-1} into the exponent and consider the saddlepoint condition

$$\Psi'(\tau) - (m+1)/\tau - x = 0 \quad (26)$$

Proposition 5.1 from [9] shows that a choice of two real saddlepoints solving this equation is typically available:

Proposition 1 *Suppose that $p_j, l_j > 0$ for all j . Then*

1. *There is a solution τ^* , unique if it exists, of $\Psi'(\tau) - x = 0$ if and only if $0 < x < \sum_j l_j$. If $E[\hat{L}] > x > 0$, then $\tau^* > 0$ and if $E[\hat{L}] < x < \sum_j l_j$, then $\tau^* < 0$.*
2. *For each $m \geq 0$, there is exactly one solution τ_m^- of equation (26) on $(-\infty, 0)$, if $x < \sum_j l_j$ and no solution on $(-\infty, 0)$, if $x \geq \sum_j l_j$. Moreover, when $x < \sum_j l_j$, the sequence $\{\tau_m^-\}_{m \geq 0}$ is monotonically decreasing in m .*
3. *For each $m \geq 0$, there is exactly one solution τ_m^+ of equation (26) on $(0, \infty)$, if $x > 0$ and no solution on $(0, \infty)$, if $x \leq 0$. Moreover, when $x > 0$ the sequence $\{\tau_m^+\}_{m \geq 0}$ is monotonically increasing in m .*

At this point, the methods in [2] and [9] differ. We consider first the method in [9] for computing $F^{(m)}, m = 0, 1$. The argument of Daniels directly is applied, but with the following strategy for choosing the saddlepoint. Whenever $x < E[\hat{L}]$, τ_m^- is chosen as the center of the Taylor expansion for the integral in equation (22). Whenever $x > E[\hat{L}]$, instead, τ_m^+ is chosen as the center of the Taylor expansion for the integral in equation (23), and either of equations (24)

or (25) is used. Thus for example, when $x > E[L]$, the approximation for $m = 1$ is

$$F^{(1)}(x) \sim x - E[L] + \frac{e^{\tau_1^+ x + \Psi(\tau_1^+)}}{\sqrt{2\pi \Psi^{(2)}(\tau_1^+)}} \times \left[1 + \frac{\Psi^{(4)}(\tau_1^+)}{8(\Psi^{(2)}(\tau_1^+))^2} - \frac{5(\Psi^{(3)}(\tau_1^+))^2}{24(\Psi^{(2)}(\tau_1^+))^3} + \dots \right] \quad (27)$$

In [2], the $m = -1$ solution τ^* , suggested by large deviation theory, is chosen as the center of the Taylor expansion, even for $m \neq -1$. The factor τ^{-m-1} is then included with the other nonexponentiated terms, leading to an asymptotic expansion with terms of the form

$$\int_{-\infty}^{\infty} e^{-w^2/2} (w + w_0)^{-m-1} w^k dw w_0 = \tau^* / \sqrt{\Psi^{(2)}(\tau^*)} \quad (28)$$

These integrals can be evaluated in closed form, but are somewhat complicated, and more terms are needed for a given order of accuracy.

Numerical implementation of the saddlepoint method for portfolio credit problems thus boils down to efficient computation of the appropriate solutions of the saddlepoint condition given by equation (26). This is a relatively straightforward application of one-dimensional Newton–Raphson iteration, but must be done for a large number of values of (x, t, y) . For typical parameter values and up to 2^{10} obligors, [9] report that saddlepoints were usually found in under 10 iterations, which suggests that a saddlepoint expansion will run no more than about 10 times

slower than the Edgeworth expansion with the same number of terms. However, both [2] and [9] observe that the accuracy of the saddlepoint expansion is often far greater.

Credit Scoring

Credit scoring models play a fundamental role in the risk management practice at most banks. Commercial banks' primary business activity is related to extending credit to borrowers and generating loans and credit assets. A significant component of a bank's risk, therefore, lies in the quality of its assets that needs to be in line with the bank's risk appetite.^a To manage risk efficiently, quantifying it with the most appropriate and advanced tools is an extremely important factor in determining the bank's success.

Credit risk models are used to quantify credit risk at counterparty or transaction level and they differ significantly by the nature of the counterparty (e.g., corporate, small business, private individual). Rating models have a long-term view (through the cycle) and have been always associated with corporate clients, financial institutions, and public sector (*see Credit Rating; Counterparty Credit Risk*). Scoring models, instead, focus more on the short term (point in time) and have been mainly applied to private individuals and, more recently, extended to small- and medium-sized enterprises (SMEs).^b In this article, we focus on credit scoring models, giving an overview of their assessment, implementation, and usage.

Since 1960s, larger organizations have been utilizing credit scoring to quickly and accurately assess the risk level of their prospects, applicants, and existing customers mainly in the consumer-lending business. Increasingly, midsize and smaller organizations are appreciating the benefits of credit scoring as well. The credit score is reflected in a number or letter(s) that summarizes the overall risk utilizing available information on the customer. Credit scoring models predict the probability that an applicant or existing borrower will default or become delinquent over a fixed time horizon.^c The credit score empowers users to make quick decisions or even to automate decisions, and this is extremely desirable when banks are dealing with large volumes of clients and relatively small margin of profits at individual transaction level.

Credit scoring models can be classified into three main categories: application, behavioral, and collection models, depending on the stage of the consumer credit cycle in which they are used. The main difference between them lies in the set of variables that are available to estimate the client's creditworthiness, that is, the earlier the stage in the credit cycle,

the lower the number of specific client information available to the bank. This generally means that application models have a lower prediction power than behavioral and collection models.

Over the last 50 years, several statistical methodologies have been used to build credit scoring models. The very simplistic univariate analysis applied at the beginning (late 1950s) was replaced as soon as academic research started to focus on credit scoring modeling techniques (late 1960s). The seminal works, in this field, of Beaver [10] and Altman [1] introduced the multivariate discriminant analysis (MDA) that became the most popular statistical methodology used to estimate credit scoring models until Ohlson [26], for the first time, applied the conditional logit model to the default prediction's study. Since Ohlson's research (early 1980s), several other statistical techniques have been utilized to improve the prediction power of credit scoring models (e.g., linear regression, probit analysis, Bayesian methods, neural network, etc.), but the logistic regression still remains the most popular method.

Lately, credit scoring has gained new importance with the new Basel Capital Accord. The so-called Basel II replaces the current 1988 capital accord and focuses on techniques that allow banks and supervisors to properly evaluate the various risks that banks face (*see Internal-ratings-based Approach; Regulatory Capital*). Since credit scoring contributes broadly to the internal risk assessment process of an institution, regulators have enforced more strict rules about model development, implementation, and validation to be followed by banks that wish to use their internal models in order to estimate capital requirements.

The remainder of the article is structured as follows. In the second section, we review some of the most relevant research related to credit scoring modeling methodologies. In the third section, following the model lifecycle structure, we analyze the main steps related to the model assessment, implementation, and validation process.

The statistical techniques used for credit scoring are based on the idea of discrimination between several groups in a data sample. These procedures originated in the 1930s and 1940s of the previous century [18]. At that time, some of the finance houses and mail order firms were having difficulties with their credit management. Decision whether to give loans or send merchandise to the applicants was

made judgmentally by credit analysts. The decision procedure was nonuniform, subjective, and opaque; it depended on the rules of each financial house and on the personal and empirical knowledge of each single clerk. With the rising number of people applying for a credit card, it was impossible to rely only on credit analysts; an automated system was necessary. The first consultancy was formed in San Francisco by Bill Fair and Earl Isaac in the late 1950s.

After the first empirical solutions, academic interest on the topic rose and, given the lack of consumer-lending figures, researchers focused their attention on small business clients. The seminal works in this field were Beaver [10] and Altman [1], who developed univariate and multivariate models, applying an MDA technique to predict business failures using a set of financial ratios.^d

For many years thereafter, MDA was the prevalent statistical technique applied to the default prediction models and it was used by many authors [2, 3, 13, 15, 16, 24, 29]. However, in most of these studies, authors pointed out that two basic assumptions of MDA are often violated when applied to the default prediction problems.^e Moreover, in MDA models, the standardized coefficients cannot be interpreted such as the slopes of a regression equation and, hence, do not indicate the relative importance of the different variables. Considering these MDA's problems, Ohlson [26], for the first time, applied the conditional logit model to the default prediction's study.^f The practical benefits of the logit methodology are that it does not require the restrictive assumptions of MDA and allows working with disproportional samples. The performance of his models, in terms of classification accuracy, was lower than the one reported in the previous studies based on MDA, but he pointed out some reasons to prefer the logistic analysis.

From a statistical point of view, logit regression seems to fit well the characteristics of the default prediction problem, where the dependent variable is binary (default/nondefault) and with the groups being discrete, nonoverlapping, and identifiable. The logit model yields a score between 0 and 1, which conveniently can be transformed in the probability of default (PD) of the client. Lastly, the estimated coefficients can be interpreted separately as the importance or significance of each of the independent variables in the explanation of the estimated PD. After the work of Ohlson [26], most of the academic

literature [5, 11, 19, 27, 30] used logit models to predict default.

Several other statistical techniques have been tested to improve the prediction accuracy of credit scoring models (e.g., linear regression, probit analysis, Bayesian methods, neural network, etc.), but the empirical results have never shown really significant benefits.

Credit Scoring Models Lifecycle

As already mentioned, banks that want to implement the most advanced approach to calculate their minimum capital requirements (i.e., advanced internal rating based approach, A-IRB) are subject to more strict and common rules regarding how their internal models should be developed, implemented, and validated.^g A standard model lifecycle has been designed to be followed by the financial institutions that will want to implement the A-IRB approach. The lifecycle of every model is divided into several phases (assessment, implementation, validation) and regulators have published specific requirements for each one of them. In this section, we describe the key aspects of each model's lifecycle phase.

Model Assessment

Credit scoring models are used to risk rank new or existing clients on the basis of the assumption that the future will be similar to the past. If an applicant or an existing client had a certain behavior in the past (e.g., paid back his debt or not), it is likely that a new applicant or client, with similar characteristics, will show the same behavior. As such, to develop a credit scoring model, we need a sample of past applicants or clients' data related to the same product as the one we want to use our scoring model for. If historical data from the bank are available, an empirical model can be developed. When banks do not have data or do not have a sufficient amount of data to develop an empirical model, an expert or a generic model is the most popular solution.^h

When a data sample covering the time horizon necessary for the statistical analysis (usually at least 1 year) is available, the performance of the clients inside the sample can be observed. We define performance as the default or nondefault event associated with each client.ⁱ This binary variable is the dependent variable used to run the regression analysis. The

characteristics of the client at the beginning of the selected period are the predictors.

Following the literature discussed in the second section, a conditional probability model, logit model, is commonly used by most banks to estimate the 1-year score through a range of variables by maximizing the log-likelihood function. This procedure is used to obtain the estimates of the parameters of the following logit model [20, 21]:

$$P_1(X_i) = \frac{1}{[1 + e^{-(B_0 + B_1 X_{i1} + B_2 X_{i2} + \dots + B_n X_{in})}]} \\ = \frac{1}{[1 + e^{-(D_i)}]} \quad (1)$$

where $P_1(X_i)$ is the score given the vector of attributes X_i ; B_j is the coefficient of attribute j (with $j = 1, \dots, n$); B_0 is the intercept; X_{ij} is the value of the attribute j (with $j = 1, \dots, n$) for customer i ; and D_i is the logit for customer i .

The logistic function implies that the logit score P_1 has a value in $[0,1]$ interval and is increasing in D_i . If D_i approaches minus infinity, P_1 will be zero and if D_i approaches plus infinity, P_1 will be one.

The set of attributes that are used in the regression depends on the type of model that is going to be developed. Application models, employed to decide whether to accept or reject an applicant, typically rely only on personal information about the applicant, given the fact that this is usually the only information available to the bank at that stage.^j Behavioral and collection models include variables describing the status of the relationship between the client and the bank that may add significant prediction power to the model.^k

Once the model is developed, it needs to be tested on a test sample to confirm the soundness of its results. When enough data are available, part of the development sample (hold-out sample) is usually kept for the final test of the model. However, an optimal test of the model would require investigating its performance also on an out-of-time and out-of-universe sample.

Model Implementation

The main advantage of scoring models is to allow banks to implement automated decision systems to manage their retail clients (private individuals and

SMEs). When a large amount of applicants or clients is manually referred to credit analysts to check their information and apply policy rules, most of the benefits associated with the use of scoring models are lost. On the other hand, any scoring model has a “gray” area where it is not able to separate with an acceptable level of confidence between expected “good” clients and expected “bad” ones.^l The main challenge for credit risk managers is to define the most appropriate and efficient thresholds (cutoff) for each scoring model.

In order to maximize the benefits of a scoring model, the optimal cutoff should be set taking into account the misclassification costs related to the type I and type II error rates as Altman *et al.* [2], Taffler [29], and Koh [23] point out. Moreover, we believe that the optimum cutoff value cannot be found without a careful consideration of each particular bank peculiarities (e.g., tolerance for risk, profit-loss objectives, recovery process costs and efficiency, possible marketing strategies). Today, the most advanced banks set cutoffs using profitability analyses at account level.

The availability of sophisticated IT systems has significantly broadened the number of strategies that can be implemented using credit scoring models. The most efficient banks are able to follow the lifecycle of any client, from the application to the end of the relationship, with monthly updated scores calculated by different scorecards related to the phase of the credit cycle where the client is located (e.g., origination, account maintenance, collection, write off). Marketing campaigns (e.g., cross-selling, up-selling), automated limit changes, early collection strategies, and shadow limit management are some of the activities that are fully driven by the output of scoring models in most banks.

Model Validation

Banks that have adopted or are willing to adopt the Basel II IRB-advanced approach are required to put in place a regular cycle of model validation that should include at least monitoring of the model performance and stability, reviewing of the model relationships, and testing of model outputs against outcomes (i.e., backtesting).^m

Considering the relatively short lifecycle of credit scoring models due to the high volatility of retail markets, their validation has always been completed

by banks. Basel II has only given to it a more official shape, prescribing that the validation should be undertaken by a team independent from the one that has developed the models.

Stability and performance (i.e., prediction accuracy) are extremely important information about the quality of the scoring models. As such, they should be tracked and analyzed at least monthly by banks, regardless of the validation exercise. As we have discussed above, often scoring models are used to generate a considerable amount of automated decisions that may have a significant impact on the banking business. Even small changes in the population's characteristics can substantially affect the quality of the models, creating undesired selection bias.

In the literature, we have found several indexes that have been used to assess the performance of the models. The simple type I and type II error rates that quantify the accuracy of each model in correctly classifying defaulted and nondefaulted observations have been the first measures to be applied to scoring models. More recently, the accuracy ratio (AR) and the Gini index have become the most popular measures (see [17] for further details).

Backtesting and benchmarking are an essential part of the scoring models' validation. With the backtesting, we evaluate the calibration and discrimination of a scoring model. Calibration refers to the mapping of a score to a quantitative risk measure (e.g., PD). A scoring model is considered well calibrated if the (*ex ante*) estimated risk measures (PD) deviate only marginally from what has been observed *ex post* (actual default rate per score band). Discrimination measures how well the scoring model provides an ordinal ranking of the risk profile of the observations in the sample; for example, in the credit risk context, discrimination measures to what extent defaulters were assigned low scores and nondefaulters high scores.

Benchmarking is another quantitative validation method that aims at assessing the consistency of the estimated scoring models with those obtained using other estimation techniques and potentially using other data sources. This analysis may be quite difficult to perform for retail portfolios, given the lack of generic benchmarks in the market.¹¹

Lastly, we would like to point out that Basel II specifically requires senior management to be fully involved and aware of the quality and performance

of all the scoring models utilized in the daily business (see [9], par. 438, 439, 660, 718 (LXXVI), 728).

End Notes

^aRisk appetite is defined as the maximum risk the bank is willing to accept in executing its chosen business strategy, to protect itself against events that may have an adverse impact on its profitability, the capital base, or share price (see **Economic Capital Allocation; Economic Capital**).

^bRecently, several studies [4, 12] have shown the importance for banks of classifying SMEs as retail clients and applying credit scoring models developed specifically for them.

^cThe default definition may be significantly different by bank and type of client. The new Basel Capital Accord [9] (par.452) has given a common definition of default (i.e., 90 days past due over 1-year horizon) that is consistently used by most banks today.

^dThe original Z-score model Altman [1] used five ratios: working capital/total assets, retained earnings/total assets, EBIT/total assets, market value equity/BV of total debt, and sales/total assets.

^eMDA is based on two restrictive assumptions: (i) the independent variables included in the model are multivariate normally distributed and (ii) the group dispersion matrices (or variance-covariance matrices) are equal across the failing and the nonfailing group. See [6, 22, 25] for further discussions about this topic.

^fZmijewski [31] was the pioneer in applying probit analysis to predict default, but, until now, logit analysis has given better results in this field.

^gThe new Basel Capital Accord offers financial institutions the possibility to choose between the standardized and the advanced approach to calculate their capital requirements. Only the latter requires banks to use their own internal risk assessment tools to quantify the inputs of the capital requirements formulas (i.e., PD and loss given default).

^hExpert scorecards are based on subjective weights assigned by an analyst, whereas generic scorecards are developed on pooled data from other banks operating in the same market. For a more detailed analysis of the possible solutions that banks can consider when not enough historical data is available, see [28].

ⁱSee end note (b).

^jThe most common application variables used are sociodemographic information about the applicants (e.g., marital status, residence type, time at current address, type of work, time at current work, flag phone, number of children, installment on income, etc.). When a credit bureau is available in the market, the information that can be obtained related to the behavior of the applicant with other financial institutions is an extremely powerful variable to be used in application models.

^kVariables used in behavioral and collection scoring models are calculated and updated at least monthly. As such, the

correlation between these variables and the default event is significantly high. Examples of behavioral variables are as follows: the number of missed installments (current, max last 3/6/12 months, or ever), number of days in excess (current, max last 3/6/12 months, or ever), outstanding on limit, and so on. Behavioral score can be calculated at facility and customer level (when several facilities are related to the same client).

^lDepending on the chosen binary-dependent variable, “good” and “bad” will have different meanings. For credit risk models, these terms are usually associated with nondefaulted and defaulted clients, respectively.

^mSee par. 417 and 718 (XCix) of the new Basel Capital Accord [7–9] (see also **Model Validation; Backtesting**).

ⁿRecently, rating agencies (e.g., Standard & Poor’s and Moody’s) and credit bureau providers (e.g., Fair Isaac and Experian) have started to offer services of benchmarking for retail scoring models. For more details about backtesting and benchmarking techniques, see [14].

GABRIELE SABATO

Credit Rating

The cornerstone of credit risk measurement and management for a financial institution is the credit rating, whether supplied by an external credit rating agency (CRA) or generated by an internal credit model. A credit rating represents an overall assessment of the creditworthiness of a borrower, obligor, or counterparty, and is thus meant to reflect only credit or default risk. That obligor may be either a firm or an individual. In this way the rating is a forecast, and like all forecasts it is noisy. For that reason, credit rating agencies make use of discrete ratings. The convention used by the three largest rating agencies, namely, Fitch, Moody's, and Standard & Poor's (S&P) is to have seven credit grades. They are, from best to worst, AAA, AA, A, BBB, BB, B, and CCC using S&P and Fitch's nomenclature, and Aaa, Aa, A, Baa, Ba, B, and Caa using Moody's nomenclature.^b As a firm migrates from a higher to a lower credit rating, that is, it is downgraded, it simply moves closer to default.

The market for credit ratings in the United States is dominated by two players: S&P and Moody's Investor Services; of the smaller rating agencies, only Fitch plays a significant role in the United States (although it has a more substantial presence elsewhere).^c The combined market share of Moody's and S&P is 80%, and once market share of Fitch is added, the total exceeds 95% [20].

To be sure, it is not the obligor but the instrument issued by the obligor that receives a credit rating, though an obligor rating typically corresponds to the credit risk of a senior unsecured debenture issued by that firm. The distinction is not that relevant for corporate bonds, where the obligor rating is commensurate with the rating on a senior unsecured instrument, but is quite relevant for structured credit products such as asset-backed securities (ABS). Nonetheless, as stated in a recent S&P document, "[o]ur ratings represent a uniform measure of credit quality globally and across all types of debt instruments. In other words, an 'AAA' rated corporate bond should exhibit the same degree of credit quality as an 'AAA' rated securitized issue." (44, p.4).

This stated intent implies that an investor can assume that, say, a double-A rated instrument is the same in the United States as in Belgium or Singapore,

regardless of whether that instrument is a standard corporate bond or a structured product such as a tranche on a collateralized debt obligation (CDO) (see **Collateralized Debt Obligations (CDO)**); see also [31]. The actual behavior of rated obligors or instruments may turn out to have more heterogeneity across countries, industries, and product types, and there is substantial supporting evidence. See [37] for evidence of variation across countries of domicile and industries for corporate bond ratings, and [17] for differences between corporate bonds and structured products.

The rating agencies differ about what exactly is assessed. Although Fitch and S&P evaluate an obligor's overall capacity to meet its financial obligation, and hence is best thought of as an estimate of probability of default, Moody's assessment incorporates some judgment of recovery in the event of loss. In the argot of credit risk management, S&P measures PD (probability of default), whereas Moody's measure is somewhat closer to EL (expected loss) [9].^d These differences seem to remain for structured products. In describing their ratings criteria and methodology for structured products, S&P states the following: "[w]e base our ratings framework on the likelihood of default rather than expected loss or loss given default. In other words, our ratings at the rated instrument level don't incorporate any analysis or opinion on post-default recovery prospects." (44, p. 3). Since 2005, Fitch, followed soon after by S&P and Moody's, have started publishing recovery ratings (each on a six-point scale). Market sector coverage has been different, but expanding, across the agencies. Also, application is different between corporate *versus* structured products.^e

Credit ratings issued by the agencies typically represent an unconditional view, sometimes also called *cycle-neutral* or *through the cycle*: the rating agency's own description of their rating methodology broadly supports this view.

(33, p.6,7): .. [O]ne of Moody's goals is to achieve stable *expected* [italics in original] default rates across rating categories and time. ... Moody's believes that giving only a modest weight to cyclical conditions best serves the interests of the bulk of investors.^f

(43, p.41): Standard & Poor's credit ratings are meant to be forward looking; ... Accordingly, the anticipated ups and downs of business cycles—whether industry-specific or related to the

general economy—should be factored into the credit rating all along. . . . The ideal is to rate ‘through the cycle’.

This unconditional or firm-specific view of credit risk stands in contrast to risk measures such as EDFs (expected default frequencies) from Moody’s KMV. An EDF has two principal inputs: firm leverage and asset volatility, where the latter is derived from equity (stock price) volatility; see [24] for a description. As a result, EDFs can change frequently and significantly since they reflect the stock market’s view of risk for that firm at a given point in time, a view which incorporates both systematic and idiosyncratic risk.

Unfortunately, there is substantial evidence that credit rating changes, including changes to default, exhibit procyclical or systematic variation [7, 27, 37], especially for speculative grades [23].

Although this article’s focus is on credit ratings for corporate entities, including special purpose entities such as structured credit, individuals also receive credit ratings or scores. These are important for obtaining either unsecured credit like a credit card, or even a mobile phone, as well as secured credit such as an auto loan or lease or a mortgage. They have received considerable attention of late in the context of subprime mortgages and their securitization. Nonetheless, because the individual credit exposures are typically small, even considering mortgages, banks have tried to automate the credit assessment of retail exposures as much as possible, often with the help of outside firms called *credit bureaus*. See [22] for a discussion with application to credit cards, and [1] for a broader survey on retail credit (see also **Credit Scoring** for a review of credit scoring models).

How to Generate a Credit Rating

One of the earliest studies of predicting firm bankruptcy, perhaps the most obvious form of borrower default, is [2]. Altman constructed a balanced sample of 33 defaulted and 33 nondefaulted firms to build a bankruptcy prediction model using multiple-discriminant analysis. His choice of condition variables—ratios reflecting firm leverage and profitability—has influenced default models to this day, and therefore it is worth showing the final

model here:

$$Z = 0.012X_1 + 0.014X_2 + 0.033X_3 + 0.006X_4 + 0.999X_5 \quad (1)$$

where

X_1 = working capital/total assets,

X_2 = retained earnings/total assets,

X_3 = earnings before interest and taxes/total assets,

X_4 = market value of equity/book value of total debt, and

X_5 = sales/total assets.

A large value of Z indicates high credit quality; the firm is far from its default threshold. The simplicity of this model makes it deceptively easy to criticize: have the coefficients remained the same? is it applicable to all industries (financial firms are typically much more highly leveraged— X_4 is small—than nonfinancial firms) or all countries? is the relationship really linear in the conditioning variables? and why are nonfinancial variables such as firm age or some measure of management quality not considered? However, the Altman Z -score endures to this day; it can be found for most publicly traded firms on any Bloomberg terminal.

The next important innovation in credit modeling is arguably Merton’s [32] option-based default model (see **Default Barrier Models**). Merton recognized that a lender is effectively writing a put option on the assets of the borrowing firm; owners and owner-managers (i.e., shareholders) hold the call option. Thus a firm is expected to default when the value of its assets falls below a threshold value determined by its liabilities. To this day all credit models owe an intellectual debt to Merton’s insights. The best-known commercial application of the Merton model is the Moody’s KMV EDF (expected default frequency) model.

Clearly, quantitative information obtained from (public) accounting data, metrics such as leverage, profitability, debt service coverage, and liquidity, is important for arriving at a credit assessment of a firm. In addition, a rating agency, because it has access to private information about the firm, can and does include qualitative information such as the quality of management [3, 28]. Indeed this is partly what makes credit rating agencies unique and important: they aggregate public and private

information into a single measure of creditworthiness (riskiness) and then make that summary statistic—the credit rating—public, essentially providing a public good [47]. By contrast a Moody's KMV EDF makes use only of public information, although it transforms this information using a proprietary methodology.⁸ In fact, rating agencies are in the business of not just information production but, in the words of Boot *et al.* [12], they also act as “information equalizers” [quotes in the original]. In this way, they serve as a coordinating mechanism or focal point to the financial markets.

Model Performance

All credit scoring or rating models map a set of financial and nonfinancial variables into the unit interval: the objective is to generate a probability of default, to separate the defaulters from the nondefaulters. Unsurprisingly, there is a plethora of modeling choices as documented, for instance, by Resti and Sironi [41]. However, in the horse race of default prediction models, the hazard approach as shown in [16, 42] seems to be emerging as the winner. See [11] for a recent overview. While we can say little about the performance on bank internal credit scoring models—they are proprietary—we can examine the empirical default experience of firms with a rating from a credit rating agency.

Highly rated firms default quite rarely. For example, Moody's reports that the 1-year investment grade default rate over the period 1983–2007 was 0.069% or 6.9 bp [35]. This is an average over four letter grade ratings: Aaa through Baa. Thus in a pool of 10 000 investment grade obligors or instruments we would expect seven defaults over the course of 1 year. But what if only four default? What about 11? Higher than expected default could be the result of either bad luck or a bad model, and it is very hard to distinguish between the two, especially for small probabilities (see also [29] and **Backtesting**). Indeed the use of the regulatory color scheme—green, amber, red—which is behind the 1996 Market Risk Amendment to the Basel I, was motivated precisely by this recognition, and in that case the probability to be validated is comparatively large 1% (for 99% VaR) [8] with daily data.

Although rating agencies insist that their ratings scale reflects an ordinal ranking of credit risk,

they also publish default rates for different horizons by rating. Thus we would expect default rates or probabilities to be monotonically increasing as one descends the credit spectrum. Using S&P rating histories, Hanson and Schuermann [23] show formally that monotonicity is violated frequently for most notch-level investment grade 1-year estimated default probabilities. The precision of the PD point estimates is quite low; there have been no defaults over 1 year for triple-A or AA+ (Aa1) rated firms, yet surely we do not believe that the 1-year probability of default is identically equal to zero. The new Basel Capital Accord (*see* **Regulatory Capital**), perhaps with this in mind, has set a lower bound of 3 bp for any PD estimate (10, §285), commensurate with about a single-A rating. Trück and Rachev [46] show the economic impact resulting from such uncertainty using bank internal ratings and a corresponding loan portfolio. Pluto and Tasche [40] propose a conservative approach to generating PD estimates for low-default portfolios.

Despite this lack of statistical precision, Kliger and Sarig [26] show that bond ratings contain price-relevant information by taking advantage of a natural experiment. On April 26, 1982, Moody's introduced overnight modifiers to their rating system, much like the notching used by S&P and Fitch, effectively introducing finer credit rating information about their issuer base without any change in the firm fundamentals. They find that bond prices indeed adjust to the new information, as do stock prices, and that any gains enjoyed by bondholders are offset by losses suffered by stockholders.

Although the 1-year horizon is typical in credit analysis (and is also the horizon used in Basel II), most traded credit instruments have longer maturity. For example, the typical CDS contract (*see* **Credit Default Swaps**) is five years, and over that horizon there are positive empirical default rates for Aaa and Aa, which Moody's reports to be 7.8 bp and 18.3 bp, respectively [35].

The preceding discussion highlights the difficulty of accurately forecasting such small PDs. Empirical estimates of PDs using credit rating histories can be quite noisy, even with over 25 years of data. Under the new Basel Capital Accord (Basel II), US regulators would require banks to have a minimum of seven nondefault rating categories [21].

Internal Ratings

With the roll-out of the New Basel Capital Accord, internal credit ratings will become widespread. To qualify for the internal-ratings-based (IRB) approach (*see Internal-ratings-based Approach*), which allows a bank to use its own internal credit rating, the accord provides the following rather nonspecific guidance (10, §461):

Banks must use information and techniques that take appropriate account of the long-run experience when estimating the average PD for each rating grade. For example, banks may use one or more of the three specific techniques set out below: internal default experience, mapping to external data, and statistical default models.

Since bank internal ratings are proprietary, not much is known (publicly) about their exact construction or about their performance. Carey and Hrycay's [15] study of internal ratings in US banks suggests that such rating systems rely at least to some degree on external ratings themselves, either by using them directly, when available, or calibrating internal credit scores to external ratings. Several books by practitioners and academics with practitioner experience, for example, [18, 30, 38, 41], indicate that the methods used are, perhaps unsurprisingly, much along the lines of the models covered above: statistical approaches—discriminant models in the manner of Altman's Z-score, logistic regression, neural networks, decision trees, and so on—that make use of firm financials, augmented with a judgmental overlay that incorporates qualitative information. This more intangible information is especially important when lending to small and young firms with no footprint in the capital markets, as shown, for instance, by Peterson and Rajan [39]. Ashcraft [5] documents that the failure of even healthy banks is followed by largely permanent declines in real activity, which is attributed to the destruction of private information about informationally opaque borrowers. There are now some papers emerging that attempt to formalize the incorporation of qualitative and subjective information, for example, from a loan officer, into bank internal credit scores or ratings. See, for instance, [25, 45].

Ratings for Structured Credit Products

Corporate bond (obligor) ratings are largely based on firm-specific risk characteristics. Since ABS

structures represent claims on cash flows from a *portfolio* of underlying assets, the rating of a structured credit product must take into account systematic risk. It is correlated losses that matter especially for the more senior (higher rated) tranches, and loss correlation arises through dependence on shared or common (or systematic) risk factors.^h For ABS deals that have a large number of underlying assets, for instance, mortgage-backed securities (MBS), the portfolio is large enough such that all idiosyncratic risk is diversified away leaving only systematic exposure to the risk factors particular to that product class (here, mortgages). By contrast, a substantial amount of idiosyncratic risk may remain in ABS transactions with smaller asset pools, for instance, CDOs [4, 17].

Because these deals are portfolios, the effect of correlation is not the same for all tranches (*see CDO Tranches: Impact on Economic Capital*): equity tranche holders prefer higher correlation, whereas senior tranches prefer lower correlation (tail losses are driven by loss correlation). As correlation increases, so does portfolio loss volatility. The payoff function for the equity tranche is, true to its name, like a call option. Indeed equity itself is a call option on the assets of the underlying firm, and the value of a call option is increasing in volatility. If the equity tranche is long a call option, then the senior tranche is short a call option, so that their payoffs behave in an opposite manner. The impact of increased correlation on the value of mezzanine tranches is ambiguous and depends on the structure of a particular deal [19]. By contrast, correlation with systematic risk factors should not matter for corporate ratings (*see also Base Correlation and Modeling Correlation of Structured Instruments in a Portfolio Setting* for details on default correlation modeling).

As a result of the portfolio nature of the rated products, the ratings migration behavior may also be different than for ordinary obligor ratings. Moody's Investors Services [34] reports that rating changes are much more common for corporate bond than for structured product ratings, but the magnitude of changes (number of notches up- or downgraded) was nearly double for the structured products.ⁱ There are potentially two reasons for this difference: model error or greater sensitivity of performance to systemic factors.

The modeling approach for rating structured credit products is in flux as of this writing, driven by the poor performance during the turmoil in the credit

markets in 2007 and 2008. Moody's, for instance, has recently proposed adding two new risk measures for structured finance transactions [36]. First, an "assumption volatility score" (or "V Score") that would rate the uncertainty of a rating and the potential for future ratings volatility on a scale of 1–5 (low to high). Second, a "loss sensitivity" that would estimate the number of notches a tranche would be downgraded if the expected loss of the collateral pool were increased to the 95th percentile of the original loss distribution. Moody's decided to develop these risk measures in addition to rather than in substitution for the standard credit ratings, which are on the same scale as their corporate ratings, precisely to allow investors to make a baseline comparison to other rated securities.

End Notes

^aAny views expressed represent those of the authors only and not necessarily those of the Federal Reserve Bank of New York or the Federal Reserve System.

^bFor no reason other than convenience and expediency, we make use of the Fitch and S&P nomenclature for the remainder of the article.

^cAs of this writing, there are ten "accredited" rating agencies in the United States (see [6] for a discussion on what it means to be "accredited"): A.M. Best, Dominion Bond Rating Service (DBRS), Egan-Jones Rating Company, Fitch Inc., Japan Credit Rating Agency Ltd., Moody's Investors Services, Inc., LACE Financial Corp., Rating and Investment Information, Inc, Realpoint LLC, Standard & Poor's Ratings Services. There are several other firms that provide credit opinions; one such example is Eagan-Jones Rating. An extensive list of rating agencies across the globe can be found at http://www.defaultrisk.com/rating_agencies.htm. For an exposition of the history of the credit rating industry, see [47]. For a detailed institutional discussion, see [14].

^dSpecifically, $EL = PD \times LGD$, where LGD is loss given default. However, given the paucity of LGD data, little variation in EL that exists at the obligor (as opposed to instrument) level can be attributed to variation in LGD making the distinction between the agencies modest at best.

^eSee http://www.fitchratings.com/corporate/fitchResources.cfm?detail=1&rd_file=intro#rtng_actn.

^fThis view was recently reinforced in [13]; both authors work for Moody's.

^gIn particular, the mapping from distance-to-default to EDF is proprietary.

^hNote that correlation includes more than just economic conditions, as it includes (i) model risk by the agencies, (ii) originator and arranger effects, and (iii) servicer effects.

ⁱThe recent rash of downgrades for structured credit products in the wake of the subprime credit crisis may change this stylized fact.

Portfolio Credit Risk: Statistical Methods

This article gives a brief overview over statistical methods for estimating the parameters of credit portfolio models from default data. The focus is on models for default probability and correlations; for recovery rates, (see **Recovery Rate**). First, a rather general model setting is introduced along the lines of the models of McNeil and Wendin [10] and others, who depict portfolio models as generalized linear mixed models (GLMMs). Then, we describe the most common estimation techniques, which are the method of moments and maximum likelihood. An excellent reference for other estimation techniques is [10], in particular for Bayes estimation.

A Single Obligor's Default Risk

Let D_{it} denote an indicator variable for obligor i 's default in time period t such that

$$D_{it} = \begin{cases} 1 & \text{borrower } i \text{ defaults in } t \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

$i \in \mathbb{N}_t, t = 1, \dots, T$, where $\mathbb{N}_t$ is the set of firms under consideration at the beginning of time period t and $n_t = |\mathbb{N}_t|$ is their cardinal number. The default indicator variable can be motivated in terms of a threshold approach wherein default is said to occur when a continuous variable falls below a threshold. This approach is based on the asset value model due to Merton [11] where the firm declares bankruptcy when the value of its asset is below the principal value of its debt at maturity. Let V_{it} denote the asset value return of firm i at time t ($i \in \mathbb{N}_t, t = 1, \dots, T$), or more generally a variable representing an obligor's credit quality. Then, the obligor defaults when V_{it} falls below a threshold c_{it} , that is, $D_{it} = 1 \Leftrightarrow V_{it} < c_{it}$. Crucial parts in credit risk management now are the modeling of V_{it} , the parameterization of c_{it} , and finally the estimation of parameter. In most industry credit risk models, such as credit metrics, credit risk plus, and credit portfolio view, the triggering variable V_{it} is driven by two sources of random factors. The first is a systematic random factor F_t following a distribution G , which affects all firms jointly and therefore cannot

be diversified away. The second is an idiosyncratic part ε_{it} with variance σ^2 , which is specific for each firm, independent between the firms and from the systematic factor. The default threshold c_{it} is mostly modeled *via* credit ratings that reflect an aggregated summary of a firm's risk characteristics. In a simple case, both variables may be expressed as linear functions of the respective risk drivers, such that $V_{it} = -\omega F_t + \varepsilon_{it}$ and $c_{it} = \alpha + \beta' \mathbf{x}_{it}$ where α , β , and ω are unknown parameters, and $\mathbf{x}_{it}$ is a design vector consisting of observable covariates for obligor i , which may be time- and obligor-specific (such as balance sheet ratios) or only time-specific (such as macroeconomic variables). Then the firm defaults if $V_{it} < \alpha + \beta' \mathbf{x}_{it}$. As shown in [7], the aforementioned credit risk models mainly differ in the distributional assumptions regarding the common and the idiosyncratic random factors driving the firm value as discussed below.

The probability of the firm's default conditional on the random factor f_t can be expressed as

$$\begin{aligned} CPD_{it}(f_t) &= P(D_{it} = 1 | \mathbf{x}_{it}, f_t) \\ &= P(V_{it} < \alpha + \beta' \mathbf{x}_{it} | \mathbf{x}_{it}, f_t) \\ &= P(\varepsilon_{it} < \alpha + \beta' \mathbf{x}_{it} + \omega f_t) \\ &= f(\alpha + \beta' \mathbf{x}_{it} + \omega f_t) \end{aligned} \quad (2)$$

which in statistical terms is a *GLMM*; see [10] and the references cited therein. f_t is a realization of the systematic factor F_t , which is called the *time-specific random effect*. $f(\cdot) : \mathbb{R} \rightarrow (0, 1)$ denotes a response or link function given by the distribution of the idiosyncratic random error ε_{it} . In the credit metrics model, the idiosyncratic errors are standard normally distributed ($\sigma^2 = 1$), whereas in the credit portfolio view model the idiosyncratic error follows a logistic distribution ($\sigma^2 = \pi^2/3$). This leads to the common link functions of the probit $f(y) = \Phi(y)$ or the logit function $f(y) = 1/(1 + \exp(-y))$. In the credit risk plus approach, the systematic and the unsystematic factors are linked multiplicatively rather than linearly and their distributions are Gamma and Exponential, respectively. For details, we refer to [7].

The (with respect to the random effect unconditional) probability of default (PD) is given by the

expectation

$$\begin{aligned} PD_{ti} &= P(D_{ti} = 1 | \mathbf{x}_{ti}) \\ &= \int f(\alpha + \beta' \mathbf{x}_{ti} + \omega f_t) dG(f_t) \end{aligned} \quad (3)$$

which depends on the distribution of the random factor. For example, in the credit metrics model, the random effect is assumed to follow a standard normal distribution. Then, in the probit model, the simple expression for the unconditional PD

$$PD_{ti} = P(D_{ti} = 1 | \mathbf{x}_{ti}) = \Phi(\tilde{\alpha} + \tilde{\beta}' \mathbf{x}_{ti}) = \Phi(\tilde{c}_{ti}) \quad (4)$$

results, where $\tilde{c}_{ti} = \tilde{\alpha} + \tilde{\beta}' \mathbf{x}_{ti}$, $\tilde{\alpha} = \alpha / \sqrt{1 + \omega^2}$ and $\tilde{\beta} = \beta / \sqrt{1 + \omega^2}$. The correlation between the latent variables of obligor i and j , $i \neq j$ is given by $\rho_{ij} \equiv \rho = \frac{\omega^2}{1 + \omega^2}$, which is sometimes referred to as *asset correlation* since the latent variables are interpreted as asset value return. See [5] for a detailed description of correlations. For the aforementioned distributions in the credit portfolio view and the credit risk plus approach and the empirical estimation, compare [8].

Portfolio Default Risk

The vector of default indicators of the portfolio is denoted by $\mathbf{D}_t = (D_{t1}, \dots, D_{tn_t})$. Conditional on the systematic random factor and given the $\mathbf{x}_{ti}$, the defaults are independent. Then the joint distribution of defaults conditional on the systematic factor is given by

$$\begin{aligned} P(\mathbf{D}_t = \mathbf{d}_t | \mathbf{x}_{ti}, f_t) &= \prod_{i \in \mathbb{N}_t} P(D_{ti} = 1 | \mathbf{x}_{ti}, f_t)^{d_{ti}} \\ &\times (1 - P(D_{ti} = 1 | \mathbf{x}_{ti}, f_t))^{1-d_{ti}} \end{aligned} \quad (5)$$

which is also known as a *Bernoulli mixture model* [6]. The unconditional distribution (where unconditional refers w.r.t. the random effect) is obtained as

$$P(\mathbf{D}_t = \mathbf{d}_t | \mathbf{x}_{ti}) = \int P(\mathbf{D}_t = \mathbf{d}_t | \mathbf{x}_{ti}, f_t) dG(f_t) \quad (6)$$

Extensions of model (5) include more than one random effect and are, therefore, called *multifactor models*.

A special case of this model results if the obligors are homogeneous in $\mathbf{x}_{ti}$, that is, $\mathbf{x}_{ti} = \mathbf{x}_t$ and thus $c_{ti} = c_t$ for all i . Then, all obligors exhibit the same conditional PD and the Bernoulli mixture distribution (5) drops to the binomial mixture distribution. Let $D_t = \sum_{i \in \mathbb{N}_t} D_{ti}$ be the number of defaults. Then,

$$\begin{aligned} P(D_t = d_t | \mathbf{x}_t, f_t) &= \binom{n_t}{d_t} P(D_{ti} = 1 | \mathbf{x}_t, f_t)^{d_t} \\ &\times (1 - P(D_{ti} = 1 | \mathbf{x}_t, f_t))^{n_t - d_t} \end{aligned} \quad (7)$$

with the unconditional distribution analogous to equation (6). Define the default rate $p_t = d_t / n_t$ as the ratio of defaulting obligors divided by the total number of obligors. As shown in [15, 16], the distribution of the default rate converges against the ‘‘Vasicek’’-distribution if the random effect is standard normally distributed and the number of obligors goes to infinity. The density is then given as

$$\begin{aligned} f(p_t) &= \frac{\sqrt{1 - \rho}}{\sqrt{\rho}} \cdot \exp\left(\frac{1}{2}(\Phi^{-1}(p_t))^2\right. \\ &\quad \left. - \frac{1}{2\rho^2}(c_t - \sqrt{1 - \rho^2} \cdot \Phi^{-1}(p_t))^2\right) \end{aligned} \quad (8)$$

For a thorough description of large pool approximations, see [9].

Estimation Techniques

There are basically two ways of estimating the unknown model parameters. As the first way, one can use asset values and asset value returns as in the KMV approach [1]. Given the level of liabilities, the default probabilities can be derived. Correlation estimates are obtained by calculating historical correlations from asset value returns. As the crucial part of these methods is deriving the asset values and the capital structure of the firm rather than the statistical procedures, they are not discussed here in detail. Instead, we refer to [3] and the references cited therein. As the second way, the parameters can be estimated using time series $\mathbf{d}_1, \dots, \mathbf{d}_T$ of observed default events. The simplest methods can

be employed for the case of the homogeneous portfolio with time-constant parameters where closed-form solutions for the estimators exist. In the GLMM model, more advanced numerical techniques have to be used. Here, we briefly describe the method of moments and the maximum-likelihood method. For Bayes estimation, we refer to [10] and the references cited therein.

Method of Moments

If the obligors in the portfolio or the segment are homogeneous and the parameters are constant, only two parameters are to be estimated, namely, the PD and the correlation. Gordy [7] applies the method of moments estimator to the probit model. He shows that expectation and variance of the conditional default probability are

$$E(CPD(F_t)) = PD \quad (9)$$

and

$$\begin{aligned} \text{Var}(CPD(F_t)) \\ = \Phi_2(\Phi^{-1}(PD), \Phi^{-1}(PD), \rho) - PD^2 \end{aligned} \quad (10)$$

where $\Phi_2(\cdot)$ is the bivariate normal cumulative distribution function for two random variates, with expectation zero and variance one each and correlation ρ . An unbiased estimator for the unconditional PD is given by the average default rate:

$$\bar{p} = \frac{1}{T} \sum_{t=1}^T p_t \quad (11)$$

The left-hand side of equation (10) can be estimated by the sample variance of the default rate:

$$s_p^2 = \frac{1}{T-1} \sum_{t=1}^T (p_t - \bar{p})^2 \quad (12)$$

Given the two estimates, the asset correlation ρ can be backed out numerically from equation (10). Gordy [7] also provides a finite sample adjustment for the estimator. However, this modified estimator turns out to perform similar to the simple estimator [3].

Maximum-likelihood Method

In the limiting case (8), asymptotic maximum-likelihood estimators of the (homogeneous) PD and

the (homogeneous) asset correlation can be derived as

$$\hat{\rho} = \frac{m_2/T - m_1^2/T^2}{1 + m_2/T - m_1^2/T^2} \quad (13)$$

$$\widehat{PD} = \Phi(T^{-1} \sqrt{1 - \hat{\rho}} m_1) \quad (14)$$

where $m_1 = \sum_{t=1}^T p_t$ and $m_2 = \sum_{t=1}^T p_t^2$ [4].

In the general case of the GLMM where obligors are heterogeneous, the log-likelihood is given via equation (6) as

$$\begin{aligned} l = \sum_{t=1}^T \ln \int \prod_{i \in \mathbb{N}_t} P(D_{ti} = 1 | \mathbf{x}_{ti}, f_i)^{d_{ti}} \\ (1 - P(D_{ti} = 1 | \mathbf{x}_{ti}, f_i))^{1-d_{ti}} dG(f_i) \end{aligned} \quad (15)$$

As the log-likelihood function includes solving several integrals, it is numerically optimized w.r.t. the unknown parameters for which several algorithms, such as the Newton–Raphson method, exist and are implemented in many statistical software packages. The integral approximation can be conducted by, for example, the adaptive Gaussian quadrature as described in [12]. Under usual regulatory conditions, the resulting estimators asymptotically exist, are consistent, and converge against normality. See [2], p.243, for a detailed discussion. Applications and estimation results can, for instance, be found in [6, 8, 13, 14]. For the extension of higher dimensional random effects, there are also some approximation methods that can be used, particularly penalized quasi-likelihood (PQL) and marginal quasi-likelihood (MQL) [10].

Bayes Estimation

Finally, Bayes estimation can be used for estimation as thoroughly shown in [10]. The joint prior distribution of F_t , $\boldsymbol{\beta}$ (including a constant) and some hyperparameters θ can be given as

$$p(\boldsymbol{\beta}, F_t, \theta) = p(F_t | \theta) \cdot p(\theta) \cdot p(\boldsymbol{\beta}) \quad (16)$$

where *a priori* independence between $\boldsymbol{\beta}$ and θ is assumed. Mostly, Markov chain Monte Carlo methods are applied, which can deal with even more complex models than shown here, such as autocorrelated random effects or multifactor models. For a detailed description, we refer to [10].

Recovery Rate

A recovery rate (RR) is the fraction of an obligor's debt that a creditor stands to recover in the event of default. Recovery rates are usually expressed as a percentage of the par value of the claim (RP). Alternatively, recovery rates can be expressed as a percentage of the market value of the claim prior to default (RMV), or as a percentage of an equivalent treasury bond (RT). Recovery rates are closely associated to the concept of loss-given-default (LGD) where $LGD = 1 - RR$. Recovery rates are not known prior to default and can vary between 0 (full loss) and 1 (full recovery). Recovery rate risk in credit portfolios exists because of the uncertainty regarding recovery rates in the event of default.

Along with the probability of default, recovery rates are important parameters in determining the loss distribution of a credit portfolio. For this purpose, the Basel II Accords expressly recommend that the calculation of regulatory capital on banking institutions include the estimated recovery rates on their credit portfolios. The most widespread methodologies for estimating recovery rates use historical averages that are conditioned on the type of credit instrument, seniority (priority of repayment), and collateral [3]. However, these estimation methods do not account for the fact that recovery rates are known to be negatively correlated to the probability of default [1, 2]. The correlation between recovery rates and default probabilities is important because it exacerbates potential losses on credit portfolios. To this effect, recent credit models have attempted to capture the endogenous nature of recovery rates [2, 4, 9, 11]. Furthermore, recent products in the credit derivatives market have enabled the extraction of recovery rates either directly [5] or indirectly [10, 14]. In addition, since 2003, major credit rating agencies have been offering recovery rate ratings based on proprietary models [8].

Historical Recovery Rates

Historical recovery rates for different types of credit securities are considered as important parameters in many credit risk models. There are various ways to estimate historical recovery rates. The most common are value-weighted mean recovery rates, issuer-weighted mean recovery rates, and issuer-weighted

median recovery rates. The value-weighted mean recovery rate is the average recovery rate on all defaulted issuers weighted by the face value of those issues. Issuer-weighted mean recovery rates and the issuer-weighted median recovery rates are the average and median, respectively, of the recovery rates on each issuer. Varma *et al.* [17] report historical recovery rates from 1982 to 2003 internationally. Globally, the value-weighted mean recovery rate for all bonds over that period was 33.8%, whereas the issuer-weighted mean and median recovery rates were 35.4% and 30.9%, respectively. In the United States, the value-weighted mean recovery rate for all bonds over that period was 35.4%, whereas the issuer-weighted mean and median recovery rates were 35.4% and 31.6%, respectively. For sovereign bonds, the value-weighted mean recovery rate for all bonds over that period was 31.2%, whereas the issuer-weighted mean and median recovery rates were 34.4% and 39.8%, respectively. Furthermore, recovery rates will differ depending on seniority and collateral of the bond. For instance, senior secured corporate bonds have a value-weighted mean recovery rate of 50.3%, compared to 22.9% for junior subordinated bonds, over 1982–2003. Carayon *et al.* [7] find that recovery rates on European bonds tend to be smaller. For instance, over 1987–2007, they find that senior secured bonds in Europe recover (issuer weighted) 61% compared to 70.6% in North America. In the Asia-Pacific (excluding Japan) region, Tennant *et al.* [16] find lower recovery rates of 35.61% on senior secured bonds over the 1990–2007 period.

Recovery Rates and Default Risk

The major problem for credit risk models is that there is a large body of empirical evidence suggesting that recovery rates are negatively correlated with default probabilities. High periods of default are associated with low recovery rates and *vice versa*. The correlation between default probabilities and recovery rates may be ascribed to at least two nonmutually exclusive reasons. First, economic downturns can simultaneously cause increases in the probability of default and lower the value of recovered assets. Second, the price at which recovered assets are sold will depend on the financial condition of peer firms [15]. Under the latter argument, in periods of high default, recovered assets are forced to be sold at “fire-sale” prices.

Acharya *et al.* [1] find both theories to be at work in explaining recovery rates. Altman *et al.* [2] empirically estimate the relationship between recovery rates (y) and default rates (x) using one linear and three nonlinear specifications:

$$\begin{aligned} y &= 0.51 - 2.61x; & R^2 &= 0.51 \\ y &= 0.002 - 0.113 \ln(x); & R^2 &= 0.63 \\ y &= 0.61 - 8.72x + 54.8x^2; & R^2 &= 0.65 \\ y &= \frac{0.138}{x^{0.29}}; & R^2 &= 0.65 \end{aligned} \quad (1)$$

All these specifications show a strong negative relationship between default rates and recovery rates.

Economic Features of Recovery Rates

There are several economic features of recovery rates that are important:

1. As described above, recovery rates are negatively correlated with default rates. This is the case when the data is examined historically as shown in [2] as well as when implied from the data, as in [10].
2. Recovery rates are highly variable and depend on regime (see [12]). They vary within rating and seniority class as well.
3. Seniority and industry are statistically significant determinants of recovery rates, as shown by Acharya *et al.* [1]. These authors also find that, in industries with high asset-specificity, recovery rates are lower.

Implied Recovery Rates

Recovery rates can also be implied from prices of certain credit derivatives. One then speaks of “implied” (or risk-neutral) recovery rates, which may not coincide with historically observed recovery rates. Recovery rate swaps are agreements to exchange a fixed recovery rate for the realized recovery rate allowing the market’s expected recovery rate to be directly recovered [5]. Digital credit default swaps (DDS) are credit default swaps (CDSs) where the recovery rates on default are prespecified, irrespective

of the final recovery rate. Arthur and Kapoor [6] show how recovery rates can be recovered using a DDS and a CDS. Finally, Pan and Singleton [14] and Das and Hanouna [10] use CDS with different maturities to extract default probabilities and recovery rates.

Approximately, if credit spreads are known, we may write the spread s as a function of default probability (λ) and recovery rate (ϕ): $s \approx \lambda(1 - \phi)$, implying that recovery may be written in a reduced-form setting as follows:

$$\phi = 1 - \frac{s}{\lambda} \quad (2)$$

More formalized and exact versions of this approximate relation may be derived from a CDS pricing model or a bond pricing model. Recovery may also be derived in the class of Merton [13] models. The expression for recovery rate is

$$\begin{aligned} E[\phi] &= E \left[\frac{V_T}{D} | V_T < D \right] = \frac{1}{D} E [V_T | V_T < D] \\ &= \frac{V_0}{D} e^{rT} \{1 - N(d_1)\} \\ d_1 &= \frac{\ln(V_0/D) + (r + \frac{1}{2}\sigma_V^2)T}{\sigma_V \sqrt{T}} \end{aligned} \quad (3)$$

where $\{V_0, \sigma\}$ are the initial value and volatility of the firm, D is the face value of debt with maturity T , and r is the risk-free interest rate. $N(\cdot)$ is the normal distribution function.

Internal-ratings-based Approach

Within the new Basel capital rules for banks (*see Regulatory Capital*), the internal-ratings-based approach (IRBA) represents perhaps the most important innovation for regulatory minimum capital requirements. For the first time, subject to supervisory approval, banks are allowed to use their own risk assessments of credit exposures in order to determine the capital to be held against them. Within the IRBA, banks estimate the riskiness of each exposure on a stand-alone basis. The risk estimates serve as input for a supervisory credit risk model (implicitly given by risk weight functions) that provides a value for capital that is deemed sufficient to cover against the credit risk of the exposure, given the assumed portfolio diversification. In order to obtain supervisory approval for the IRBA, banks must apply for IRBA and fulfill a set of minimum requirements. Until approval is granted for the entire book or specific portfolios, banks must apply the simpler and less risk-sensitive standardized approach for credit risk, where minimum capital requirements are determined in dependence on asset class (sovereign, bank, corporate, or retail exposure) only and, if applicable, ratings by external credit assessment agencies like rating agencies or credit export agencies.

The Conception of Internal Rating Systems in Basel II

Bank internal rating systems are, in the most general sense, risk assessment procedures, which are used for the assignment of internally defined borrower and exposure categories. A rating system is based on a set of predefined criteria to be evaluated for each borrower or exposure subject to the system, and result in a final “score” or “rating grade” for the borrower or exposure. The choice and weighting of the criteria can be manifold; there are no rules or guidance on which criteria to include or exclude. The main requirement on IRBA systems is that their rating grades or scores do indeed discriminate borrowers according to credit default risk.

In practice, rating systems are often designed as purely or partly statistical tools, for example, by

identifying criteria (typically financial ratios) with good discriminatory power and combining them by means of statistical regression or other mathematical methods.

However, in order to use such tools, there must be sufficient historical data—both on defaulted and surviving borrowers and exposures—for determining the discrimination criteria and calibrating their weightings. In practice, obtaining such data often proves to be more difficult than the statistical analysis as such, either because historically borrower and exposure characteristics were not stored in a readily usable manner, or simply because for some portfolios there is not sufficient default data. In general, rating systems may include a set of quantitative and some qualitative criteria. The weighting of these criteria may also be determined by expert opinion rather than by statistical tools. In the extreme, for example, in international project finance where certain criteria are deal breakers for loan arrangements (i.e., the existence of sovereign risk coverage *via* export insurance for projects in regions with high political risk), there might be no predetermined weighting scheme at all.

Notions appear to be not entirely uniform in practice. Often, but not always, the notion of a “scoring system” or a “score card” is used for a purely statistical rating system or the statistical part of a mixed quantitative and qualitative rating system. Moreover, the notion of scores tends to be more often used for retail and small business portfolios, while for corporate, bank, and sovereign portfolios, the literature tends to speak of rating systems. From an IRBA perspective, there are no conceptual differences between these notions: they all depict different forms of IRBA systems. Likewise, there is no IRBA requirement for the number of rating systems a bank should apply. Usually, one would expect different systems for retail, small businesses and self-employed borrowers, corporates, specialized lending portfolios, sovereigns, and banks. Many of these asset classes might again see different rating systems, depending on, for example, product type (very common for retail portfolios, but not constrained to them) or sales volume and region (both common for corporate portfolios), because the different borrower and exposure categories might call for different sets of rating criteria. Within a large, internationally active and well-diversified bank, one might expect to see a large number of different rating systems.

IRBA Risk Parameters

Credit risk per rating grade is quantified by probabilities of default (PDs), which give the probabilities of borrowers to default on their obligations, with regard to the Basel default definition, within 1 year's time. The PD per rating grade is usually estimated by the use of bank internal historical default data, which may be supplemented by external default data. A specific problem within the IRBA comes from the fact that not all institutions have readily available default data according to the Basel definition. In this case, adjustments to the estimates must be made.

PDs may be estimated just for the next year (point in time (PIT)) or as long term average PDs (through the cycle (TTC)). PIT estimates take into account the current state of the economy—as a consequence, PDs per rating grade might change over time—while TTC estimates do not. The Basel Accord seems to implicate TTC estimates. Nonetheless, many supervisors might be prepared to accept PD estimates that are more of PIT type because eliminating all cyclical effects from rating systems and PD estimates might be difficult to afford in practice.

In the Basel sense, an IRBA rating system contains two additional dimensions: an exposure at default (EAD) dimension, assessing the expected exposure at the point in time when the borrower defaults, and a loss given default (LGD) dimension, measuring the expected percentage of exposure that is lost in case a borrower defaults. The EAD dimension is mainly driven by product characteristics, for example, how easily lines can be drawn by the borrower or reduced by the bank prior to default, while the LGD dimension is heavily dependent on collateral, guarantees, and other risk mitigants. Here again, Basel notions slightly differ from literature and practice: in industry, the notion of a rating system often refers to the PD dimension only, while for Basel it includes all three dimensions. Within the IRBA, banks must provide a PD, LGD, and EAD for all their exposures. While the PD must always be estimated by the bank itself, banks can choose whether they want to use supervisory LGD and EAD estimates for given product and collateral types (thus applying the so-called foundation IRBA) or whether they want to estimate these values themselves, too (thus using the so-called advanced IRBA).

The Basel II Risk Weight Functions

In order to assess the overall risk of a bank portfolio, credit portfolio risk models have to evaluate the portfolio composition and its diversification. Within the Basel II IRBA, banks are not allowed to use their own credit portfolio risk models and diversification estimates for minimum regulatory capital ratios. Rather, they must input the risk parameters PD, LGD, and EAD into a supervisory credit portfolio risk model. This model can be roughly described as Vasicek's [6] multivariate extension of Merton's [5] model of the default of a firm. In statistical terms, the model could be characterized as a one-factor probit model where the events to be predicted are the borrowers' defaults and the single factor reflects the state of the global economy. Moreover, the Basel model assumes an infinitely granular portfolio, such that all idiosyncratic single name risk is diversified away. In this sense, the Basel model is an asymptotic single risk factor (ASRF) model. For further details of the model, see [1, 4].

The assumptions of a single risk factor and of infinite granularity lead to the following characteristics of the Basel credit risk model:

1. The capital charge per exposure can be described in closed form by risk weight functions (cf [3], paragraphs 272 and 273 for corporate, sovereign, and bank exposures and paragraphs 328, 329, and 330 for retail exposures). The specifications of the risk weight function for the different exposure classes can be derived from the following generic formula for the capital requirement K per dollar of exposure:

$$K = \text{LGD} \left[N \left(\frac{G(\text{PD})}{\sqrt{1-R}} + G(0.999) \sqrt{\frac{R}{1-R}} \right) - \text{PD} \right] \frac{1 + (M - 2.5)b}{1 - 1.5b} \quad (1)$$

In this equation,

- the probability of default PD and the loss given default LGD are measured as decimals;
- the *maturity adjustment* b is given by $(0.11852 - 0.05478 \ln(\text{PD}))^2$;

- N denotes the standard normal distribution function;
- G denotes the inverse standard normal distribution function;
- the *effective maturity* M was fixed at 1 year for retail exposures, and assumes values between 0 and 5 years for other exposures as described in detail in paragraph 320 of [3].

The risk weight functions for the different exposure classes differ mostly in the specification of the *asset correlation* R . For the retail mortgage exposure class, R was fixed at 15%. For revolving retail credit, R is 4%. In contrast, in the corporate, sovereign, and bank exposure classes, R depends on PD by

$$R = 0.12 \frac{1 - e^{-50PD}}{1 - e^{-50}} + 0.24 \left(1 - \frac{1 - e^{-50PD}}{1 - e^{-50}} \right) \quad (2)$$

and also for other retail exposures, R is given as a function of PD by

$$R = 0.03 \frac{1 - e^{-35PD}}{1 - e^{-35}} + 0.16 \left(1 - \frac{1 - e^{-35PD}}{1 - e^{-35}} \right) \quad (3)$$

2. The capital charge per exposure depends only on the risk parameters PD, LGD, and EAD of the exposure, but not on the portfolio composition. Thus, the capital charge for each exposure is exactly the same, no matter which portfolio it is added to (portfolio invariance). From a supervisory point of view, portfolio invariance was an important characteristic in developing the Basel risk weight functions, as it ensures computational simplicity and the preservation of a level playing field between well diversified and specialized banks. The capital charge for the entire portfolio is the sum of the capital charges for individual exposures. The downside of portfolio invariance is that the Basel formula cannot account for risk concentrations. If it did, the capital charge for an exposure would again have to depend on the portfolio to which it is added. If banks are concerned about concentration effects

or want to measure the diversification benefits of their portfolio, they need to develop their own, fully fledged credit risk models.

3. The capital charge for each exposure, given its risk parameters, depends on the correlation with the single systematic risk factor and the so-called confidence level. The confidence level for minimum capital requirements was set by the Basel Committee to be 99.9%. As a consequence, the probability that the bank will suffer losses from the credit portfolio that exceed the capital requirements should be of an order of magnitude like 0.1%. The correlations were estimated from supervisory data bases and are assumed to decrease with decreasing creditworthiness.
4. The ASRF takes only the default event as stochastic and treats the loss in case of default as deterministic. As in practice loss amounts are stochastic as well, and potentially correlated with the drivers of the default events, banks are supposed to take account of this effect in their LGD estimates, by estimating the downturn LGDs instead of average LGDs.
5. Lastly, the ASRF is a default mode (DM) model that only accounts for losses due to defaults within a given time horizon (1 year) but not for losses due to rating migrations and future losses after 1 year. This simplification does not comply with modern accounting practice. It was therefore adjusted by introducing the maturity adjustments, which can be seen as an extension of the model toward a marked-to-market (MtM) mode.

Minimum Requirements

In order to apply the IRBA, banks must have explicit approval from their supervisors. Approval is subject to a set of minimum requirements aimed to ensure the integrity of the rating model, rating process, and thus of the risk parameters and capital charges. The minimum requirements ([3], Part 2, Section III. H) hence assemble around the following themes:

- *Rating system design.* As mentioned before, there are no regulatory requirements with regard to the rating criteria. Rating grades must, in a sensible way, discriminate for credit risk, and the onus of proof is with the bank. Moreover, there must be at least seven rating grades for performing and one grade for nonperforming

exposures in the PD dimension. No minimum grade numbers are given for the LGD and EAD dimension. Also, there is no requirement of a common master scale across all rating systems, although many banks develop such a scale for internal risk management and communication purposes.

- *Rating system operations.* By this set of minimum requirements, banks are asked to ensure the integrity of the rating process. Most notably, the rating assignments must be independent from any business units gaining from credit approval (e.g., the sales department). Moreover, there should be no “cherry picking” between rated and nonrated exposures (the latter being treated in the less risk-sensitive standardized approach), although a temporary partial use of IRBA, coupled with a supervisory approved implementation (roll-out plan) for bankwide IRBA use, and a permanent partial use for insignificant portfolios are allowed. Another important aspect is the integration of the ratings into day-to-day credit processes, including IT systems and input data availability.
- *Corporate governance and oversight.* This set of criteria requires banks to embed their rating systems into the overall governance structure of the bank. Most notably, senior management is supposed to buy into the systems and formally approve for wide use within the bank, such that the systems become accepted risk management tools at all levels in the organization. Also, the role of internal audit in regular rating audits is defined.
- *Use of internal ratings.* Banks will only receive IRBA approval if they use their ratings for a wide range of bank internal applications. Examples include credit approval, limit systems, risk-sensitive pricing and loss provisioning. Rating systems solely developed for regulatory purposes will not be recognized, as only the deep rooting into day-to-day credit risk management actions will ensure their integrity.
- *Risk quantification.* Banks need to quantify the risk parameters PD, LGD, and EAD, based on their rating grades and on the Basel default and loss definitions ([3], paragraphs 452, 453, and 460). In doing so, they should employ a variety of data sources: preferentially internal data, but

enhanced with external data sources and expert judgment if needed.

- *Validation of internal estimates.* The PD, LGD, and EAD estimates must be validated against actually observed default rates and losses. Owing to relatively short time series for the latter, validation remains one of the more difficult issues within the IRBA. For available statistical techniques see, for example, [2]. Where statistical validation is not reliable, banks should use more qualitative validation techniques, like ensuring good rating process governance, integrity of the input data, and so on.
- *Disclosure requirements.* Banks that use the IRBA must base their capital and risk disclosure requirements (the Third Pillar of Basel II) on their IRBA figures.

In practice, compliance with the minimum requirements often seems to prove much more difficult and costly than the development of the rating systems as such. The most difficult issues seem to be data availability, IT system implementation, and data feed, the actual rating of entire portfolios, which often require large amounts of data for all exposures to be fed into the systems (in the worst case manually, as often data not consistent with the rating criteria have been stored in the past) and, connected to this, the buy-in of senior management and the entire credit business into the more risk-sensitive and more transparent IRBA.

Implications for the Bank Internal Use of IRBA Figures

Risk quantification *via* IRBA can be of great use for the bank internal credit risk measurement and management. However, there are some limitations. The most important of these is surely that due to the asymptotic single risk factor model, the IRBA provides no measure of risk concentrations, be they single name, industry, or regional concentrations. If banks are concerned about concentration effects or—as the other side of the same coin—want to measure the diversification benefits of their portfolio, they need to go further and develop their own, full-fledged credit risk models with more than one risk factor and their own correlation estimates. Likewise, the asymptotic assumption needs to be given up in order to capture idiosyncratic single name risk.

The most significant benefit of the IRBA for bank internal risk management lies in the standardized assessment and measurement of stand-alone borrower and exposure credit risk. Credit risk becomes much more transparent within the organization, and there is “one common currency” for risk, expressed by the risk parameters PD, LGD, and EAD and the regulatory capital charges based on them.

Exposure to Default and Loss Given Default

In the study of credit risk, the most relevant factor has traditionally been the borrower's probability of default (or intensity of default), expressing default risk and, indirectly, migration risk. However, there are other risk profiles that significantly affect the loss experienced by the lender upon the occurrence of a default: exposure at default and loss given default. The uncertainty surrounding these variables gives rise, respectively, to exposure risk and recovery risk. These risks (captured through parameters like EAD, LGD, and RR, as explained below) have become increasingly popular thanks to the preliminary drafts of the new accord on bank capital requirements ("Basel II") that were circulated by the Basel Committee after 1999 and led to a new regulatory text in 2004 [12].

Exposure at Default and Exposure Risk

In the simplest forms of credit exposure, the amount due to the lender in the event of a default (that is, the exposure at default (EAD)) is known with certainty. This is the case, for example, of zero-coupon bonds or fixed-term loans, where the balance outstanding is predetermined in advance and cannot be modified without a formal credit restructuring.

However, the amount outstanding in the event of a default might also be uncertain, basically due to the following reasons:

1. changes in the value of the contract to which the defaulted party had committed itself (typically, an OTC derivative affected by a number of underlying variables);
2. the presence of a revolving credit line (e.g., a loan commitment) where the borrower could increase his/her credit usage before default.

While case 1, known as *counterparty risk*, can be considered as a sort of intersection between credit and market risk, case 2 represents a typical example of exposure risk. Here, the borrower's current exposure (that is, the drawn part of the credit line, DP) can increase to a larger EAD, with the increase (ΔE)

potentially as large as the current unused portion (UP) of the credit line. To account for exposure risk, banks compute credit conversion factors (CCF) as $CCF \equiv \Delta E / UP$.^a Once a set of CCFs, associated with different types of borrowers and exposures, has been estimated, a bank can forecast EAD as

$$EAD = DP + CCF \cdot UP \quad (1)$$

CCFs are usually calibrated through a statistical analysis of past defaults (see, e.g., [9, 11, 25, 27]), where the CCF is explained through the characteristics of the borrower, the exposure, and the economic environment. When past events are analyzed, the UPs must be recorded some time before the default: this can be a fixed interval ("fixed time horizon," e.g., 12 months before the default) or a fixed moment in time for all defaults that occurred in the same period ("cohort approach," e.g., January 1 for all exposures defaulted in a given year); multiple UPs can also be recorded at several different instants in time ("variable time horizon," e.g., 6, 12, 24 months before default) to assess the impact of time-to-default on exposure risk.^b

In fact, CCFs can be expected to increase with time-to-default: a study based on some 400 borrowers in the period 1995–2000 [9] has shown that one-year CCFs average 32%, while five-year CCFs average 72%; this may be due to a rating migration effect and a greater opportunity to draw down. CCFs also seem to be driven by the percent usage ratio of the credit line ($DP / (DP + UP)$): lower usage rates are usually associated with higher CCFs and with better ratings [9].

A well-known relationship also exists between ratings and CCFs: indeed, the latter have often been found to increase for borrowers with better ratings.^c In other words, exposure risk is especially significant when default risk is comparatively low. This is an expected result, given that firms with investment-grade ratings can get funds from the commercial paper market or by negotiating better terms with their suppliers, and hence tend to use a small portion of the available credit lines (which are comparatively more expensive); however, as their financial shape deteriorates and default gets closer, firms quickly resort to bank credit lines, as other sources of funds dry up.

Besides focusing on loan behavior at default, one can assess exposure risk by monitoring credit usage throughout the life of a facility, including both defaulted and performing exposures. These "usage

ratios” have been found to behave very differently for firms that eventually default, even several years later, as opposed to nondefaulting obligors. For example, a sample of about 770 000 lines of committed credit lines recorded in the Spanish central credit register^d shows that defaulting exposures have a median usage ratio of 50%, in contrast to 43% for nondefaulting facilities; this median usage ratio was found to increase (71%) in the last year before default. Usage ratios are instead lower, all other things being equal, for “seasoned” credit lines (i.e., credit lines that have been in place for a number of years); this suggests that relationship banking may play a role in preventing usage peaks in credit lines.

Other borrower characteristics may also help explain exposure risk: for example, usage ratios have been found to be higher for younger, smaller, and less profitable firms (as age, size, and profitability tend to be inversely related to PD, this is consistent with poorly rated companies being more dependent on bank credit lines).^e Other important explanatory variables are the borrower’s leverage, liquidity, and debt cushion; also, exposure risk tends to be higher for larger companies and for those having a larger share of bank debt in their liabilities mix [25]. However, generally, firm characteristics tend to have a comparatively limited impact on CCFs and usage statistics.

Exposure risk also seems to be affected by the macroeconomic cycle. For example, the gross domestic product (GDP) growth rate has been found [27] to be inversely related to credit line usage, and such a link is especially meaningful in the case of a slow-down or recession. This makes sense, as credit lines are often used to provide a liquidity buffer for borrowers in times of financial strain.

Other measures have been proposed as an alternative to CCFs: these are the *EAD factor*, $EADF = EAD/(DP + UP)$, and the *exposure multiplier*, $EM = EAD/DP$. The former can be considered as a special case of the usage ratio, recorded at the time of default; the latter cannot be computed when a credit line was totally undrawn before the borrower’s default^f.

CCFs can usually be expected to lie between 0 (if the UP is still unused at default) and 1 (if the whole UP gives rise to an extra exposure). However, the ΔE and hence the CCF could also be negative; this is likely to be the case if the credit line is revocable or has some covenant entitling the bank to claim its money back before a proper default takes

place. Curiously, however, Basel II states that CCFs cannot be set below zero, regardless of any empirical evidence that a bank may produce to its supervisors.

Apart from OTC derivatives and credit lines, exposure risk can also arise from the issuance of guarantees and other off-balance-sheet items (e.g., letters of credit, bid bonds, and performance bonds) that might be used by third parties to get relief after the default of the guaranteed entity (leading to monetary outflow for the guarantor, that is, to an EAD). In this case, the EAD can be anywhere between zero and the amount of the off-balance sheet item (OBS), and CCFs can be computed as $CCF \equiv EAD/OBS$. CCF estimates associated with different types of guarantees and OBS can then be used to forecast the EAD as $EAD = CCF \cdot OBS$

Loss Given Default and Recovery Risk

The loss rate given default—or simply loss given default (LGD^g)—is the loss rate experienced by a lender on a credit exposure if the borrower defaults. It is given by 1 minus the recovery rate (*RR*) (see equation (3)) and can take any value between 0 and 100%. Formally,

$$LGD = 1 - RR \quad (2)$$

LGD is never known when a new loan is issued, although a reasonable estimate can be produced when the default occurs, at least if there is a secondary market where the defaulted exposure can be traded. In fact, RRs can be computed based on several approaches [8,33]:

1. The *market LGD* approach uses prices of defaulted exposures as an estimate of the RR. In practice, if a defaulted bond trades at 30 cents a euro, one can infer that the market is estimating a 30% RR (hence, a 70% LGD). This approach can be used only for exposures traded on a secondary market.

A variation of this approach (*emergence LGD* approach) estimates the RR on the basis of the market value of the new financial instruments (usually, shares or long-term bonds) that are offered to lenders in exchange for their defaulted claims. These are usually issued only when the restructuring process is over and the company

emerges from default; their market price must, therefore, be discounted back in time to the moment when the default took place, using an adequate discount rate.

A third version of market LGD involves the use of spreads on performing bonds as a source of information; in fact, spreads on corporate bonds depend on both the borrower's PD and the expected RR. Assuming the PD can be estimated otherwise, one can then work out the LGD implied by market spreads (*implicit market LGD*); alternatively, by assuming that some relationship exists between PD and LGD (see below), PD and LGD can be derived jointly [13]. Note that implicit market LGD makes it possible to use a considerably larger dataset, including performing exposures, and not only defaulted ones. However, note that LGDs derived from market prices often are risk-neutral quantities; therefore, some assumption on the relationship between them and real world LGDs is needed if implicit market LGDs are to be used.

2. When market data are not available (as for most traditional banking loans, where no secondary market exists) one must turn to the *workout approach*. This is based on the actual recoveries (and recovery costs) experienced by the lender in the months (years) after the default took place. It therefore requires to set up a database, where all recoveries on defaulted exposures are filed. According to this approach, the RR (also known as *ultimate recovery*) can be computed using the following equation:

$$RR = \frac{\sum_i R_i \cdot (1+r)^{-T_i}}{EAD} \quad (3)$$

where R_i is the i th recovery flow associated with the defaulted exposure (negative R_i s denote recovery costs), r is the appropriate discount rate,^h and T_i is the time elapsed between the default and the i th recovery. Note that, based on equation (3), RR can be negative (hence LGD can exceed 100%) if recoveries do not offset recovery costs.

The determinants of RRs have been extensively investigated, mainly based on the market LGD approach, although some examples of workout LGDs exist (mainly for bank loans). Indeed, one of the first

studies estimating RRs in the 1970s [6] was based on a survey carried out among the workout departments of a number of large banks in the period 1971–1975; the average recovery on unsecured loans (based on the face value of cash flows on defaulted exposures, recorded in the first three years after default and not discounted) was found to be about 30%.

In the following years, recoveries on bank loans have been foundⁱ to be affected by many factors, including the size of the loan and different collateral types. More generally, the four main drivers of RRs and LGDs can be summarized as follows:

Exposure characteristics

These include the presence of any collateral (be it represented by financial assets of other goods, such as plants, real estate, inventories) and its degree of effectiveness (that is, how easily it can be seized and liquidated); the priority level of the exposure, which can be senior or subordinated to other exposures; any guarantees provided by third parties (like banks, holding companies of public sector entities). An important driver of recoveries is also the exposure's "debt cushion", that is, the amount of the liabilities in the borrower's balance sheet that are junior to the one being evaluated; as the volume of such junior securities increases, so does the RR on the senior exposure, as its holders are more likely to find an adequate volume of assets to be liquidated and used as a source of cash [28,34].

Borrower characteristics

These include the industry where the company operates, which may affect the liquidation process, that is, the ease with which the firm's assets can be sold and turned into cash for the creditors,^j the country of the obligor, which affects the speed and effectiveness of the bankruptcy procedures; some financial ratios, like the leverage (namely, the ratio between total assets and liabilities, which shows how many euros of assets are reported in the balance sheet for each euro of debt to be paid back) and the ratio of EBITDA (earnings before interest, taxes, depreciation, and amortization) to total turnover (which indicates whether the defaulted company is still capable of generating an adequate level of cash flow for its would-be borrowers). Another interesting variable affecting LGD is the borrower's *original* rating: indeed, "fallen angels" (i.e., investment-class obligors that were downgraded to junk) appear to behave

differently from straight speculative-grade issuers, and have been found to recover significantly more than bonds of the same seniority that were rated as speculative-grade at issuance.^k

Lender (e.g., bank) characteristics

These may include the efficiency levels of the department that takes care of the recovery process (workout department) or the frequency with which out-of-court settlements are reached with the borrowers, or nonperforming loans are spun-off and sold to third parties; in fact, sales of nonperforming loans and out-of-court settlements, while reducing the face value of the recovery (compared to what could be obtained by the bank on the basis of a formal bankruptcy procedure), also significantly shorten the duration of the recovery process. The financial effect of this shorter recovery time usually more than offsets the lower recovered amount.

Macroeconomic variables

These mainly include the level of the interest rates (higher rates reduce the present value of recoveries) and the state of the economic cycle (if the economy is in recession, the value at which the companies assets can be liquidated is likely to be lower).

During the last years, an important stream of research has addressed the relationship between PD and LGD. From a theoretical point of view, the same macroeconomic background variables that affect the default probability of the borrowers (and cause default rates to rise) may drive down the liquidation value of assets and increase LGD (so that the distribution of LGDs is different in high-default and low-default periods).^l This intuition has prompted a number of models^m generalizing the “classic” single-factor model in [17] and [22] to the case where recoveries and defaults are driven by a common component (usually systemic in nature).

From an empirical point of view, several pieces of evidence indicate that LGDs and default rates tend to increase together when the overall economic cycle deteriorates. For example, using data on US corporate bonds (Moody’s Default Risk Service database) for 1982–1997, one finds that in a severe economic downturn (when defaults are more frequent), recoveries can be expected to drop by 20–25% compared with their unconditional average [20]. Similar results are found using Standard and Poor’s Credit Pro database (bond and loan defaults) for 1982–1999

[15], as well as junk bond data for 1982–2000.ⁿ Evidence of a strong relationship between LGD and the state of the economy, including default frequencies, is also found by Moody’s KMV in its LossCalc model [23], estimated on a dataset of over 3000 recoveries on loans, bonds, and preferred stock.

The correlation between economic cycle and recoveries appears stronger if estimated at the industry level [1]. In fact, if the sector where the borrower used to operate is undergoing a recession, the lender will find it more difficult to find a buyer for the defaulted company or its assets (as competitors are likely to suffer from excess production capacity) and recoveries will be lower than expected. As recessions may occur at the industry level when the economy as a whole is doing reasonably well, moving from economy-wide to industry-specific conditions can make the empirical link between default rates and recoveries much easier to detect.

The PD/LGD correlation has wide-ranging implications for credit risk models. First, the expected loss rate can no longer be considered as the product of the expected LGD times the borrower’s unconditional PD, since a second, positive addendum must be factored in, accounting for covariance. Second, unexpected loss and Value at Risk prove to be considerably higher than they are if independence is assumed, as shown by [7]; in other words, if systematic risk plays an important role for RRs, estimates of economic capital turn out to be downward biased.^o

While most RR studies focus on mean or median values, it is also important to understand the whole probability distribution of recoveries, if extreme scenarios are to be fully understood and managed. In the case of bank loans, the probability distribution of workout LGDs is usually strongly bimodal, with peaks at 0% and 100%. In the case of bonds, unimodal distributions may be sensible, but still it is strongly advisable to use flexible distributions, such as the beta (which can be either uni- or bimodal depending on the estimated parameters, and can easily be fit to the data by the generalized method of moments).^p

Finally, it is worth emphasizing that, as with all other risks, recovery risk may also produce profits. Indeed, the price performance of defaulted bonds (estimated by comparing market LGDs to emergence LGDs) can prove extremely brilliant, although this is not always the case: while senior bonds (both secured and unsecured) have been found to perform

very well in the postdefault period (with per annum returns of 20–30%), junior bonds often show negative returns [3].

Acknowledgments

Part of this article, especially the LGD section, draws on previous work carried out with Andrea Sironi, to whom I wish to express my gratitude.

End Notes

^aCCFs are sometimes also known as *loan equivalents* (*LEQs*).

^bSee [30] for further details on fixed time horizon, cohort approach, and variable time horizon.

^cSee, for example, [11], where a sample of loan commitments in 1987–93 is analyzed, [25], based on 3281 defaulted exposures issued by 720 borrowers in 1985–2006, or [9].

^dThese are all loan commitments above €6000 issued by Spanish banks after 1984. See [27] for further details.

^eSee again [27], based on a subset of about 86 000 companies.

^fThe EM is sometimes referred to as the *CCF* (in which case, what we called CCF is indicated as *LEQ*. Note that, given the important role played by bank capital regulation in shaping credit risk measurement techniques and jargon, we chose to use the word CCF in a way that is consistent with the terminology of the new Basel accord.

^gIn principle, one should indicate the loss rate given default as LGDR (LGD rate) and use LGD for the absolute LGD (in euros or dollars). However, “LGD” is used by most practitioners (and by the new Basel accord on bank capital) to indicate the loss rate, while the absolute loss is usually indicated as $LGD \cdot EAD$.

^hThe choice of a suitable risk-adjusted r is far from trivial, and basically depends on the amount of systemic risk of the defaulted exposure. See [29].

ⁱSee, for example, [10], based on 24 years of data compiled by Citibank, or [14], using a sample of 371 loans issued by Portugal’s largest private bank during 1985–2000; both studies are based on the workout approach. A study on bank loans (large syndicated loans traded on the secondary market) based on the market LGD approach is, for example, [16].

^jSee [1] based on market LGDs observed during the United States during 1982–1999. See also [5] and the literature survey in [33].

^kSee [4], based on a sample of corporate bonds stratified by original rating and seniority: in the case of senior-secured exposures, for example, the median RR for fallen angels was 50.5% versus 33.5%.

^lA somewhat different approach has been proposed by Peura and Jovivuolle [31]. Using an option-pricing, *à la*

Merton framework, they present a model where collateral value is correlated with the value of the borrower’s assets and hence to his/her PD. This leads to an *inverse* relationship between default rates and RRs.

^mSee [19–21]. Jarrow [26] presents a model where, as in Frye’s works, RRs and PDs are correlated and depend on the state of the economy; however, his methodology explicitly incorporates equity prices in the estimation procedure, allowing the separate identification of RRs and PDs and the use of a larger dataset. Furthermore, he explicitly incorporates a liquidity premium to account for the high variability in the spreads on US corporate debt. In [32] and [15] also models are proposed that account for the dependence of recoveries on systematic risk by extending Gordy’s single-factor model.

ⁿSee [2]. Note, however, that this study finds that a single systematic risk factor—that is, the performance of the economy as a whole—is less predictive than theoretical models would suggest, while a key role is played by the supply of defaulted bonds.

^oSee also the empirical results in [15].

^pFor a more flexible approach, see [24] where a variation of the Gaussian kernel, known as *Beta kernel*, is used to fit the distribution of RRs of a sample of defaulted bonds from the period 1981–1999. See also [18], for an interesting utility-based approach to the estimation of the conditional probability distribution of RRs.

Credit Portfolio Simulation^a

Portfolio Modeling

In risk management, quantitative techniques are mainly used for measuring the risk in a portfolio of assets rather than computing the prices of individual securities. The quantification of portfolio risk is traditionally split into separate calculations for market and credit risk, which are performed in different types of portfolio models. This article focuses on credit risk, more precisely on simulation techniques in structural credit portfolio models. We refer to [4] for a comprehensive exposition of Monte Carlo (MC) methods in quantitative finance including applications in market risk models.

In a typical bank, risk capital for credit risk far outweighs capital requirements for any other risk class. Key drivers of credit risk are concentrations in a bank's credit portfolio. Depending on their formulation, credit portfolio models can be divided into reduced-form models and structural (or firm-value) models (*see Reduced Form Credit Risk Models; Structural Default Risk Models*). The progenitor of all structural models is the model of Merton [13], which links the default of a firm to the relationship between its assets and the liabilities that it faces at the end of a given time period $[0, T]$. More precisely, in a structural credit portfolio model, the i th counterparty defaults if its ability-to-pay variable A_i falls below a default threshold D_i : the default event at time T is defined as $\{A_i \leq D_i\} \subseteq \Omega$, where A_i is a real-valued random variable on the probability space $(\Omega, \mathcal{A}, \mathbb{P})$ and $D_i \in \mathbb{R}$. The portfolio loss variable is defined by

$$L := \sum_{i=1}^n l_i \cdot \mathbf{1}_{\{A_i \leq D_i\}} \quad (1)$$

where n denotes the number of counterparties and l_i is the loss-at-default of the i th counterparty. To reflect risk concentrations, each A_i is decomposed into a sum of systematic factors $X_1, \dots, X_m$, which are often identified with geographic regions or industries, and an idiosyncratic (or firm-specific) factor Z_i , that

is A_i has the representation

$$A_i = \sqrt{R_i^2} \sum_{j=1}^m w_{ij} X_j + \sqrt{1 - R_i^2} Z_i \quad (2)$$

The idiosyncratic factors are independent of each other as well as independent of the systematic factors. It is usually assumed that the factors follow a multivariate Gaussian distribution. We refer to this class of models as *Gaussian multifactor models*.^b The impact of the risk factors on A_i is determined by $R_i^2 \in [0, 1]$ and the factor weights $w_{ij} \in \mathbb{R}$.

To quantify portfolio risk, measures of risk are applied to the portfolio loss distribution (1). The most widely used risk measures in banking are Value-at-Risk and expected shortfall: Value-at-Risk $\text{VaR}_\alpha(L)$ of L at level $\alpha \in (0, 1)$ is simply an α -quantile of L , whereas expected shortfall of L at level α is defined by

$$\text{ES}_\alpha(L) := (1 - \alpha)^{-1} \int_\alpha^1 \text{VaR}_u(L) du$$

For most practical applications, the average of all losses above the α -quantile is a good approximation of $\text{ES}_\alpha(L)$: for $c := \text{VaR}_\alpha(L)$ we have

$$\text{ES}_\alpha(L) \approx \mathbb{E}(L | L > c) = (1 - \alpha)^{-1} \int L \cdot \mathbf{1}_{\{L > c\}} d\mathbb{P} \quad (3)$$

This approximation is an exact equality unless the distribution of L has an atom at c , a situation that very rarely arises in practice.

Simulation Techniques

Since the portfolio loss distribution (1) does not have analytic form, the actual calculation and allocation of portfolio risk is a challenging problem. Saddle-point techniques have been successfully applied to certain types of portfolios; see, for example, [10] or *see Saddlepoint Approximation*. The most flexible approach, however, is based on MC simulation of the portfolio loss distribution. The following are the main steps in generating one MC sample:

1. calculation of a sample $(x_1, \dots, x_m)$ of the correlated systematic factors and a sample $(z_1, \dots, z_n)$ of the independent idiosyncratic factors;

2. calculation of the corresponding values $(a_1, \dots, a_n)$ of the ability-to-pay variables using equation (2);
3. calculation of the set of defaulted counterparties defined by $Def := \{i \in \{1, \dots, n\} \mid a_i \leq D_i\}$;
4. calculation of the portfolio loss: the sum $\sum_{i \in Def} l_i$ is a sample of the portfolio loss distribution.

The MC scenarios of the portfolio loss distribution are used as input for the calculation of risk measures. As an example, we compute expected shortfall with respect to the $\alpha = 99.9\%$ quantile based on $k = 100\,000$ MC samples $s_1 \geq s_2 \geq \dots \geq s_k$ of the portfolio loss L . Then $ES_\alpha(L)$ becomes

$$(1 - \alpha)^{-1} \int L \cdot \mathbf{1}_{\{L > c\}} d\mathbb{P} \approx \sum_{i=1}^{100} s_i / 100 \quad (4)$$

Since $ES_\alpha(L)$ is calculated as the average of 100 samples only, the MC estimate is subject to large statistical fluctuations and is numerically unstable. This is even truer for expected shortfall contributions of individual transactions. A significantly higher number of samples has to be computed, which makes straightforward MC simulation impracticable for large credit portfolios.

Different techniques have been developed that reduce the variance of MC simulations and—as a consequence—the number of samples required for stable results. We refer to [4] for a general introduction to variance reduction techniques including control variates, antithetic variables, stratified sampling, moment matching, and importance sampling. Recent research [3, 5–9, 12, 14] has shown that importance sampling is particularly efficient for stabilizing MC simulation in Gaussian multifactor models. Importance sampling attempts to reduce variance by changing the probability measure used for generating MC samples. In the above setting, the integral in equation (3) is replaced by the equivalent integral on the right-hand side of the equation

$$\int L \cdot \mathbf{1}_{\{L > c\}} d\mathbb{P} = \int L \cdot \mathbf{1}_{\{L > c\}} \cdot f d\tilde{\mathbb{P}} \quad (5)$$

where $\mathbb{P}$ is absolutely continuous with respect to the probability measure $\tilde{\mathbb{P}}$ and has (Radon–Nikodym) density f . This change of measure results in the MC

estimate

$$ES_\alpha(L)_{k, \tilde{\mathbb{P}}} := \frac{1}{k} \sum_{i=1}^k L_{\tilde{\mathbb{P}}}(i) \cdot \mathbf{1}_{\{L_{\tilde{\mathbb{P}}}(i) > c\}} \cdot f(i) \quad (6)$$

where $L_{\tilde{\mathbb{P}}}(i)$ is a realization of the portfolio loss L under the probability measure $\tilde{\mathbb{P}}$ and $f(i)$ is the corresponding value of the density function. The objective is to choose the probability measure $\tilde{\mathbb{P}}$ in such a way that the variance of the MC estimate for the integral (5) is minimal under $\tilde{\mathbb{P}}$. A general formula for the optimal importance sampling measure $\tilde{\mathbb{P}}$ is given in [15], which transforms equation (6) into a zero-variance estimator. However, since the construction requires knowledge of the integral (3) itself, the optimal measure cannot be used in the actual calculation. Nevertheless, it provides guidance on the design of an effective importance sampling strategy. Another technique for measure transformation, called *exponential tilting*, applies exponential families of distributions, which are specified by cumulant generating functions [1, 4]. As a general rule, detailed knowledge about the model (often in the form of asymptotic approximations) is indispensable for the construction of importance sampling algorithms. It is precisely this feature of importance sampling that makes the practical application more difficult but, on the other hand, increases the effectiveness of the methodology.

Importance sampling in Gaussian multifactor models utilizes the conditional independence of ability-to-pay variables by splitting the simulation of the portfolio loss distribution into two steps (compare to [11] in the more general context of mixture models). In a first step, importance sampling is used to simulate the systematic factors, and then the independence of the ability-to-pay variables conditional on systematic scenarios is exploited, for example, by another application of importance sampling or by limit theorems [7, 8].

A natural importance sampling measure $\tilde{\mathbb{P}}$ for the systematic factors is a negative shift, that is, the systematic factors have a negative mean under $\tilde{\mathbb{P}}$, which enforces a higher number of defaults and therefore increases the stability of the MC estimate. For calculating the shift, Glasserman and Li [7] minimize an upper bound on the second moment of the importance sampling estimator of the tail probability. Furthermore, they show that the corresponding importance sampling scheme is asymptotically optimal. The approach in [8, 9] utilizes the infinite

granularity approximation of the portfolio loss distribution (compare to [16]). More precisely, the original portfolio P is approximated by a homogeneous and infinitely granular portfolio $\bar{P}$. The loss distribution of $\bar{P}$ can be specified by a Gaussian one-factor model. The calculation of the shift of the systematic factors is now done in two steps: in the first step, the optimal mean is calculated in the one-factor setting and then the scalar mean is lifted to a mean vector for the systematic factors in the original multifactor model. Other importance sampling techniques [3, 6] are based on the Robbins–Monro stochastic approximation method or use large deviation analysis to calculate multiple mean shifts.

The efficiency of the proposed variance reduction schemes heavily depends on the portfolio characteristics. For example, the technique proposed in [8, 9] is tailored to large and well-diversified portfolios. For those portfolios the analytic loss distribution of the infinitely granular portfolio provides an excellent fit, which typically reduces the variance—and therefore the number of required MC scenarios—by a factor of more than 100. Smaller portfolios with low dependence on systematic factors, on the other hand, are dominated by idiosyncratic risk, which increases the relative importance of variance reduction techniques on idiosyncratic factors [7, 8], for example, importance sampling based on exponential tilting.

Counterparty Credit Risk^a

Counterparty credit risk (CCR) is the risk that a counterparty in a financial contract will default prior to the expiration of the contract and will fail to make all the payments required by the contract. Only the contracts privately negotiated between the counterparties—over-the-counter (OTC) derivatives and securities financing transactions (SFT)—bear CCR. Exchange-traded derivatives are not subject to CCR because all contractual payments promised by these derivatives are guaranteed by the exchange.

CCR is similar to other forms of credit risk (such as lending risk) in that the source of economic loss is an obligor's default. However, CCR has two unique features that set it apart from lending risk:

- **Uncertainty of credit exposure** Credit exposure of one counterparty to the other is determined by the market value of all the contracts between these counterparties. While one can obtain the current exposure from the current contract values, the future exposure is uncertain because the future contract values are not known at present.
- **Bilateral nature of credit exposure** Since both counterparties can default and the value of many financial contracts (such as swaps) can change sign, the direction of future credit exposure is uncertain. Counterparty A may be exposed to default of counterparty B under one set of future market scenarios, while counterparty B may be exposed to default of counterparty A under another set of scenarios.

The uncertainty of future credit exposure makes managing and modeling CCR of the trading book challenging. For a comprehensive introduction to CCR, see [1, 5, 17].

Managing and Mitigating Counterparty Credit Risk

One of the most conventional techniques of managing credit risk is setting counterparty-level *credit limits*. If a new transaction with the counterparty would result in the counterparty-level exposure exceeding

the limit, the transaction is not allowed. The limits usually depend on the counterparty's credit quality: higher rated counterparties have higher limits. To compare uncertain future exposure with a deterministic limit, *potential future exposure* (PFE) profiles are calculated from exposure probability distributions at future time points. PFE profiles are obtained by calculating a quantile of exposure at a high confidence level (typically, above 90%). Some institutions use different exposure measures, such as *expected exposure* (EE) profiles, for comparing with the credit limit. It is important to understand that a given credit limit amount is meaningful only in the context of a given exposure measure (e.g., 95%-level quantile).

Future credit exposure can be greatly reduced by means of risk-mitigating agreements between two counterparties, which include *netting agreements*, *margin agreements*, and *early termination agreements*. Netting agreement is a legally binding contract between two counterparties that, in the event of default of one of them, allows aggregation of transactions between these counterparties. Instead of each trade between the counterparties being settled separately, the entire portfolio covered by the netting agreement is settled as a single trade whose value equals the net value of the portfolio. Margin agreements limit the potential exposure of one counterparty to the other by means of requiring collateral should the unsecured exposure exceed a predefined threshold. The threshold value depends primarily on the credit quality of the counterparty: the higher the credit quality, the higher the threshold.

There are two types of early termination agreements: *termination clauses* and *downgrade provisions*. Termination clause is specified at the trade level. A unilateral (bilateral) termination clause gives one (both) of the counterparties the right to terminate the trade at the fair market value at a predefined set of dates. Downgrade provision is specified for the entire portfolio between two counterparties. Under a unilateral (bilateral) downgrade provision, the portfolio is settled at its fair market value the first time the credit rating of one (either) of the counterparties falls below a predefined level.

Contract-level Exposure

Let us consider a financial institution (we will call it a *bank* for brevity) that has a single derivative

contract with a counterparty. The bank's *exposure* to the counterparty at a given future time is given by the bank's economic loss in the event of the counterparty's default at that time. If the counterparty defaults, the bank must close out its position with the counterparty. To determine the loss arising from the counterparty's default, it is convenient to assume that the bank enters into a similar contract with another counterparty in order to maintain its market position. Since the bank's market position is unchanged after replacing the contract, the loss is determined by the contract's *replacement cost* at the time of default.

If the trade value at the time of default is negative for the bank, the bank receives this amount when it replaces the trade, but has to forward the money to the defaulting counterparty, so that the net loss is zero. If the trade value at the time of default is positive for the bank, the bank pays this amount when replacing the trade, but receives nothing (assuming no recovery) from the defaulting counterparty, so that the net loss is equal to the trade value.

Summarizing this, we can write the bank's credit exposure to the counterparty at future time t as

$$E_i(t) = \max\{V_i(t), 0\} \quad (1)$$

where $V_i(t)$ is the value of trade i with the counterparty at time t from the bank's point of view and $E_i(t)$ the bank's contract-level exposure to the counterparty created by trade i at time t .

Since the contract value changes unpredictably over time as the market moves, only the current exposure is known with certainty, while the future exposure is uncertain.

Counterparty-level Exposure and Netting Agreements

If the bank has more than one trade with the counterparty and counterparty risk is not mitigated in any way, the bank's exposure to the counterparty is equal to the sum of the contract-level exposures:

$$E_c(t) = \sum_i E_i(t) = \sum_i \max\{V_i(t), 0\} \quad (2)$$

where the subscript 'c' stands for 'counterparty'.

Netting agreements allow for a significant reduction of the credit exposure. There may be several netting agreements between the bank and the counterparty, as well as some trades that are not covered

by any of the netting agreements. Counterparty-level exposure in this most general case is given by

$$E_c(t) = \sum_k \max \left[\sum_{i \in \text{NA}_k} V_i(t), 0 \right] + \sum_{i \notin \{\text{NA}\}} \max[V_i(t), 0] \quad (3)$$

The inner summation in the first term of equation (3) aggregates the values of all trades covered by the k th netting agreement (hence the notation $i \in \text{NA}_k$), while the outer summation aggregates exposures across all netting agreements. The second term in equation (3) is simply the sum of the contract-level exposures of all trades that do not belong to any netting agreement (hence the notation $i \notin \{\text{NA}\}$).

Margin Agreements and Collateral Modeling

Margin agreements can further reduce credit exposure. Margin agreements can be either *unilateral* or *bilateral*. Under a unilateral agreement, only one of the counterparties has to post collateral. If the agreement is bilateral, both counterparties have to post collateral.

Usually a margin agreement covers one or more netting agreements. We can generalize equation (3) by specifying collateral amount $C_k(t)$ available to the bank under netting agreements NA_k at time t with the convention that this amount is positive when the bank holds collateral and negative when the bank has posted collateral:

$$E_c(t) = \sum_k \max \left[\sum_{i \in \text{NA}_k} V_i(t) - C_k(t), 0 \right] + \sum_{i \notin \{\text{NA}\}} \max[V_i(t), 0] \quad (4)$$

For netting agreements that are not covered by a margin agreement, collateral is identically zero.

Unilateral Margin Agreements

Let us consider a single unilateral (in the bank's favor) margin agreement with the threshold $H_c \geq 0$

and minimum transfer amount (MTA). When the portfolio value exceeds the threshold, the counterparty must post collateral to keep the bank's exposure from rising above the threshold. As the exposure drops below the threshold, the bank returns collateral to the counterparty. MTA limits the frequency of collateral exchange. It is difficult to model collateral subject to MTA exactly because that would require daily simulation time points, which is not feasible given the long-term nature of exposure modeling. In practice, the actual threshold H_c is often replaced by the effective threshold defined as $H_c^{(e)} = H_c + \text{MTA}$. After this replacement, the margin agreement is treated as if it had zero MTA.

The simplest approach to modeling collateral is to limit the future exposure from above by the threshold (i.e., for all scenarios with portfolio value above the threshold, set the exposure equal to the threshold). However, this approach is too simplistic because it ignores the time lag between the last delivery of collateral and the time when the loss is realized. This time lag is known as the *margin period of risk (MPR)*, which we will denote by δt . While the MPR is not known with certainty, it is typically assumed to be a deterministic number that is defined at the margin agreement level. Its value depends on the contractual margin call frequency and the liquidity of the portfolio. For example, $\delta t = 2$ weeks is usually assumed for portfolios of liquid contracts and daily margin call frequency.

Applying the rules of posting collateral under the assumption of the effective threshold with zero MTA and taking into account the MPR, the collateral $C(t)$ available to the bank at time t is given by

$$C(t) = \max\{V(t - \delta t) - H_c^{(e)}, 0\} \quad (5)$$

where $V(t)$ is the portfolio value from the bank's point of view at time t .

Bilateral Margin Agreements

Under a bilateral margin agreement, both the counterparty and the bank have to post collateral: the counterparty posts collateral when the bank's exposure to the counterparty exceeds the counterparty's threshold, while the bank posts collateral when the counterparty's exposure to the bank exceeds the bank's threshold. Since we are doing our analysis from the point of view of the bank, we will keep

the counterparty's threshold H_c *nonnegative*, but will specify the bank's threshold H_b as *nonpositive*. Then, the bank posts collateral when the portfolio value (defined from the bank's point of view) is *below* the bank's threshold. The MTA is the same for the bank and the counterparty and $\text{MTA} > 0$.

Similar to the unilateral case, we will create effective thresholds for the bank and for the counterparty. Effective threshold for the counterparty, $H_c^{(e)}$, remains unchanged. From the counterparty's point of view, effective threshold for the bank must be defined in exactly the same way. After taking into account that we do not switch our point of view and $H_b \leq 0$, the definition of the effective threshold for the bank will be $H_b^{(e)} = H_b - \text{MTA}$. Now the bilateral agreement can be treated as if it had zero MTA.

Collateral available to the bank at time t under the bilateral agreement is modeled as

$$C(t) = \max\{V(t - \delta t) - H_c^{(e)}, 0\} + \min\{V(t - \delta t) - H_b^{(e)}, 0\} \quad (6)$$

The first term in the right-hand side of equation (6) describes the scenarios when the bank receives collateral (i.e., $C(t) > 0$), while the second term describes the scenarios when the bank posts collateral (i.e., $C(t) < 0$).

For more details on collateral modeling, see [9, 15, 16].

Simulating Credit Exposure

Because of the complex nature of banks' portfolios, exposure distribution at future time points is usually obtained *via Monte Carlo Simulation* process. This process typically consists of three major steps:

- **Scenario generation** Dynamics of market risk factors (e.g., interest rates, foreign exchange (FX) rates, etc.) is specified *via* relatively simple stochastic processes (e.g., geometric Brownian motion). These processes are calibrated either to historical data or to market implied data. Future values of the market risk factors are simulated for a fixed set of future time points.
- **Instrument valuation** For each simulation time point and for each realization of the underlying market risk factors, valuation is performed for each trade in the counterparty portfolio.

- **Aggregation** For each simulation time point and for each realization of the underlying market risk factors, counterparty-level exposure is obtained by applying the necessary netting and collateral rules, conceptually described by equations (3) and (4).

The outcome of this process is a set of realizations of the counterparty-level exposure (each realization corresponds to one market scenario) at each simulation time point.

Because of the computational intensity required to calculate counterparty exposures—especially for a bank with a large portfolio—certain compromises between the accuracy and the speed of the calculation are usually made: relatively small number of market scenarios (typically, a few thousand) and simulation time points (typically, in the 50–200 range), simplified valuation methods, and so on.

For more details on simulating credit exposure, see [7, 17].

Pricing Counterparty Risk—Unilateral Approach

Let us assume that the bank is default-risk-free. Then, when pricing transactions with a counterparty, the bank should require a risk premium to be compensated for the risk of the counterparty defaulting. The market value of this risk premium, defined for the entire portfolio of trades with the counterparty, is known as unilateral *credit valuation adjustment* (CVA).

A **Risk-neutral Pricing** valuation framework is used for pricing CCR. The bank's economic loss arising from the counterparty's default and discounted to today is given by

$$L_{u-l} = 1_{\{\tau_c \leq T\}} (1 - R_c) E_c(\tau_c) \frac{B_0}{B_{\tau_c}} \quad (7)$$

where τ_c is the time of default of the counterparty; $1_{\{A\}}$ is the indicator function that assumes the value 1 if Boolean variable A is TRUE and value 0, otherwise; $E_c(t)$ is the bank's exposure to counterparty's default at time t ; R_c is the counterparty **Recovery Rate** (i.e., percentage of the bank's exposure to the counterparty that the bank will be able to recover in the event of the counterparty's default); and B_t is the value of the money-market account at time t .

One should keep in mind that counterparty-level exposure $E_c(t)$ incorporates all netting and margin agreements between the bank and the counterparty, as discussed above.

Unilateral CVA is obtained by taking the risk-neutral expectation of the loss in equation (7). Under the assumption that recovery rate is independent of the market factors and the time of default, this results in

$$\text{CVA}_{u-l} = (1 - \bar{R}_c) \int_0^T EE_c^*(t) dPD_c(t) \quad (8)$$

where $EE_c^*(t)$ is the risk-neutral discounted EE at time t , conditional on the counterparty defaulting at time t , given by

$$EE_c^*(t) = E^Q \left[\frac{B_0}{B_t} E_c(t) \mid \tau_c = t \right] \quad (9)$$

and $\bar{R}_c$ is the expected recovery rate; $PD_c(t)$ is the counterparty's cumulative from today to time t , estimated today; and T is the maturity of the longest trade in the portfolio.

The term structure of the risk-neutral PDs is obtained from the **Credit Default Swaps** spreads quoted in the market [19].

We would like to emphasize that the expectation of the discounted exposure at time t in equation (9) is conditional on the counterparty's default occurring at time t . This conditioning is material when there is a significant dependence between the exposure and the counterparty credit quality. This dependence, known as *right/wrong-way risk*, was first considered in [8] and [12]. To account for it, the counterparty's credit quality must be modeled jointly with the market risk factors. For more details on modeling right/wrong-way risk, see [4, 10, 18].

In practice, the dependence between exposure and the counterparty's credit quality is often ignored and conditioning on default in equation (9) is removed. Discounted EE is calculated for a set of simulation time points $\{t_k\}$ under the exposure simulation framework outlined above. Then, CVA is calculated by approximating the integral in equation (8) by a sum:

$$\begin{aligned} \text{CVA}_{u-l} \approx (1 - \bar{R}_c) \sum_k EE_c^*(t_k) \\ \times [PD_c(t_{k-1}) - PD_c(t_k)] \end{aligned} \quad (10)$$

Since the exposure expectation in equation (10) is risk neutral, scenario models for all market risk factors should be arbitrage free. This is achieved by appropriate calibration of drifts. Moreover, risk factor volatilities should be calibrated to the available market prices of options on the risk factors.

For more details on unilateral CVA, see [3].

Pricing Counterparty Risk—Bilateral Approach

In reality, banks are not default-risk-free. Because of the bilateral nature of credit exposure, the bank and the counterparty will never agree on the fair price of CCR if they apply unilateral pricing outlined above: each of them will demand a risk premium from the other. The bilateral approach specifies a single quantity—known as bilateral CVA—that accounts both for the bank's loss caused by the counterparty's default and the counterparty's loss caused by the bank's default.

Bilateral loss of the bank is given by

$$L_{b-1} = 1_{\{\tau_c \leq T\}} 1_{\{\tau_c < \tau_b\}} (1 - R_c) E_c(\tau_c) \frac{B_0}{B_{\tau_c}} - 1_{\{\tau_b \leq T\}} 1_{\{\tau_b < \tau_c\}} (1 - R_b) E_b(\tau_b) \frac{B_0}{B_{\tau_b}} \quad (11)$$

where τ_b is the time of default of the bank; $E_b(t)$ is the counterparty's exposure to bank's default at time t ; and R_b is the bank recovery rate (i.e., percentage of the counterparty's exposure to the bank that the counterparty will be able to recover in the event of the bank's default).

The first term in equation (11) describes the bank's loss when the counterparty defaults, but the bank does not default. The second term describes the loss of the counterparty in the event of the bank's default and the counterparty's survival. From the bank's point of view, the counterparty's loss is gain arising from the bank's option not to pay the counterparty when the bank defaults, so this term is subtracted from the bank's loss. Equation (11) is completely symmetric: if we change the sign of the right-hand side, we will obtain the bilateral loss of the counterparty.

Bilateral CVA is obtained by taking risk-neutral expectation of equation (11):

$$\begin{aligned} \text{CVA}_{b-1} = & (1 - \bar{R}_c) \int_0^T \mathbb{E} E_c^*(t) \\ & \times \Pr[\tau_b > t | \tau_c = t] \text{dPD}_c(t) \\ & - (1 - \bar{R}_b) \int_0^T \mathbb{E} E_b^*(t) \\ & \times \Pr[\tau_c > t | \tau_b = t] \text{dPD}_b(t) \end{aligned} \quad (12)$$

where $\mathbb{E} E_c^*(t)$ is the discounted EE of the counterparty to the bank at time t , conditional on the counterparty defaulting at time t , defined in equation (9), and $\mathbb{E} E_b^*(t)$ is the discounted EE of the bank to the counterparty at time t , conditional on the bank defaulting at time t , defined as

$$\mathbb{E} E_b^*(t) = \mathbb{E} \left[E_b(t) \frac{B_0}{B_t} \middle| \tau_b = t \right] \quad (13)$$

If the dependence between credit exposure and the credit quality of the counterparty and of the bank can be ignored, the conditional expectations in equations (9) and (13) should be replaced with the unconditional ones. As expected, equation (12) is symmetric between the bank and the counterparty, so that the bank and the counterparty will always agree on the price of CCR for their portfolio.

One can use **Default Time Copulas; Gaussian Copula Model; Copulas: Estimation** to express the conditional probabilities in equation (12) as functions of the counterparty's and the bank's risk-neutral PDs. For example, if the normal copula model [13] is used to describe the dependence between τ_c and τ_b , the conditional probabilities in equation (12) take the form

$$\begin{aligned} \Pr[\tau_b > t | \tau_c = t] \\ = 1 - \Phi \left(\frac{\Phi^{-1}[\text{PD}_b(t)] - \rho \Phi^{-1}[\text{PD}_c(t)]}{\sqrt{1 - \rho^2}} \right) \end{aligned} \quad (14)$$

and

$$\begin{aligned} \Pr[\tau_c > t | \tau_b = t] \\ = 1 - \Phi \left(\frac{\Phi^{-1}[\text{PD}_c(t)] - \rho \Phi^{-1}[\text{PD}_b(t)]}{\sqrt{1 - \rho^2}} \right) \end{aligned} \quad (15)$$

where ρ is the normal copula correlation and $\Phi(\cdot)$ is the standard normal cumulative distribution function.

Portfolio Loss and Economic Capital

Until now we have discussed modeling credit exposure and losses at the counterparty level. However, the distribution of the credit loss of the bank's entire trading book provides more complete information about the risk a bank is taking. Portfolio loss distribution is needed for such risk management tasks as calculation and allocation of **Economic Capital** (EC). For a comprehensive introduction to EC for CCR, see [14].

Portfolio credit loss $L(T)$ for a time horizon T can be expressed as the sum of the counterparty-level losses over all counterparties:

$$L(T) = \sum_j 1_{\{\tau_j \leq T\}} (1 - R^{(j)}) E^{(j)}(\tau_j) \frac{B_0}{B_{\tau_j}} \quad (16)$$

where τ_j is the time of default of counterparty j ; $R^{(j)}$ is the recovery rate for counterparty j ; and $E^{(j)}(t)$ is the bank's counterparty-level exposure at time t created by all trades that the bank has with counterparty j .

The economic capital $\text{EC}_q(T)$ for time horizon T and confidence level q is given by

$$\text{EC}_q(T) = Q_q[L(T)] - E[L(T)] \quad (17)$$

where $Q_q[X]$ is the quantile of random variable X at confidence level q (in risk management, this quantity is often referred to as **Value-at-Risk** (VaR)). The distribution of portfolio loss $L(T)$ can be obtained from equation (16) via joint Monte Carlo simulation of trade values for the entire bank portfolio and of default times of individual counterparties.

However, the joint simulation process is very expensive computationally and is often replaced by

a simplified approach, where simulation of counterparty defaults is completely separate from exposure simulation. The simplified approach is a two-stage process. During the first stage, exposure simulation is performed and a deterministic loan equivalent exposure (LEQ) is calculated from the exposure distribution for each counterparty. The second stage is a simulation of counterparty default events according to one of the credit risk portfolio models (see **Credit Migration Models**; **Structural Default Risk Models**; **CreditRisk+**) that are used for loan portfolios. Portfolio credit loss is calculated as

$$L(T) = \sum_j 1_{\{\tau_j \leq T\}} (1 - R^{(j)}) \text{LEQ}^{(j)}(T) \quad (18)$$

where $\text{LEQ}^{(j)}(T)$ is the LEQ of counterparty j for time horizon T .

Note that many loan portfolio models do not produce the time of default explicitly. Instead, they only distinguish between two events: "default has happened prior to the horizon (i.e., $\tau_j \leq T$)" and "default has not happened prior to the horizon (i.e., $\tau_j > T$)". Note also that, because the time of default is not known, discounting to present is not applied in equation (18).

For an infinitely fine-grained portfolio with independent exposures, it has been shown [6, 20] that LEQ is given by the EE averaged from zero to T —this quantity is often referred to as *expected positive exposure* (EPE):

$$\text{EPE}^{(j)}(T) \equiv \frac{1}{T} \int_0^T \text{EE}^{(j)}(t) dt \quad (19)$$

If one uses LEQ given by equation (19) for a real portfolio, the EC will be understated because both exposure volatility and correlation between exposures are ignored. However, this understated EC can be used in defining a scaling parameter commonly known as *alpha*:

$$\alpha_q(T) = \frac{\text{EC}_q^{(\text{Real})}(T)}{\text{EC}_q^{(\text{EPE})}(T)} \quad (20)$$

where $\text{EC}_q^{(\text{Real})}(T)$ is the EC of the real portfolio with stochastic exposures, and $\text{EC}_q^{(\text{EPE})}(T)$ is the EC of the fictitious portfolio with stochastic exposures replaced by EPE.

If α of a real portfolio can be estimated, its LEQ can be defined according to

$$\text{LEQ}^{(j)}(T) = \alpha_q(T) \text{EPE}^{(j)}(T) \quad (21)$$

Because the EC of a portfolio with deterministic exposures is a homogeneous function of the exposures, using the LEQ defined in equation (21) will produce the correct $\text{EC}_q^{(\text{Real})}(T)$. The caveat of this approach is that one has to run a joint simulation of trade values and counterparties' defaults to calculate α .

Several estimates of typical values of α for a large dealer portfolio and the time horizon $T = 1$ year are available. An International Swaps and Derivatives Association (ISDA) survey [11] has reported α calculated by four large banks for their actual portfolios to be in the 1.07–1.10 range. Theoretical estimates of α under a set of simplifying assumptions [6, 20] are 1.1 when market-credit correlations are ignored, and 1.2 when they are not.

The framework described above has found its place in the regulatory capital calculations under Basel II (see **Regulatory Capital**): a slightly modified version of equation (21) is used to calculate exposure at default (EAD) under the internal models method for CCR [2]. Basel fixes α at 1.4, but it allows banks to calculate their own α , subject to the supervisory approval and a floor of 1.2.

Loan Valuation

A loan is an agreement in which one party, called a *lender*, provides the use of property, the *principal*, to another party, the *borrower*. The borrower customarily promises to return the principal after a specified period along with payment for its use, called *interest* [3]. When the property loaned is cash, the documentation of the agreement between borrower and lender is called a *promissory note*.

Although cash loans can take many forms, traditionally, banks and other financial institutions are the primary lenders of cash and businesses, organizations, and individuals are the borrowers. Most loans to corporations share a common set of structural characteristics [2, 5].

1. Interest on loans is typically paid quarterly at a rate specified relative to some reference rate such as LIBOR (i.e., $L + 250$ bp).^a Thus, loans have *floating-rate* coupons whose absolute values are not known with certainty except over the next quarter.
2. Often the firm's assets or receivables are pledged against the borrowed principal. Because of this, their recovery rates are generally higher than corporate bonds, which are most commonly unsecured.
3. Most loans are prepayable on any coupon date at par, although some agreements contain a prepayment penalty or have a noncall period. The loan prepayment feature ensures that loan prices rarely exceed several points above par.
4. Finally, unlike bonds which are public securities, loans are private credit agreements. Thus, access to firm fundamentals and loan terms may be limited and loan contracts are less standardized. It is not uncommon to find "nonstandard" covenants or other structural features catering to specific needs of borrowers or investors.

Loan valuation concerns the amount of interest that a lender requires for use of the property or an investor will charge for purchasing the loan agreement. That valuation depends on several factors, such as

1. the likelihood of failure to receive timely payments of principal, called *risk of default*;
2. the residual value of the loan in the event of default, called its *recovery value*;

3. the time by which the principal of the loan must be repaid, the *maturity*;
4. the current market rate of interest for the obligor's likelihood of default, called the *market credit spread*;
5. the likelihood of the event that a borrower will have repaid the principal at any particular date prior to maturity.

Although the bulk of the loans outstanding are rated investment-grade or better, these loans trade very infrequently because of their high credit quality and lack of price differentiation. In fact, most loans that trade after origination are those made by banks to borrowers having speculative-grade credit ratings. These loans, made to high-yield firms are typically referred to as *leveraged loans*, though the exact definition varies slightly among market participants.^b

The types of loan facilities commonly traded in secondary markets include the following:

1. **Amortizing term loans.** Usually called "term loan A", the periodic payments from these loans include partial payment of principal, similar to what a mortgage loan does. These loans are usually held by banks and are becoming less popular.
2. **Institutional term loans.** These loans are structured to have bullet or close-to-bullet payment schedules and are targeted for institutional investors. They are referred to as "*term loan B*", "*term loan C*" and so on. Institutional term loans constitute the bulk of leveraged loan market.
3. **Revolving credit lines.** These are unfunded or partially funded commitments by lenders that can be drawn at the discretion of the borrowers. The facility is analogous to a corporate credit card. It can be drawn and repaid multiple times during the term of the commitment. These commitments are traded in secondary market. They are also known as *revolvers*.
4. **Second-lien term loans.** They have cash-flow schedule similar to that of institutional term loans, except that their claims on borrowers' assets are behind first-lien loan holders in the event of default.
5. **Covenant-lite loans.** These are borrower-friendly versions of institutional term loans that have fewer than the typical stringent covenants

that restrict use of the principal or subsequent borrowing activities of the firm.

Loan Pricing

Like bonds, loans contain risk of default; an obligor may fail to make timely payments of interest and/or principal. Thus, the notion of a credit spread to LIBOR has been used to characterize the riskiness of loans, where the credit spread, s , to LIBOR is calculated as

$$V = \sum_{t=1}^{4n} \frac{c_t/4}{\left(1 + \frac{r_t + s}{4}\right)^t} + \frac{F}{\left(1 + \frac{r_{4n} + s}{4}\right)^{4n}} \quad (1)$$

where V is the market value of the loan, c_t is the coupon (LIBOR + contractual spread), r_t is the spot rate for maturity t LIBOR rates, and F is the face value of the loan to be repaid at maturity. Loan coupons are generally paid quarterly and then reset relative to LIBOR and this is reflected in equation 1. Using equation 1, we can calculate a credit spread for any loan whose market price is known.

One problem with equation 1 for loan valuation is that it fails to account for the fact that loans, unlike bonds, are typically prepayable at par on any given coupon date. The loan prepayment option creates uncertainty in the expected pattern of cash flows and complicates comparisons of value among loans based on their credit spreads. Pricing the prepayment option has proved difficult because of its dependence

on the evolution of an obligor's credit state and the changing market costs of borrowing. For example, if a firm's credit improves or the loan rate over LIBOR decreases, the likelihood of prepayment increases; the borrower can refinance at a lower rate. Conversely, if a borrower's credit deteriorates or lending rates increase, it will not be advantages for the borrower to refinance.

To account for the prepayment option, we price the loans using a credit-state-dependent backward induction method.^c To illustrate, consider pricing a term loan with face value F , intermediate floating-rate coupon payments of c_t , and a maturity at time T , to a borrower of known credit quality, J . Specifically, Figure 1 displays pricing lattices for a five-year loan to a double-B rated (i.e., $J = BB$) obligor having a coupon of LIBOR + 3%,^d and face value of 100 at maturity.^e Figure 1(a) shows how the obligor's credit state evolves over time. In the lattice, probabilities are assigned reflecting transitions from each node at time t to all nodes at $t + 1$. Thus, the probability of being at a given node will be conditional upon all the previous transitions. In practice, ratings transition probabilities are based on historical data from credit rating agencies,^f and these are typically modified by the current market price of risk to produce *risk-neutral* ratings transition matrices.^{g,h}

Having calculated transition probabilities between all future nodes, we then apply the backward induction method. At maturity T , the borrower pays the principal plus coupon, $F + c_T$, or the recovery

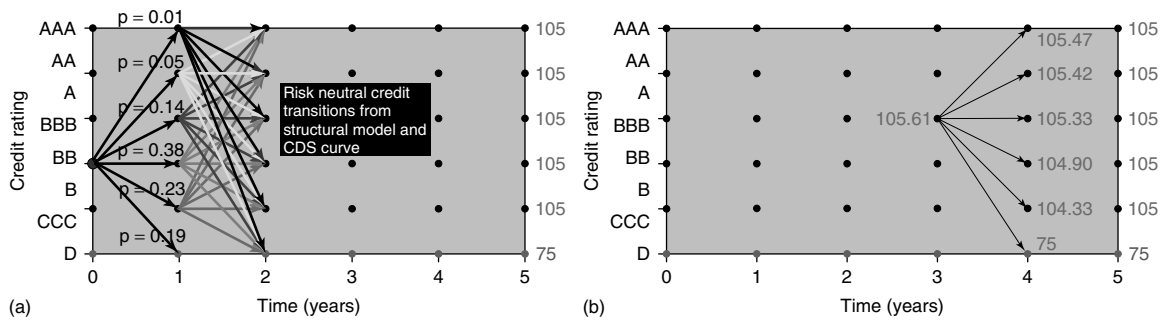

Figure 1 Credit-dependent backward induction method. (a) Double-B rated obligor, whose credit transitions are derived from historical data and incorporate market risk premiums are used to specify the likelihood of being in any credit state at future times to maturity. (b) Calculation of node values using backward induction, whereby values at each non-defaulted node are the coupon value at that node plus the sum of the conditional cash flows from the later date, discounted one period at forward LIBOR. In the example in (b), we assume a refinancing penalty of 0.5% of the principal

value in default $R * F$. Those cash flows are discounted back to each node at the previous period using forward LIBOR at $T - 1$. In other words, for each node at time $i < T$ and credit state j , and $j = (AAA, AA, \dots, CCC)$ we calculate an induced value, $v_{i,j}$, as

$$v_{(i,j)} = \min \left\{ \left(\frac{1}{\left(1 + \frac{f_{i+1,i}}{4}\right)} \sum_{k=D}^{AAA} (P_{j,k,i} * v_{i+1,k}) \right) + c_i, K_i \right\}, \quad (2)$$

where $P_{j,k,i}$ is the probability of migrating from state j to state k from time i to $i + 1$, f_i is the forward LIBOR rate from time i to $i + 1$, K_i is the terminal value of the loan at time i ,¹ and $v_{T,j} = F + c_T$. Thus, at each node i, j we compute the induced value, compare it with the terminal value, K_i , and set the value at that node, $v_{i,j}$ to the lesser of the two. In other words, if the induced value exceeds the terminal value, the loan is effectively repaid and terminates at i, j . Also, if the loan defaults at time i , the loan terminates with a value $v_{i,D} = R * F$ for all i . Finally, the value of $v_{i,j}$ at time 0 (in this example, at $v_{0,BB}$) is the *model* price of the loan.

Although equation 2 is useful for calculating prices of illiquid loans and for estimating the coupon premiums to charge for new loans, it is less useful for evaluating relative value among existing loans, which are better assessed using credit spreads. In fact, we can calculate the credit spread for a loan by discounting its expected nondefault cash flows by a constant amount over the LIBOR curve such that the discounted value matches its current market price. For all nondefault cash flows at a given time, the borrower will either prepay the principal and terminate, or pay a coupon and continue. The prepayment region in the time-and-credit-state lattice can be determined using the values of $v_{i,j}$ in equation 2. The probability of prepaying at period i is the sum of the probabilities of reaching nodes whose value of $v_{i,j}$ equal those capped at the terminal values K_i . Given the probability transition matrix and the set ω of all prepayment nodes, we can calculate the probability of prepayment at time i conditional on no prepayment before time i .

Let the conditional probability of prepayment at time be q_i ,² then the discounted cash flow is given by

$$V_J = \sum_{i=1}^T D_i * \prod_{j=1}^{i-1} (1 - q_j) * [(q_i * K_i) + ((1 - q_i) * CF_i)] \quad (3)$$

where $CF_i = c_i/4$ for $i < T$; $CF_i = (c_i/4 + F)$ for $i = T$, and the discount margin D_i is given by

$$D_i = \prod_{j=0}^i \frac{1}{\left(1 + \frac{f_{j,j-1} + \hat{s}}{4}\right)} \quad (4)$$

The credit spread, s , is determined by iteratively changing the parameter $\hat{s}$ and recalculating the discounted value of the cash flows, V_J , until V_J converges to P , the market price.

Revolving lines of credit are priced by assuming that the fraction of the loan drawn at a particular time, called the *usage*, is directly related changes to the obligor's credit quality. In other words, if a borrower's credit rating improves, it can access credit more cheaply and is also less likely to draw on existing lines of credit. Conversely, a borrower with deteriorating credit will likely draw on the credit lines it obtained when more highly rated. In this framework, usage can be interpreted as credit-dependent face value. Thus, in the equations above the face value is modified by $F \rightarrow U_j * F$ where j is the credit state and usage U_j ranges from 0 to 1.

End Notes

^aLIBOR stands for London interbank offered rate, which roughly corresponds to the interest rate charged between banks when lending large amounts of US dollars outside the United States. The coupon rate for a given quarter is set at the beginning of the period. For example, the L + 250 bp coupon in the text indicates that the borrower will pay one-quarter of 250 bp (0.625%) plus the current three-month LIBOR rate on the next coupon date.

^bAlthough some people define leveraged loans on the basis of their balance sheet leverage ratio, it is more common to use credit ratings (i.e., below BBB-) or credit spread to LIBOR above some maximum.

^cSeveral versions of the backward induction method have been proposed over the years [1, 6, 7, 9]. The version presented in equations (1–3) embodies elements that are common to most of these methodologies.

^dLoan spreads are typically quoted in basis points such as LIBOR + 300 bp, where 1% = 100 bp.

^eFor convenience, we assume LIBOR is constant at 2%, thereby generating a constant 5% coupon, and that the loan pays annually, rather than the typical quarterly coupon payment.

^fThe most well-known credit rating agencies are Fitch, Moody's, and Standard & Poor's.

^gRatings transition matrices are published regularly by the major agencies [4, 8].

^hMost models specify adjustment of physical credit transitions so that the default probabilities at each time, i , match the risk-neutral probabilities of default as implied by the bond and loan markets. For example, the risk-neutral default probability for a single risky cash flow at time t is given as $P_t^Q = \frac{1 - e^{-ts}}{(1 - R)}$ and $P_t^Q = N(N^{-1}(P_t) + \beta\lambda\sqrt{t})$ where, $P(t, Q)$ is the cumulative risk-neutral default probability to time t , s is the market credit spread, and R is the recovery rate in default. On the right, we calculate P_t^Q from P_t the physical default probability by adding a term related to the volatility of the credit relative to the market, the market price of risk, and the time to receipt of the cash flow. (For an elaboration and discussion of the derivation of this relation, see Bohn [1]. Zeng and Wen [9] describe its application to loan pricing.)

ⁱIt is common to add a refinancing premium to the principal plus coupon when defining the terminal value for evaluating prepayment as there are costs and/or penalties associated with the refinancing process.

^jThe probability of prepayment at time 1 from the initial state J is given by $q_1 = \sum_{k \in \omega} P_{J,k,0}$. For time $i > 1$, we must add the condition that the loan was not prepaid before time i ; thus, $q_i = \prod_{m=1}^{i-1} (1 - q_m) * \sum_{k \in \omega, l \notin \omega} P_{l,k,i-1}$.

Credit Risk

Credit risk is the risk of an economic loss from the failure of a counterparty^a to fulfill its contractual obligations. For example, credit risk in the loan portfolio of a bank materializes when a borrower fails to make a payment, either the periodic interest charge or the periodic reimbursement of principal on the loan he contracted with the bank. Credit risk can be further decomposed into four main types: default risk, bankruptcy risk, deterioration in creditworthiness (or downgrading) risk, and settlement risk.

Default risk corresponds to the debtor's incapacity or refusal to meet his/her debt obligations, whether interest or principal payments on the loan contracted, by more than a reasonable relief period from the due date, which is usually 60 days in the banking industry.

Bankruptcy risk is the risk of actually taking over the collateralized, or escrowed, assets of a defaulted borrower or counterparty, and liquidating them.

Creditworthiness risk is the risk that the perceived creditworthiness of the borrower or counterparty might deteriorate. In general, deteriorated creditworthiness translates into a downgrade action by the rating agencies, such as Standard and Poor's (S&P) or Moody's, and an increase in the risk premium, or credit spread of the borrower. A major deterioration in the creditworthiness of a borrower might be the precursor of default.

Settlement risk is the risk due to the exchange of cash flows when a transaction is settled. Failure to perform on settlement can be caused by a counterparty defaulting, liquidity constraints, or operational issues. This risk is greatest when payments occur in different time zones, especially for foreign exchange transactions, such as currency swaps, where notional amounts are exchanged in different currencies.^b

Credit risk is only an issue when the position is an asset, that is, when it exhibits a positive replacement value. In that situation, if the counterparty defaults, the firm loses either all of the market value of the position or, more commonly, the part of the value that it cannot recover following the credit event. The value it is likely to recover is called the *recovery value* or *recovery rate* when expressed as a percentage; the amount it is expected to lose is called the *loss given default* (see **Recovery Rate**).

Unlike the potential loss given default on coupon bonds or loans, the one on derivative positions is

usually much lower than the nominal amount of the deal, and in many cases is only a fraction of this amount. This is because the economic value of a derivative instrument is related to its replacement, or market value, rather than its nominal or face value. However, the credit exposures induced by the replacement values of derivative instruments are dynamic: they can be negative at one point in time and yet become positive at a later point in time after market conditions have been changed. Therefore, firms must examine not only the current exposure, measured by the current replacement value, but also the profile of potential future exposures up to the termination of the deal.

Credit Risk at the Portfolio Level

The first factor affecting the amount of credit risk in a portfolio is clearly the credit standing of specific obligors (see **Rating Transition Matrices; Credit Rating**). The critical issue, then, is to charge the appropriate interest rate, or spread, to each borrower so that the lender is compensated for the risk he/she undertakes and to set the right amount of risk capital aside (see **Economic Capital**).

The second factor is "concentration risk" or the extent to which the obligors are diversified in terms of number, geography, and industry.

This leads us to the third important factor that affects the risk of the portfolio: the state of the economy. During economic boom, the frequency of default falls sharply compared with the periods of recession. Conversely, the default rate rises again as the economy enters a downturn. Downturns in the credit cycle often uncover the hidden tendency of customers to default together, with banks being affected to the degree that they have allowed their portfolios to become concentrated in various ways (e.g., customer, region, and industry concentrations) [1].

Credit portfolio models are an attempt to discover the degree of correlation/concentration risk in a bank portfolio (see **Portfolio Credit Risk: Statistical Methods**).

The quality of the portfolio can also be affected by the maturities of the loans, as longer loans are generally considered more risky than short-term loans. Banks that build portfolios that are not concentrated in particular maturities—"time diversification"—can

reduce this kind of portfolio maturity risk. This also helps reduce liquidity risk or the risk that the bank will run into difficulties when it tries to refinance large amounts of its assets at the same time.

Credit Derivatives and the ISDA Definition of a Credit Event

With the spectacular growth of the market for credit default swaps (CDSs) (*see Credit Default Swaps*), it has become necessary to be specific about what is a credit event? A credit event, usually a default, triggers the payment on a CDS. This event, then, should be clearly defined to avoid any litigation when the contract is settled. CDSs normally contain a “materiality clause” requiring that the change in credit status be validated by third-party evidence.

The new CDS market has struggled to define the kind of credit event that should trigger a payout under a credit derivatives contract. Major credit events as stipulated in CDS documentations and as formalized by the International Swaps and Derivatives Association (ISDA) are the following.

- Bankruptcy, insolvency, or payment default.
- Obligation/cross default that means the occurrence of a default (other than failure to make a payment) on any other similar obligation.
- Obligation acceleration which refers to the situation where debt becomes due and repayable prior to maturity. This event is subject to a materiality threshold of \$10 million unless otherwise stated.
- Stipulated fall in the price of the underlying asset.
- Downgrade in the rating of the issuer of the underlying asset.
- Restructuring: this is probably the most controversial credit event.
- Repudiation/moratorium: this can occur in two situations. First, the reference entity (the obligor of the underlying bond or loan issue) refuses to honor its obligations. Second, a company could be prevented from making a payment because of a sovereign debt moratorium (City of Moscow in 1998).

One of the most controversial aspects of the debate is whether the restructuring of a loan—which can include changes such as an agreed reduction in

interest and principal, postponement of payments, or change in the currencies of payment—should count as a credit event. The Conseco case famously highlighted the problems that restructuring can cause. In October 2000, a group of banks led by Bank of America and Chase granted to Conseco a three-month extension of the maturity of approximately \$2.8 billion of short-term loans, while simultaneously increasing the coupon and enhancing the covenant protection. The extension of credit might have helped to prevent an immediate bankruptcy, but as a significant credit event it also triggered potential payouts on as much as \$2 billion of CDS.

The original sellers of the CDS were not happy and were annoyed further when the CDS buyers seemed to play the “cheapest to deliver” game by delivering long-dated bonds instead of the restructured loans; at the time, these bonds were trading significantly lower than the restructured bank loans. (The restructured loans traded at a higher price in the secondary market due to the new credit-mitigation features.)

In May 2001, following this episode, ISDA issued a restructuring supplement to its 1999 definitions concerning credit derivative contractual terminology. Among other things, this document requires that to qualify as a credit event, a restructuring event must occur to an obligation that has at least three holders, and that at least two-thirds of the holders must agree to the restructuring. The ISDA document also imposes a maturity limitation on deliverables—the protection buyer can only deliver securities with a maturity of less than 30 months following the restructuring date or the extended maturity of the restructured loan—and it requires that the delivered security be fully transferable. Some key players in the market have now dropped restructuring from their list of credit events.

End Notes

^aIn the following, we use indifferently the term *borrower* or *counterparty* for a debtor. In practice, we refer to issuer risk, or borrower risk, when credit risk involves a funded transaction such as a bond or a bank loan. In derivatives markets, counterparty risk is the credit risk of a counterparty for an unfunded derivatives transaction such as a swap or an option.

^bSettlement failures due to operational problems result only in payment delays and have only minor economic consequences. In some cases, however, the loss can be quite

substantial and amount to the full amount of the payment due. A famous example of settlement risk is the 1974 failure of Herstatt Bank, a small regional German bank. The day it went bankrupt, Herstatt had received payments in Deutsche Mark from a number of counterparties but defaulted before payments were made in US dollars on the other legs of maturing spot and forward transactions.

Bilateral netting is one of the mechanisms that reduce settlement risk. In a netting agreement, only the net balance outstanding in each currency is paid instead of making payments on the gross amounts to each other. Currently, 55% of the foreign exchange (FX) transactions are settled through the CLS Bank that provides a payment-*versus*-payment (PVP) service that virtually eliminates the principal risk associated with settling FX trades [2].

Credit Default Swaps

A credit default swap (CDS) is a contract between two parties, the *protection buyer* and a *protection seller*, whereby the protection buyer is compensated for the loss generated by a *credit event* in a reference instrument (see Figure 1). The credit event can be the default of the reference entity, lack of payment of coupon, or other corporate events defined in the contract. In return, the protection buyer pays a premium, equal to an annual percentage X of the notional, to the protection seller. The premium X , quoted in basis points or percentage points of the notional, is called the *CDS spread*. This spread is paid (semi)annually or quarterly in arrears until either maturity is reached or default occurs.

There are various methods for settlement at default. In a *cash settlement*, the protection seller pays the protection buyer the face value of the reference asset minus its postdefault market value. In a *physical settlement*, the protection buyer receives the initial price of the reference minus the postdefault market value, but, in turn, must make physical delivery of the reference asset or a bond from a pool of eligible assets to the protection seller in exchange for par. In both cases, the postdefault market value of the reference is typically determined by a dealer poll. The contract may also stipulate a fixed or “digital” cash payment at default, representing a fixed percentage of the notional value.

Example A protection buyer purchases 5-year protection on an issuer with notional \$10 million at an annual premium (spread) of 300 basis points or 3%. Suppose the reference issuer defaults 4 months after inception and that the reference obligation has a recovery rate (see **Recovery Rate**) of 45%. Thus, 3 months after inception, the protection buyer makes the first spread payment, roughly equal to $\$10\text{ million} \times 0.03 \times 0.25 = \$75\,000$. At default, the protection seller compensates the buyer for the loss by paying $\$10\text{ million} \times (100 - 45\%) = \5.5 million , assuming the contract is settled in cash. At the same time, the protection buyer pays to the seller the premium accrued since the last payment date, roughly equal to $\$10\text{ million} \times 0.03 \times 1/12 = \$25\,000$. The payments are netted. With these cash flows the swap expires; there are no further obligations in the contract.

CDS contracts are usually documented according to International Swaps and Derivatives Association (ISDA) standards and specify the following:

- A reference entity, whose default (the “credit event”) triggers the default payments in the CDS.
- A reference obligation, which can be a loan, a bond issued by a corporation or a sovereign nation, or any other debt instrument.
- A maturity, the common maturities being 1, 3, 5, 7, and 10 years although the majority of standardized CDSs are 5-year swaps.
- A calculation agent, responsible for computing the payouts related to the transaction. The calculation agent can be one of the counterparties of the CDS or a third party.
- A set of deliverable obligations, in case of physical settlement.

CDSs were introduced in 1997 by JPMorgan and subsequently became the most common form of credit derivative, amounting to a notional value of USD 64 trillion in 2008. With the onset of the financial crisis, this notional volume has gone down to around USD 38 trillion in the first half of 2009, but it remains large.

CDSs are over-the-counter (OTC) derivatives and are not yet exchange traded. The CDS market is a dealer market where a dozen major institutions control an overwhelming proportion of the volume and post quotes for protection premiums on various reference entities.

Uses of Credit Default Swaps

To gain exposure to the credit risk of a firm, an investor can purchase a bond issued by the corporation by paying the face value (or current price) of the bond and collect the interest paid by the issuer. Alternatively, he/she could sell protection in a credit swap referenced on the issuer’s bond. Relative to buying the reference security directly, the CDS position has the advantage of leading to the same exposure but not requiring a capital at inception. Also, if the reference entity is a foreign or sovereign entity, a CDS with a domestic counterparty might greatly simplify the legal structure of the transaction.

The protection buyer is short the credit risk associated with the reference obligation. If the buyer actually owns the reference security, then the CDS

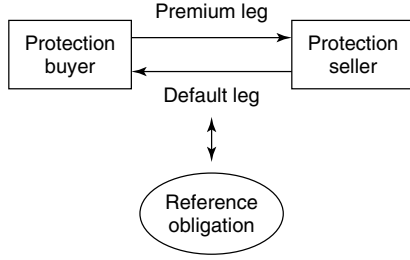

Figure 1 Structure of a credit default swap (CDS)

acts as a hedge against default. For a bank hedging its loans, this can lead to economic and regulatory capital relief. If the buyer does not have exposure to the reference security, the CDS enables him/her to take a speculative short position that benefits from a deterioration of the issuer's creditworthiness.

CDSs are often used to hedge against losses in the event of a default. Thus, CDSs can be viewed as insurance contracts against default or, more generally, as insurance against credit events. However, it is important to note that, unlike the case of insurance contracts, the protection buyer does not need to own the underlying security or have any exposure to it. In fact, an investor can speculate on the default of an entity by buying protection on a reference entity. Thus, they are more like deep out-of-the-money equity puts rather than insurance contracts.

The sheer volume of the CDS market indicates that a large portion of contracts are speculative since, in many cases, the outstanding notional of CDSs is (much) larger than the total debt of the reference entity. For example, when it filed for bankruptcy on September 14, 2008, Lehman Brothers had \$155 billion of outstanding debt, but more than \$400 billion notional value of CDS contracts had been written with Lehman as reference entity [8].

Also, unlike insurance companies, which are required to hold reserves in accordance with their issued insurance claims, a protection seller in a CDS is not required to maintain any reserves to pay off buyers. An important case is the event where a protection seller has insufficient funds to cover the default payment, thereby defaulting on its CDS payment. A famous example is the downfall of AIG, in which CDSs sold by its Financial Products subsidiary (AIGFP) played a major role.

CDSs, like many other credit derivatives, are unfunded and typically do not appear as a liability

on the balance sheet of the protection seller. This off-balance sheet nature makes them attractive to many investors, allowing them to take a synthetic exposure to a reference entity without directly investing in it. However, it can also lead to a lack of transparency and generate large exposures, which are not readily visible to regulators and market participants, and not subject to adequate capital requirements.

Valuation

A basic question is to determine the fair swap spread, or the premium, at inception. The CDS spread must equate the present value at inception of the premium payments (premium leg) and the present value of the payments at default. After inception, the swap must be marked to the market. Arbitrage-free valuation of credit default swaps can be done by using the risk-neutral pricing principle (*see Risk-neutral Pricing*): we assume a pricing measure $\mathbb{Q}$ such that the present value at t of any payout H at $T > t$ is $E^{\mathbb{Q}}[B(t, T)H]$ where $B(t, T)$ is the (risk-free) discount factor.

Consider a CDS with the notional N , payment dates $T_1, T_2, \dots, T_n = T$. Denote the (random) date of the underlying credit event as τ . A key role is played by the conditional risk-neutral survival probability $S(t, T) = \mathbb{Q}(\tau > T | \mathcal{F}_t)$ where $\mathcal{F}_t$ represents information available at date t . We denote $S(T) = S(0, T)$, its value at the inception of the contract. Denote the recovery rate by R , and $\bar{R} = E^{\mathbb{Q}}[R]$, the “implied” recovery rate (*see Recovery Swap*).

The premium leg pays a fixed annual percentage X on the notional N at dates T_i until default: the cash flow at T_i is therefore

$$XN(T_i - T_{i-1})1_{\tau > T_i} \quad (1)$$

The value at inception $t = 0$ of this stream of cash flows is therefore

$$\begin{aligned} & \sum_{i=1}^n XN(T_i - T_{i-1})B(0, T_i)E^{\mathbb{Q}}[1_{\tau > T_i} | \mathcal{F}_0] \\ &= XN \sum_{i=1}^n (T_i - T_{i-1})B(0, T_i)S(0, T_i) \\ &= XN \sum_{i=1}^n (T_i - T_{i-1})D(0, T_i) \end{aligned} \quad (2)$$

where $D(0, T) = B(0, T)S(T)$ is the risky discount factor and we have assumed independence of default times, recovery rates, and interest rates.

The protection leg (or default leg) can be modeled as a lump payment $N(1 - R)$ at T_i if default occurs between T_{i-1} and T_i (alternatively, one can consider other payment schemes such as payment at default [3, 4]). This can be represented as a stream of cash flows $N(1 - R)1_{T_{i-1} \leq \tau \leq T_i}$ paid at T_i . The value at inception ($t = 0$) of this cash-flow stream

$$\begin{aligned} & N \sum_{i=1}^n B(0, T_i) E^{\mathbb{Q}}[(1 - R)1_{T_{i-1} \leq \tau \leq T_i} | \mathcal{F}_0] \\ &= N(1 - \bar{R}) \sum_{i=1}^n B(0, T_i) \mathbb{Q}(T_{i-1} \leq \tau \leq T_i) \\ &= N(1 - \bar{R}) \sum_{i=1}^n B(0, T_i) (S(T_{i-1}) - S(T_i)) \end{aligned} \quad (3)$$

If payments are made at dates other than T_i , then accrued interest must be added. If payment dates are frequent (e.g., quarterly) the correction is small.

The fair spread for maturity T_n (or contracted spread or par spread) is defined as the spread that

equalizes at inception the values of the fixed and protection legs:

$$\begin{aligned} & XN \sum_{i=1}^n (T_i - T_{i-1}) D(0, T_i) \\ &= N(1 - \bar{R}) \sum_{i=1}^n B(0, T_i) [S(T_{i-1}) - S(T_i)] \end{aligned} \quad (4)$$

which yields

$$\begin{aligned} X &= \text{CDS}(T_n) \\ &= \frac{(1 - \bar{R}) \sum_{i=1}^n B(0, T_i) (S(T_{i-1}) - S(T_i))}{\sum_{i=1}^n (T_i - T_{i-1}) B(0, T_i) S(T_i)} \end{aligned} \quad (5)$$

Figure 2 shows the term structure of CDS spreads written on Lehman Brothers in September 2008.

To derive this formula, we have assumed that the firm's default time and recovery rate are independent, that interest rate movements are independent from

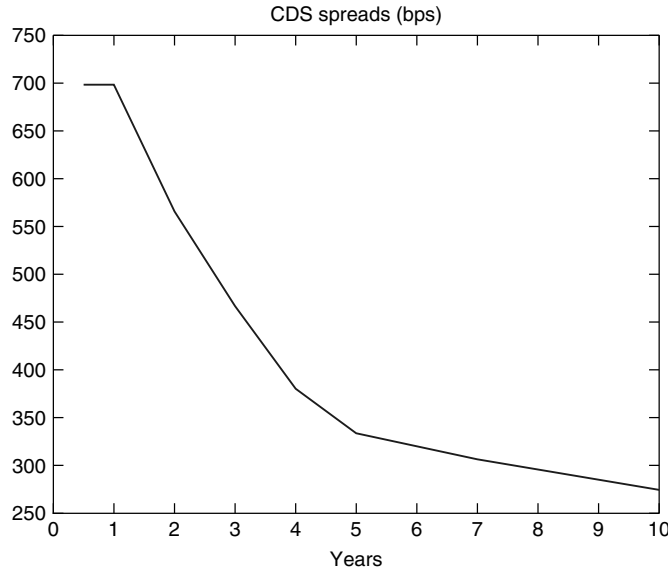

Figure 2 Term structure of CDS spreads on Lehman Brothers on September 8, 2008

default times, and that the protection seller has negligible default probability (no counterparty risk **Counterparty Credit Risk**). All these assumptions can be relaxed, especially in the context of reduced-form (see **Reduced Form Credit Risk Models; Intensity-based Credit Risk Models**) pricing models [3, 5–7]. Hull and White [6] discuss the incorporation of counterparty risk in CDSs. We note that

- CDS spreads depend on the term structure of default probabilities and on the term structure of interest rates, but only through payment dates $T_1, \dots, T_n$: two models that agree on the term structure of default probabilities will agree on CDS spreads.
- CDS spread depends on the recovery rate only through its expectation $\bar{R}$ under the pricing measure $\mathbb{Q}$. In market quotes, $\bar{R}$ has been usually chosen to be 40% for corporates, although this convention is subject to change.

Implied Default Probability

Given an estimate for the expected recovery rate $\bar{R}$ and the term structure of discount factors, one can solve equation (5) for the term structure

of default probabilities given the CDS spreads $\text{CDS}(T_1), \dots, \text{CDS}(T_n)$. The solution $S(T_i)$ is called the *implied survival probability* and $1 - S(T_i)$ is the implied default probability or the “risk-neutral” default probability implied by CDS quotes.

This procedure of inverting survival probabilities from CDS spreads is analogous to the procedure of stripping discount factors/zero coupon bond prices from bond yields (see **Yield Curve Construction**). Note that, as for yield curve construction, there are, in general, many more dates T_i (quarterly payments) than CDS maturities; hence, reconstructing $S(T)$ from CDS spreads requires interpolation or extra assumptions on survival probabilities. For example, survival probabilities are commonly parameterized as

$$S(t, T) = \exp \left[- \int_t^T h(t, u) du \right] \quad (6)$$

where $h(t, T) = -\partial_T S(t, T)/S(t, T)$ is the *forward hazard rate* (defined analogously to the forward interest rate **Heath–Jarrow–Morton Approach**).^a Reduced-form models (see **Reduced Form Credit Risk Models; Intensity-based Credit Risk Models**) lead to parametric functional forms for $h(t, \cdot)$, which can then be used to calibrate parameters to the observed CDS spreads.

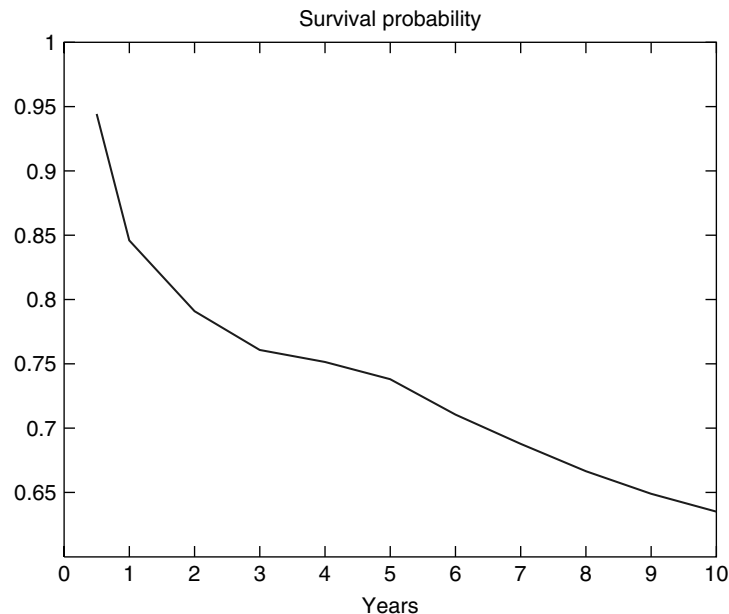

Figure 3 Risk-neutral survival probabilities implied by CDS spreads on Lehman Brothers on September 8, 2008

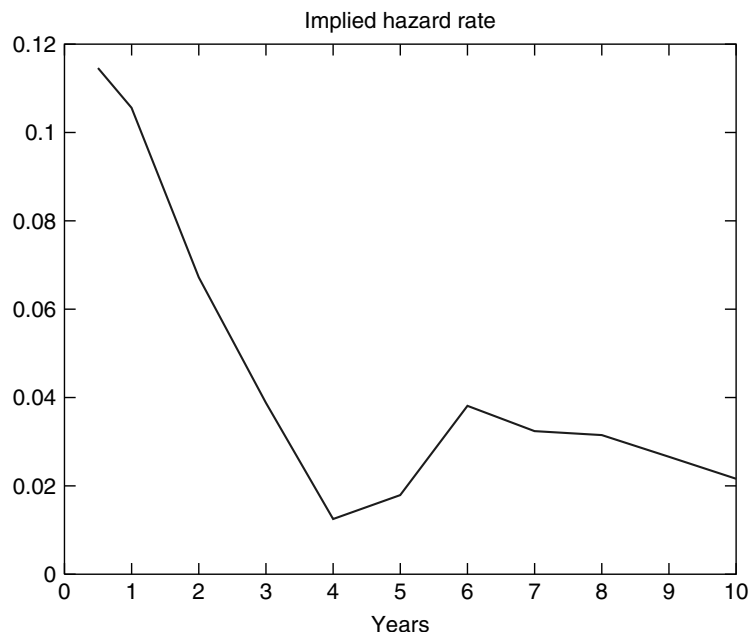

Figure 4 Hazard rates implied by CDS spreads on Lehman Brothers on September 8, 2008

Figure 3 shows survival probabilities for Lehman Brothers implied from CDS quotes on September 8, 2008, shortly before Lehman's default. Assuming that the hazard rate $h(t, T)$ is piecewise linear in T , we obtain the forward (annual) hazard rates shown in Figure 4.

This example might serve as a warning: such implied or "risk-neutral" default probabilities do not necessarily convey any information about the actual likelihood of the default of the reference entity, but they simply convey a market consensus on the premium for default protection at various maturities. Note also that the implied default probabilities and hazard rates depend on the assumption used for recovery rates.

Mark-to-Market Value of a Credit Default Swap (CDS) Position

At inception (say, $t = 0$) the mark-to-market value of a CDS position is zero for both counterparties. At a later date $t > 0$, this value is no longer zero: the mark-to-market value for the protection seller is the difference between the values of the fixed and protection legs:

$$\begin{aligned} & \text{CDS}(T_n)N \sum_{T_i > t} (T_i - T_{i-1})B(t, T_i)S(t, T_i) \\ & - N(1 - \bar{R}) \sum_{T_i > t} B(t, T_i)(S(t, T_{i-1}) - S(t, T_i)) \end{aligned} \quad (7)$$

where the sum runs over the remaining payments and the survival probabilities are now computed at time t . This quantity can be positive or negative, just as in an interest rate swap.

The mark-to-market value of the protection seller's position is the negative of the buyer's value (7). Note that the mark-to-market value (7) can be negative. This occurs when the credit quality of the reference name has improved since inception, and default protection is cheaper at current conditions, that is, available for a lower spread than that agreed upon at inception.

Triangle Formula

Consider now the simple case where the default time is described by a constant hazard rate λ (see **Hazard**

Rate):

$$S(0, T) = \exp\left(-\int_0^T \lambda dt\right) = \exp(-\lambda T) \quad (8)$$

If payments are assumed frequent, $T_i - T_{i-1} = \Delta T \ll T$, we can approximate the terms in equation (5) as

$$\begin{aligned} S(T_{i-1}) - S(T_i) &= -S'(T_i)(T_i - T_{i-1}) + o(T_i - T_{i-1}) \\ &= \lambda S(T_i) \Delta T + o(\Delta T) \end{aligned} \quad (9)$$

So

$$\begin{aligned} &\sum_{i=1}^n B(0, T_i)(S(T_{i-1}) - S(T_i)) \\ &= \sum_{i=1}^n \underbrace{B(0, T_i) S(T_i)}_{D(0, T_i)} \lambda(T_i) \Delta T \\ &\quad + o(1) \xrightarrow{\Delta T \rightarrow 0} \int_0^T dt \lambda \quad D(0, t) \end{aligned} \quad (10)$$

and

$$\sum_{i=1}^n (T_i - T_{i-1}) D(0, T_i) \xrightarrow{\Delta T \rightarrow 0} \int_0^T dt D(0, t) \quad (11)$$

Substituting in equation (5) we obtain the “triangle” relation

$$\text{CDS}(T) = (1 - \bar{R})\lambda$$

$$\text{CDS spread} = (1 - \text{recovery rate}) \times \text{hazard rate} \quad (12)$$

The assumption of a flat term structure of hazard rates is rather crude, but this formula is very useful in practice to get an order of magnitude of the risk-neutral default rate λ from CDS quotes.

Risk Management of Credit Default Swaps

Various factors affect the mark-to-market value of a CDS position. On a day-to-day basis the main concern is *spread volatility*: the value of a CDS position is primarily affected by changes in the CDS spread. Fluctuations in CDS spreads tend to exhibit heavy tails and strong asymmetry (upward moves in spreads have a heavier tail than downward moves) at daily and weekly frequencies. Figure 5 shows the daily returns in the CDS spread of CIGNA Corp. from 2005 to 2009: note the large amplitude of daily returns, which can attain 20% or 30%, especially on the upside. These tails are exacerbated by the relative *illiquidity* of many single-name CDS contracts.

Another concern is obviously the occurrence of the underlying credit event, which results in large payouts, whose magnitude is linked to the recovery rate and is difficult to determine in advance.

To provision for these risks, typically one or both parties to a CDS contract must post collateral and there can be margin calls requiring the posting of additional collateral during the lifetime of the contract, if the quoted spread of the CDS contract or the credit rating of one of the parties changes.

Additionally, as with other OTC derivatives, CDSs are exposed to counterparty risk. The counterparty risk exposure can be particularly large in a scenario where the protection seller and the underlying entity default together. This can happen, for example, if the protection seller has insufficient reserves to cover CDS payments. Counterparty risk affects the CDS spread if the default of the protection seller and the reference entity are perceived to be correlated [6]. The AIG fiasco in 2008 and the default of Lehman exacerbated the market perception of counterparty risk and has since distorted the level of CDS spreads, making it imperative to account for counterparty risk in the risk management of CDS portfolios.

To mitigate counterparty risk in the CDS market, it has been proposed by various market participants and regulators to clear CDS trades in clearinghouses. In a clearinghouse, the central counterparty acts as the buyer to every seller and seller to every buyer, thereby isolating each participant from the default of other participants. Participants post collateral with the central counterparty and are subject to daily margin calls. The introduction of a CDS clearinghouse can also reduce systemic risk resulting from CDS

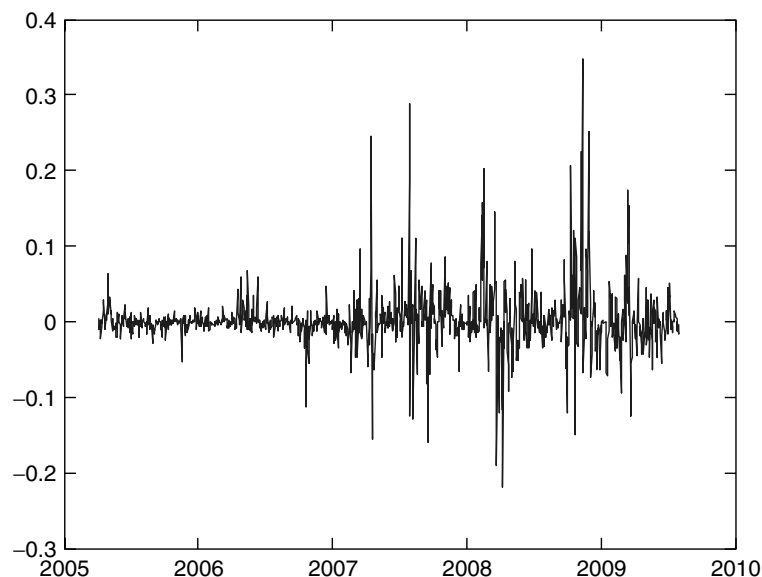

Figure 5 Daily (log-)increments of CDS spreads for CIGNA (CI), 2005–2009

transactions [1]. In the United States the first CDS clearinghouse, ICE Trust, began operating in March 2009. Other proposals to clear credit default swaps have been made by CME, NYSE Euronext, Eurex AG, and LCH Clearnet.

Credit Default Swap (CDS) Basis

An asset swap is a transaction between two parties in which the asset swap buyer purchases a bond from the other party and simultaneously enters into an interest rate swap transaction, usually with the same counterparty, to exchange the coupon on the bond for Libor plus a spread. The spread is called the *asset swap spread*. A common asset swap is the par asset swap where the buyer pays par at the inception of the deal. Unlike a CDS, an asset swap continues following bond default.

The *CDS-Bond basis* is the difference between the CDS spread and the asset swap spread on the same bond. It is an indicator of relative value of CDS *versus* the cash bond [2]. For example, when the CDS spread is higher than the asset swap spread, that is, the basis is positive, the CDS is generally considered to be more attractive than the bond. The reverse is true if the basis is negative. Negative CDS basis has been frequently observed during the recent financial crisis.

Changes in Conventions

Since 2009, the CDS market has been evolving in the direction of trading standardized single-name contracts with an upfront payment and a fixed coupon of either 100 or 500 bp and a common set of coupon payment dates (see www.cdsmodel.com). Standard maturity dates are March/June/September/December 20. Coupon payment dates are like standard maturity dates, but are adjusted to fall on the following business day. Each coupon is equal to $(\text{annual coupon}/360) \times (\text{number of days in accrual period})$. This simplifies processing and computation of coupons and cash flows. For example, every \$10 mm 100 bp standard CDS contract will pay the same 2Q09 coupon, \$26 111, on Monday, June 22, 2009, regardless of trade date, maturity, or reference entity.

The upfront payment is then set at the inception such that the buyer and seller positions have the same present value. In this convention, the dealer will quote not a spread (which is fixed) but an upfront payment. This convention applies to standardized CDS contracts on names contained in CDX and ITRAXX indices and may set the example for all other CDS contracts in the future.

End Notes

^a.Not to be confused with the (instantaneous) hazard rate or the default intensity (see **Hazard Rate**).

Total Return Swap

A total return swap (TRS) is a financial contract between two counterparties to synthetically replicate the economic returns of an underlying asset. The principal mechanism and interaction are shown in Figure 1.

The reference asset still belongs to the TRS payer, who is buying protection from the TRS receiver. This reference asset contains typically a fixed interest payment and experiences a certain credit risk to be protected. The TRS payer transfers any payment made by the reference asset to the TRS receiver, who conversely pays a variable payment (typically the London interbank offered rate (LIBOR)) and a positive (or negative) spread as risk premium. Additionally, settlements for price depreciation and appreciations of the reference asset are made between the counterparties.

The TRS payer thus sells the market and credit risk of the reference asset to the TRS receiver without selling the reference asset itself. In the case of a credit event, the TRS receiver pays the difference between the value of the reference asset and the recovery value to the TRS payer. He acquires the counterparty risk of the TRS receiver instead.

Note that payments are not made continuously but rather at discrete times, that is, at given and specified reset periods. Occasionally, the reference asset consists of a whole portfolio of assets.

Reasons for Investing in a Total Return Swap

The TRS receiver explores the possibility of investing in the risk profile of the reference asset without owning it legally. Thus, insurance companies, hedge funds, and so on, count among the typical investors. They aim to work on a leveraged basis, diversify their portfolio, and achieve higher yields by taking on risk exposure. They can explore a synthetic way to make loans without having the costs and administrative burden; they explore possibilities to originating credit. Sometimes, for certain investors with capital constraints, TRS may be an effective way to leverage the use of capital.

TRS payers are typically lenders and investors who want to reduce their respective exposure to the

given borrower and potentially diversify a concentrated portfolio without removing the asset itself from their balance sheet, while maintaining the relationship with the borrower. However, TRS payers do not have to hold the asset itself on their balance sheets. If a TRS payer is taking an outright position, i.e. without holding the asset itself on the balance sheet, a TRS is an efficient way to go the asset short synthetically.

A TRS can help to activate comparative advantages of financing, depending on whether a certain market plays a role in a certain part of the market. Typically, a TRS is an off-balance-sheet deal.

Comparison with an Outright Investment in the Bond

The most striking difference from an outright investment in a bond or a loan is that with a TRS, price changes become cash flows at the predefined reset periods, at which settlements are made. For a bond, they are only accounting profits or losses and become effective at maturity or when the position is unwound. Thus, the TRS resembles a futures contract whereas the direct investment is more similar to a forward one (see, e.g., Schönbucher [3]).

Valuation and Risk Management

Schönbucher [3] gives an indication about the payoff streams of a TRS from the point of view of the TRS receiver to be counted for valuation purposes:

- Initially the TRS is closed at a fair value; hence, no cash flow is proceeded.
- If the bond does not default, the TRS receiver pays a variable coupon plus (or minus) a spread at every predefined reset point; he receives the interest from the bond and the difference in market value of the bond since the last reset is exchanged.
- If the bond defaults, the TRS receiver pays for a last time the variable coupon plus (or minus) a spread and the difference between the last market value of the bond and its recovery.

Thus, several risk factors influence the value of the TRS: the interest rate risk driven by the changing yield curve and the default probability of the

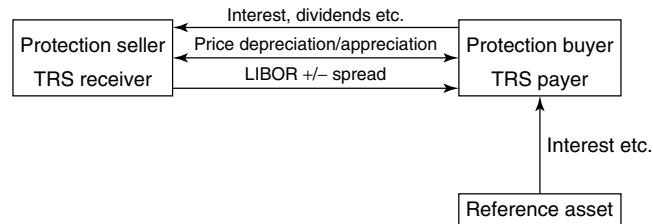

Figure 1 Mechanism of a total return swap (see Martin *et al.* [2])

reference asset (we neglect, for instance, the counterparty risk). Typical valuation models include the Duffie–Singleton model, hazard rates, and forward measure. The credit risk is reflected in the fair spread (fair means that initially there has to be no cash flow) (see also Anson *et al.* [1]).

Recovery Swap

A recovery swap (RS), also called a *recovery lock* or a *recovery default swap* (RDS), is an agreement to exchange a fixed recovery rate R_S for the realized recovery rate ϕ , the latter being determined under prespecified contractual terms. The fixed recovery rate may be specified in terms of a recovery of par amount (RP), or as the recovery percentage of an equivalent Treasury bond, known as *recovery of Treasury* (RT), or as a fraction of the market value of the bond prior to default, also known as *recovery of market value* (RMV).

A recovery swap is no different than a forward contract at rate R_S on the underlying recovery rate ϕ . The maturity of the contract is denoted as T . If the reference credit underlying the recovery swap does not default before T , the swap expires worthless. There are no intermediate or periodic cash flows in a recovery swap. In a liquid market for recovery swaps, the quoted rate R_S is the best forecast of the expected recovery rate for default at time T . This recovery rate may then be used to price credit default swaps (CDSs).

We assume that the buyer of the recovery swap will receive R_S and pay ϕ . Hence, the buyer gains when the realized recovery rate is lower than that of the strike rate R_S . The net payoff to the contract is $(R_S - \phi)$. Recovery swaps are quoted in terms of the “strike” rate R_S . For example, a dealer might quote a recovery swap in GM at 37/40. This means the dealer is prepared to sell a recovery swap with $R_S = 37\%$ and buy at $R_S = 40\%$.

Replication and No-arbitrage

A recovery swap may be synthesized by selling a fixed recovery CDS (also known as a *digital default swap* or DDS) at a predetermined recovery rate R_D and buying a standard CDS. When the reference name defaults, the seller of the DDS pays the loss amount on default $(1 - R_D)$ and receives $(1 - \phi)$ on the CDS, thereby generating cash flow $(R_D - \phi)$. There is a triangular arbitrage restriction between the three securities: RS, DDS, and CDS. If we hold 1 unit each of the RS, CDS, and DDS, then we would need that $R_S = R_D$.

In order to state the triangular arbitrage relation more generally, consider the case when $R_S \neq R_D$, that is, when the strike recovery rates of the recovery swap and DDS are not the same. Let the premium on the CDS be c_1 and the premium on the DDS be c_2 . In order to replicate the RS, we will hold x units of the CDS and y units of the DDS. The replication has two conditions:

1. The cashflows at default must be equal for the RS and the replicating portfolio of CDS and DDS. In other words,

$$x \cdot (1 - \phi) - y \cdot (1 - R_D) = R_S - \phi \quad (1)$$

2. The premiums of the replicating portfolio must be net zero as the recovery swap does not have any intermediate cash flows. Hence the following equation must hold:

$$y \cdot c_2 - x \cdot c_1 = 0 \quad (2)$$

Set $x = 1$ in equation (1) so as to eliminate dependence on ϕ in the equation. Then we have that

$$x = 1 \quad \text{implies} \quad y = \frac{1 - R_S}{1 - R_D} \quad (3)$$

Substituting this result for x, y in equation (2) results in the following:

$$\frac{c_1}{c_2} = \frac{1 - R_S}{1 - R_D} = \frac{\mathcal{L}_S}{\mathcal{L}_D} \quad (4)$$

where $\mathcal{L}$ denotes the loss rate. We note the following:

- The no-arbitrage condition in equation (4) between the three securities implies that the ratio of the premium on the CDS to the premium on the DDS is equal to the ratio of loss rates on the recovery swap and the digital CDS. This is because the quote on the recovery swap R_S is the expected recovery rate on the CDS contract.
- It follows immediately that if R_D is specified, then equation (4) mandates a precise relation between the quotations on the three types of contracts, that is, rate R_S for the recovery swap, premium c_1 on the CDS, and premium c_2 on the DDS. Given the quotes on any two of these securities, the quote on the third security is immediately obtained.

- These no-arbitrage based results do not depend in any way on the underlying process for default or that of recovery. This makes the relationships in equation (4) very general and easy to apply in practice, as well as easy to assess empirically for academic purposes.

Applications and Uses of Recovery Swaps

Recovery swaps were first developed by BNP Paribas in early 2004 [10]. In response to market demand, banks started issuing fixed-rate recovery collateralized debt obligations (CDOs) and as a consequence were bearing recovery rate risk. In order to hedge against this recovery rate risk, market participants started selling recovery swaps.

Recovery swap markets are predominantly traded on reference entities with a high risk of default or of declining credit quality. For this reason, the largest activity in the recovery swaps market is in the auto parts and auto manufacturing sectors and geographically on North American entities [7]. Trading volumes in recovery swaps, although still small relative to the overall credit derivatives market, increased in 2005 with the defaults of Delphi Corporation and the Collins & Aikman Corporation [7]. Still, the market remains largely undeveloped and the International Swaps and Derivatives Association (ISDA), in May 2006, issued a template for the documentation on recovery swaps but the full documentation remains to be completed at this time [13].

There are two primary uses of recovery swaps. The first is to isolate the probability of default from the recovery rate. Traders may have in-house expertise in determining default probabilities but not in determining recovery and thus may wish to hedge their recovery risks through recovery swaps. The second use of recovery swaps is to eliminate recovery basis risk. Recovery basis risk occurs because of different settlement procedures between CDSs and CDOs. CDSs are often settled physically, meaning that when default occurs the seller of protection receives the defaulted bonds, whereas CDOs are almost always cash settled. The difference in settlement procedures is the source of recovery basis risk. For instance, an investor might hold a CDS Index that includes a given reference entity and have an offsetting position by selling the single-name CDS of the same entity. The investor is hedged

against the default risk of this entity, but because of differences in settlement at default between the CDS Index and the single-name CDS, the investor might get different recovery rates on the two instruments (recovery basis risk). Hence, recovery swaps can hedge against recovery basis risk by locking-in recovery rates.

Furthermore, in the case where the CDSs specify a physical settlement, it is possible that the underlying bonds might be scarce compared to the notional amount of CDS traded on the bond. This causes a “delivery squeeze” where the price, and therefore the recovery of the bond, is artificially increased because the buyers of CDS need to buy the bonds for delivery to their counterparty. For instance, in October 2005, Delphi Corporation had \$27.1 billion of outstanding CDSs against notional outstanding bonds of just \$2 billion causing the price of the defaulted bonds to surge by as much as 24% [9]. The consequence of this delivery squeeze is to reduce the profits accruing to buyers of CDSs, and recovery swaps provide a hedge against this by locking in the recovery rate ahead of time. More recently though, most CDSs are being settled in cash, thereby circumventing this problem.

Recovery Risk

There is a growing literature on recovery risk. Berd [3] provides a nice introduction and analysis of recovery swaps. DDSs are analyzed in [4]. Altman *et al.* [2] present a detailed study showing how recovery rates depend on default rates, positing and finding an inverse relationship. Chan-Lau [6] presents a method to obtain the upper bound on recovery on emerging market debt. Das and Hanouna [8] develop a methodology for identifying implied recovery rates and default probabilities from CDS spreads and data on stock prices and volatilities. Acharya *et al.* [1] provide empirical evidence that recovery rates depend on the industry, state of the economy, and specificity of assets to the industry in which the firm operates. Carey and Gordy [5, 14] show that recovery has systematic risk. Guo *et al.* [11] look at recoveries in reduced form models by explicitly modeling the postbankruptcy process of recoveries. The well-known loss given default model of Gupton and Stein [12] is well liked and used. Absolute priority rule (APR) violations are modeled in [15]. For a nice overview, see [16].

Constant Maturity Credit Default Swap

A constant maturity credit default swap (CM CDS) is a credit derivative with payments linked to periodic fixings of a standard CDS rate with a fixed tenor (e.g., 5 years) on a particular credit entity. In business practice, CM CDS is usually presented as an elaboration of a plain CDS suitable for use in trading strategies expressing certain views on the steepening or flattening of credit spreads. From the point of view of quantitative modeling, CM CDS is best understood as a simple representative of a family of structured credit exotics, more complicated members of which would depend on a nonlinear combination of CDS spreads of more than one maturity and/or refer to more than one credit entity. Both business practice and quantitative modeling of CM CDS are based on ideas and techniques originally developed for CMS-linked fixed income exotics and adapted to credit modeling.

Instrument Structure

A CM CDS trade usually consists of two legs, one of which is a CM CDS leg, which is a sequence of payments $P_1, P_2, \dots, P_n$ made on a schedule of payment dates $T'_1, T'_2, \dots, T'_n$ (which is typically set following conventions of a standard CDS schedule) and is computed by the following formula:

$$P_i = \Delta_i \min[C, a \cdot S(T_i, T_{i+M})] \quad (1)$$

Here $S(T_i, T_{i+M})$ is the rate of a CDS spanning M payment periods and observed at the fixing date T_i associated with the payment date T'_i , Δ_i is the daycount fraction for the accrual period i , a is the multiplier called *participation rate*, and C is the fixed rate reset cap.^a Notional amount of the trade is set to 1. The fixing normally happens at the beginning of the accrual period, so that $T'_i = T_{i+1}$.^b In the case of a default of the reference credit, the fraction of the last payment accrued before the default is paid and further payments stop.

The second leg of a CM CDS is normally a standard CDS protection leg; however, structures where the second leg is either a standard CDS premium leg or another CM CDS leg corresponding

to a different tenor are also possible. The quote for a CM CDS is usually given in terms of the participation rate, a , of the CM CDS leg. With the second leg being the standard CDS protection leg, a participation rate of less than 100% reflects the expectation of rising credit spreads, whereas a participation rate of more than 100% corresponds to the expectation of decreasing credit spreads.

Trading Aspects

Descriptions of CM CDS structures started circulating in research communications of securities firms in early 2004, [3, 5, 6]. On November 21, 2005, ISDA provided a publication [4] setting a standard for the terms and condition of the CM CDS leg, including a mechanism for the determination of CDS rate resets. Establishing undisputable resets for CDS rates presents a problem because no standard source of information on CDS rates similar to Telerate pages of interest rates has emerged.

The primary mechanism stipulated by ISDA compels the seller of protection in a CM CDS to make a binding bid for the fixed rate premium that the seller is willing to pay in exchange for protection in a standard CDS on the same credit entity. This bid will be used as a CDS rate reset and is expected to be a good proxy for the true CDS rate because the seller has no incentive to quote a value that is too high (in which case the seller can be forced to buy overpriced CDS protection) or too low (in which case the seller will lose on the coming CM CDS payment). A fallback mechanism, which comes into effect if the receiver fails to provide a bid, puts on the buyer the burden of obtaining CDS quotes from a set of fallback dealers, subsequently using the highest quote as the rate reset.

At the time of this study, the volume of CM CDS transactions remains limited, taming optimistic predictions for the development of multilayered structures, such as tranches of CM CDS portfolios, but not destroying such prospects completely. We also note that more exotic structures with payoffs linked to nonlinear combinations of CDS rates of different maturities were observed in the market and have potential for further growth.

Quantitative Modeling

The present value of a CM CDS leg is given by the sum of expectations of the payments (1) discounted

under risk-neutral measure:

$$V = \sum_i \Delta_i E[\min[C, a \cdot S_{T_i}(T_i, T_{i+M})] P_{T'_i} D(0, T'_i)] + A \quad (2)$$

$$A = \sum_i \sum_{T'_{i-1} < \tau'_k \leq T'_i} \Delta(T'_{i-1}, \tau'_k) \times E[\min[C, a \cdot S_{T_i}(T_i, T_{i+M})] \times (P_{\tau'_{k-1}} - P_{\tau'_k}) D(0, \tau'_k)] \quad (3)$$

Here $P_{T'_i}$ is the indicator of survival of the underlying name until time T'_i , and $D(0, T'_i)$ is the stochastic discount factor from 0 to T'_i . We equipped the notation $S_{T_i}(T_i, T_{i+M})$ for the CDS rate reset with a subscript T_i to indicate that this rate is modeled as a value at time T_i of a certain stochastic process. The contribution A of the interest accrued within the period of time $\Delta(T'_{i-1}, \tau'_k)$ between the last coupon payment and the time of default is written in a discretized form using a sufficiently frequent subdivision $\{\tau'_k\}$ of the segment $[T'_{i-1}, T'_i]$.

We consider major types of modeling approaches in the order of increasing sophistication, including the nonstochastic approximation, convexity adjustments, instantaneous hazard rate modeling, and forward credit spread modeling.

Nonstochastic Approximation

We can obtain a simple approximation assuming that the CDS rates are nonstochastic. In this approximation, each process $S_t(T_i, T_{i+M})$ of the expectation of the time T_i CDS rate reset conditional on the information accumulated until time t is frozen at $t = 0$. As a result, the relevant CM CDS rate at date T_i is equal to the forward CDS rate $F(T_i, T_{i+M})$, which can be expressed in terms of the survival probability function, $p_s(t) = E[P_t]$, and the deterministic discount function, $D_0(t) = E[D(0, t)]$,

$$F(T_i, T_{i+M}) = \frac{(1 - R) \sum_{T_i < \tau_j \leq T_{i+M}} (p_s(\tau_{j-1}) - p_s(\tau_j)) D_0(\tau_j)}{\sum_{j=i+1}^{i+M} (\Delta_j p_s(T_j) D_0(T_j) + A_j)} \quad (4)$$

$$A_j = \sum_{T_{j-1} < \tau_k \leq T_j} \Delta(T_{j-1}, \tau_k) \times (p_s(\tau_{k-1}) - p_s(\tau_k)) D_0(\tau_k) \quad (5)$$

Here R is the recovery rate and $\{\tau_j\}$ is a subdivision of the segment $[T_i, T_{i+M}]$, sufficiently frequent to enable an accurate calculation of the default leg and the contributions A_j of the premium accrued in the time $\Delta(T_{j-1}, \tau_k)$ between the last CDS coupon date and the event of default.^c

The value of a CM CDS leg obtained by setting $S_{T_i}(T_i, T_{i+M}) \rightarrow F(T_i, T_{i+M})$, $P_{T'_i} \rightarrow p_s(T'_i)$, and $D(0, T'_i) \rightarrow D_0(T'_i)$ in equations (2–3) gives a quick estimate sufficient for a qualitative understanding of the relationship between the term structure of CDS spreads and the CM CDS participation rate but missing the essential effects of the dynamics of credit spreads. Indeed, even apart from the obvious problem of not handling the cap condition, the expectation $E[S_{T_i}(T_i, T_{i+M}) P_{T'_i} D(0, T'_i)]$ can be very different from $F(T_i, T_{i+M}) p_s(T'_i) D_0(T'_i)$ when credit spread volatility is taken into account.

Convexity Adjustments

In this section a discussion on volatility-dependent corrections to the results obtained in the nonstochastic approximation is provided. Such correction can be either derived from a fully consistent model capable of computing $E[S_{T_i}(T_i, T_{i+M}) P_{T'_i} D(0, T'_i)]$ or introduced in an *ad hoc* manner. We begin by looking at the convexity adjustments in the more limited sense of instrument-specific adjustments without building a full-fledged model. In the remainder of this article, we omit the discussion of the accrued interest term A and focus on the main term in equation (2).^d

The first step is to switch to a new measure in which the process $S_t(T_i, T_{i+M})$ is a martingale. The numeraire $N_t(T_i, T_{i+M})$ of the desired measure is known as the *risky basis point value (RBPV)* and is given as

$$N_t(T_i, T_{i+M}) = P_t \sum_{j=i+1}^{i+M} \left(\Delta_j B_t(T_j) + \sum_{T_{j-1} < \tau_k \leq T_j} \Delta(T_{j-1}, \tau_k) H_t(\tau_{k-1}, \tau_k) \right) \quad (6)$$

where $B_t(T_j)$ is the time t value of a risky unit payment at T_j and $H_t(\tau_{k-1}, \tau_k)$ is the time t value of a unit payment at τ_k conditional on a default event in the interval $(\tau_{k-1}, \tau_k]$. We used a discretized form of the accrued interest consistent with equation (3).

The existence of the required measure follows from a representation of the CDS rate as a ratio of two tradable assets:

$$S_t(T_i, T_{i+M}) = L_t(T_i, T_{i+M})/N_t(T_i, T_{i+M}) \quad (7)$$

where $L_t(T_i, T_{i+M})$ is the time t expectation of the CDS default leg,

$$L_t(T_i, T_{i+M}) = (1 - R)P_t \sum_{T_i < \tau_k \leq T_{i+M}} H_t(\tau_{k-1}, \tau_k) \quad (8)$$

(For a rigorous discussion of the mathematics of measure change involving risky basis point value as a numeraire, see [8].) After the measure change, the contribution of each individual coupon payment to the CM CDS leg can be written as

$$\Delta_i N_0(T_i, T_{i+M}) E \left[\frac{B_{T_i}(T'_i)}{N_{T_i}(T_i, T_{i+M})} f(S_{T_i}(T_i, T_{i+M})) \right] \quad (9)$$

where $f(X) = \min(C, aX)$. The next step is to assume that S_t follows a lognormal martingale, $F \exp(\sigma W_t - 0.5\sigma^2 t)$, and to replace the true value of the ratio $B_{T_i}(T'_i)/N_{T_i}(T_i, T_{i+M})$ by the value of a suitable increasing function $g(S)$ at $S = S_{T_i}$. Imposing the condition $N_0(T_i, T_{i+M})g(F(T_i, T_{i+M})) = p_s(T'_i)D_0(T'_i)$ ensures that the calculation of the average (9) for $\sigma = 0$ brings us back to the nonstochastic valuation. A nonzero volatility $\sigma > 0$ leads to a positive correction due to the convexity of the product $g(S)f(S)$ in the region of values of S close to $F(T_i, T_{i+M})$ and distant from the cap C .

This approach has an advantage of relative simplicity and potential ability of calibrating the model volatility σ to CDS options. The disadvantage is an uncontrollable assumption in the choice of the function $g(S)$.

Instantaneous Hazard Rate Modeling

A more systematic modeling of CM CDS is possible in the framework of stochastic instantaneous hazard rates. This approach starts with postulating a stochastic differential equation (SDE) for the stochastic default intensity $\lambda(t)$. A reasonable choice is a lognormal process (similar to the Black–Karasinski model of interest rates) or an affine process (similar to the Cox–Ingersoll–Ross model of interest rates). A normal process (similar to the Hull–White model of interest rates) was also used despite a conceptual problem posed by positive probabilities of negative hazard rates. Multifactor models for joint stochastic evolution of hazard rates and instantaneous interest rates are also possible.

An exact analytical solution for a CM CDS is not available in any of these models because of a two-layered structure involving inner expectations for CDS rates fixings conditional on the state achieved on the fixing dates. The machinery of trees, lattices, or partial differential equation (PDE) solvers, however, can be accommodated to handle CM CDS structures. The key element is a construction of a slice of values of CM CDS rate fixings on the set of model states achieved on the fixing date. This is done using a representation of the CDS rate in terms of conditional expectations of elementary instruments $B_t(T)$ and $H_t(T_1, T_2)$ provided by equations (7), (6), and (8). We refer to Chapter 7 of the book [7] for the details of a possible realization of a tree-based construction.

An advantage of hazard rate modeling is its consistency that allows to price a wide range of credit instruments of different maturities, including CDS options, asset swaps, bond options, and credit linked notes using the same model. A notable disadvantage is the difficulty of calibration.

Forward Credit Spread Modeling

As drawbacks of short-rate models of interest rates led to the invention and development of swap and LIBOR market models, similar progression is taking place in the space of structured credit models. We refer to the work [1] and Chapter 23 of [2] for details of a model in which the CDS rates $S_t(T_i, T_{i+M})$ are chosen as primary variables.

An advantage of this approach is the ease of calibration and ability to derive efficient analytical

approximations under minimal additional assumptions. At present, the disadvantage is the paucity of relevant market data, leaving a large freedom in specifying the structure of volatilities and correlations. A full payback from this level of model sophistication cannot be expected until the market for structured products develops enough to provide liquid quotes for CDS option volatilities for a dense set of maturities, similarly to caplet and swaption volatility matrices in the interest rate markets.

End Notes

^a. The structure can obviously be extended to admit a fixed rate reset floor, which, however, is not included in the standard ISDA template.

^b. The actual payment dates T_i' usually have a delay of at least one business day and are rolled forward or backward to fall on a valid business day in accordance with currency-dependent conventions. In the practice of quantitative modeling, proper care is taken to make sure that correct discount factors reflecting the actual payment dates are used.

^c. These expressions are often written in terms of integrals obtained in the limit of an infinitely frequent discretization. The same remark applies to equation (3).

^d. A rigorous calculation of the convexity correction to accrued interest term is technically involved and can be avoided by using a proportionally adjusted correction to the main term.

TIMUR S. MISIRPASHAEV

Credit Default Swaption

Credit default swap (CDS) options, also known as *single name credit default swaptions*, allow an investor to buy protection on a reference name by entering a CDS (*see Credit Default Swaps*) at a previously set CDS spread. CDS options may knock out if the reference entity defaults before the exercise date. Usually, the buyer of protection will also receive the default payment in that case. Such a cash flow simply corresponds to the default leg of a CDS with maturity equal to the exercise date. We will thereafter assume cancellation of the contract if the underlying name defaults before the exercise date. We refer to **Credit Default Swap Index Options** for the extensions to the portfolio case.

Denote the default time associated with the underlying name by τ . This is usually the date of a credit event; we refer to ISDA master agreement for further details, given that this notion may vary through time and differ across geographical regions. For $t \leq s$, we denote by $\tilde{B}(t, s)$ the time t price of a defaultable discount bond, paying one at time s if $\tau > s$ and zero otherwise. Clearly, $\tilde{B}(t, s)$ collapses to zero at the default of the underlying name if it occurs before s , since no payment will eventually be received by the discount bond holder. $T_1, \dots, T_N$ denote the payment dates on the premium leg of the underlying CDS. For simplicity, we will further neglect effects of accrued premiums. T is the exercise date of the European credit spread call option and p the strike. We can write the payoff at time T as $(p_T - p)^+ \sum_{T_k > T} \tilde{B}(T, T_k)$. p_T is the CDS par spread at time T . There is also usually a multiplicative adjustment to take into account the premium payment frequency, which is quarterly in most cases and which is not dealt with here for notational simplicity. For the same reason, we do not account for a possible up-front payment associated with the CDS, which is likely to be applied after the implementation of the “big bang” CDS protocol. That will result in some small adjustments to the payoff function and thus to the pricing formulas, which will be neglected thereafter. Clearly, p_T is not defined if the option has already cancelled out, that is, if $\tau < T$, but the option payoff is equal to zero in that case.

Pricing Approaches

With some adaptations due to the cancellation feature of the CDS option, the pricing methodology parallels the well-known approaches in interest rate swaptions. One may consider a suitable distribution of the forward CDS spread under an appropriate risk-neutral measure. This readily leads to a Black-type pricing formula and is dealt with first. In another approach, one can rather model the “instantaneous” CDS spread, which is related to the “intensity” of the default time.

Black Formula for Credit Default Swap Options

As usual r denotes the default-free short rate and Q is the usual risk-neutral probability associated with the savings account. We consider $G = (G_t)$, a filtration such that τ is a stopping time and r is an adapted process.

The idea of using “survival measures” was introduced in [9] and further developed in [4, 6, 7, 10], among others (*see also Credit Default Swap Index Options*). We will denote by $\sum_{T_k > T} \tilde{B}(t, T_k)$ the “risky level” which corresponds to the time t price of a unitary premium leg associated with the forward CDS starting at T . We consider the probability measure $\hat{Q}$ associated with the previous risky level numéraire (*see also Change of Numéraire* about change of numéraire techniques) defined by

$$\frac{d\hat{Q}}{dQ} = \frac{\sum_{T_k > T} \tilde{B}(T, T_k)}{\sum_{T_k > T} \tilde{B}(0, T_k)} \exp - \int_0^T r(u) du \quad (1)$$

Let us remark that $\frac{d\hat{Q}}{dQ} = 0$ on the set $\{\tau \leq T\}$. Thus $\hat{Q}$ is absolutely continuous but not equivalent to Q . $\hat{Q}(\tau > T) = 1$ which leads to the terminology “survival measure”. We can then readily express the value of the credit spread option at $t = 0$ as

$$\left(\sum_{T_k > T} \tilde{B}(0, T_k) \right) E^{\hat{Q}} [(p_T - p)^+] \quad (2)$$

We can get around the issue of the CDS premium p_T not being defined *after default* by considering $p_T 1_{\{\tau > T\}}$, which we assume to be a random variable

with respect to G_T . This does not change the computation in the previous equation since $\hat{Q}(\tau > T) = 1$.

Let us first remark that for the forward CDS to be priced normally, we must have $E^{\hat{Q}}[p_T 1_{\{\tau > T\}}] = p_{0,T}$ where $p_{0,T}$ denotes the forward CDS premium. In the case where $p_T 1_{\{\tau > T\}}$ is lognormal under $\hat{Q}$, with volatility parameter σ , we readily get a Black formula for the price of the CDS option:

$$\left(\sum_{T_k > T} \tilde{B}(0, T_k) \right) \times (p_{0,T} N(d_1) - p N(d_2)) \quad (3)$$

where $d_1 = \frac{\ln\left(\frac{p_{0,T}}{p}\right) + \frac{\sigma^2}{2}T}{\sigma\sqrt{T}}$ and $d_2 = d_1 - \sigma\sqrt{T}$.

Intensity Approaches

Another approach consists in specifying the intensity of the default time. This is the path followed in [2–4]. To circumvent the difficulty with default intensity dropping down to zero after default and the various mathematical issues related to enlargement of filtrations, the easiest way is to model the default time through a Cox process. We thus define the default time τ associated with the underlying name as

$$\tau = \inf \left\{ t, \int_0^t \lambda(s) ds \geq -\ln U \right\} \quad (4)$$

where λ is a positive process adapted to some filtration $\mathfrak{F} = (\mathfrak{F}_t)$ and U follows a standard uniform variable independent of $\mathfrak{F}$. For simplicity, we will further assume that $(\mathfrak{F}, Q)$ is a Brownian filtration. Following [1] or [8], we define as $H = (H_t)$ the filtration generated by the counting process $N_t = 1_{\{\tau \leq t\}}$ and we denote by $G_t = \mathfrak{F}_t \vee H_t$, the relevant information at time t , incorporating knowledge about occurrence of default prior to t and current and past values of financial variables such as interest rates or credit spreads of the reference entity (see **Filtrations** for mathematical details about filtrations in finance). Up to default time, $\lambda(t)$ is the default intensity of τ (we refer to **Point Processes** regarding point processes and to **Compensators** about compensators and intensities). While the default intensity drops to zero after τ , we can remark that $\lambda(t)$ is still well defined, thanks to the above Cox modeling framework. For instance, one can consider shifted Cox–Ingersoll–Ross (CIR) processes for the

short rate r and the pseudodefaut intensity λ (see **Cox–Ingersoll–Ross (CIR) Model**).

$p_{t,T}$ will further denote the time t forward CDS premium. Though $p_{t,T}$ has a financial meaning only on the set $\{\tau > t\}$, its computation can be extended to the complete set of events in the previous Cox modeling framework (see [4] for further discussion). $p_{t,T}$ solves for the following equation where, once again, we do not take into account accrued premium or up-front payments effects

$$\begin{aligned} p_{t,T} \times \sum_{T_k > T} E \left[\left(\exp - \int_t^{T_k} (r + \lambda)(u) du \right) | \mathfrak{F}_t \right] \\ = \int_T^{T_N} E \left[\left(\exp - \int_t^s (r + \lambda)(u) du \right) \right. \\ \left. \times (1 - \delta)\lambda(s) | \mathfrak{F}_t \right] ds \end{aligned} \quad (5)$$

Prior to default, the left-hand term corresponds to the value at time t of the premium leg of the underlying forward default swap, while the right-hand term is associated with the default leg. Clearly $p_{t,T}$ is $\mathfrak{F}_t$ -measurable and we can prove that it is both a $(\mathfrak{F}, \hat{Q})$ and a $(G, \hat{Q})$ martingale. Thus, the forward default swap premium shares the properties of a “true” price. It can be checked that $p_{T,T} = p_T$.

Using an extended version of Girsanov theorem (see **Equivalence of Probability Measures**) for point processes (see **Point Processes**), it can be shown that

$$\frac{dp_{t,T}}{p_{t,T}} = \sigma d\hat{W}_t \quad (6)$$

where $\hat{W}$ is a $(\mathfrak{F}, \hat{Q})$ Brownian motion.

Let us also assume that there exists some specification of r and λ such that the volatility σ is constant. Then, the forward CDS spread has a lognormal dynamics under $\hat{Q}$. This readily leads to the already stated Black formula for the price of the CDS option. The most obvious advantage is the simplicity of the outcome. The drawbacks are also rather obvious. The lognormal assumption for the forward spreads is questionable since jumps are often included in the dynamics of λ as in the affine specification within [5].

The intensity approach is easy to understand and is consistent across strikes, maturity of the option, and maturity of the CDS. However, it entails dealing with extra parameters and is numerically more involved. In the more general setting involving correlation between r and λ , Monte Carlo simulation is usually required. In special cases, such as deterministic default-free rates, analytical formulas can be derived. Fortunately enough, in most examples, the correlation parameter has little impact on option prices and analytical approximations of the implied volatility in the Black formula can be derived. Let us remark that in these approximations σ depends on the exercise date and the maturity of the underlying CDS.

Credit Default Swap (CDS) Indices

Credit markets have shown tremendous growth in the last 10 years. In particular, the telecom bubble and corporate scandals of the early 2000s increased the interest of market participants in products such as credit default swaps (CDS) (*see Credit Default Swaps*), which provide protection against credit events. In response to this demand for credit protection, credit indices were introduced in 2003, increasing the liquidity of CDS markets. These indices are, in essence, standardized baskets of CDS written on investment-grade and high-yield corporate issuers, or emerging-market governments. Table 1 shows the basic composition criteria of the main indices (more stringent criteria apply too, in particular, those concerning liquidity of the individual CDS). The specific constituents for each index are posted at www.markit.com.

In most indices, issuers are equally weighted. A new series of a given index is issued semiannually, excluding from the basket those issuers who no longer match selection criteria (e.g., downgraded issuers) and adding new ones. In case of a default event, the defaulting issuer is removed from the basket, but the weights remain and the index continues to trade. The reduced basket is referred to as a *new version* of the same series. The loss payment for a default event is determined through the same settlement auction as for single-name CDS (*see Credit Default Swaps*).

Credit indices are commonly issued with initial maturities of 3–10 years. Similar to CDS, a credit index is a contract which entails that the protection buyer pays a spread (or coupon) at a regular frequency (usually quarterly according to International Swaps and Derivatives Association (ISDA) dates) in return for default protection on some notional amount. In case of a default of one of the referenced issuers, the protection seller pays the non-recovered part of the protected notional times the weight of the issuer in the index. The contract does not terminate, but the protected notional is reduced accordingly. Importantly, the index trades with a fixed spread for each series; changes in market pricing are reflected in the upfront payment required to enter the contract. In contrast, in a standard CDS

(for all but distressed credits), the spread is set on any given day such that no upfront payment is required.^a

A standard market practice is to roll index positions so as to maintain a position in the on-the-run (i.e., most recent) series and version, in order to guarantee maximum liquidity. From an investor's point of view, in addition to enabling credit diversification, credit indices introduce the possibility of leverage without significant liquidity concerns, as several derivatives on these indices exist today (*see Collateralized Debt Obligations (CDO); Credit Default Swap Index Options*).

Pricing Framework

Credit indices are routinely priced through the standard CDS model. Indeed, though the index contracts trade with a fixed spread, the convention is to quote a theoretical fair spread (i.e., the coupon that the index would need to pay in theory in order to require no upfront payment) and use the CDS model to convert this fair spread to an upfront payment for the index. The issuers in the basket are assumed to be homogeneous in credit quality and recovery rate. When deriving the common hazard credit curve for the issuers, the convention is to assume a flat curve (*see Hazard Rate*). The expected losses are computed from the credit curve, assuming that losses are paid at the end of a coupon period, and given a particular recovery rate. The present value for the index contract is then the difference between the discounted expected losses and the discounted spread payments weighted by the survival probability (since premium is only paid on the remaining protected notional).

The contract can alternatively be valued by using information on the individual constituents, thus relaxing the homogeneity assumption. We can theoretically replicate the index by considering a basket of individual CDS that pay the same spread. We compute the expected losses on the index by aggregating the individual-constituent expected losses, each of which is derived from the full-term structures of credit spreads for the constituent. Similarly, the payment side aggregates survival probabilities over all issuers. It is worth noting that the dependence structure between the issuers does not play a role here as the whole basket is considered.

Table 1 Main credit indices

Index name	Number of constituents	Region	Credit quality
CDX.NA.IG	125	North America	Investment grades
CDX.NA.IG.HVOL	30	North America	Low-quality investment grades
CDX.NA.HY	100	North America	Noninvestment grades
CDX.NA.HY.B		North America	B rated
iTraxx Europe	125	Europe	Investment grades
iTraxx Europe HiVol	30	Europe	Low-quality investment grades

Imperfect Replication

Pricing the index through the constituents is appealing, but it is not surprising to observe significant differences with the quoted index prices. The replicating strategy is not perfect, as the mechanics behind credit indices are slightly different from those for CDS. We mentioned earlier that an index trades with a floating upfront and a fixed spread, whereas most CDS trade with a floating spread and no upfront. This implies that we cannot, in general, enter into a basket of CDS contracts that pay the same spread as the index. And while the basket can be composed without initial capital, the index requires a nonzero upfront investment. After a default event, new differences between the credit index and the basket appear. On the index, the reduction in spread payments is independent of the defaulting issuer; the spread is fixed and only the protected notional changes. On the other hand, the spread reduction for the basket is proportional to the spread on the CDS for the specific defaulting issuer. The index and the basket consequently exhibit different behaviors through time, and offer different sensitivities to interest rates.

Fair Spread Decomposition

As contracts in their own right, credit indices are subject to specific demand and supply effects, and have their own distinct risk profile. A simple, standard way of analyzing their risk is to observe the quoted index fair spread. This approach, though, cannot distinguish the risk due to specific issuers from the risk due to demand for the index as a whole.

A useful decomposition is to break the index fair spread into three components: the average fair CDS spread across the constituent issuers, the nonlinear

component, and the basis. The first two components constitute the theoretical fair spread of the index, as replicated through a basket of (market-traded) issuer CDS. The nonlinear portion of this fair spread accounts for the heterogeneity in credit quality among the issuers, and increases both with the level of the average fair spread and the dispersion of the individual fair spreads. The nonlinear component is very sensitive to an increase in default likelihood of a single issuer. The basis—defined as the difference between the observed fair spread and the theoretical fair spread—contains a risk premium rewarding the index dealer for the small portion of risk that cannot be perfectly hedged through the replicating basket, and embeds a liquidity premium as well.

End Notes

^aNote that changes to the conventional CDS protocol were instituted in early 2009. Among other things, the new protocol stipulates that single-name CDS trade with a fixed coupon of 100 or 500 bp, and settle *via* an upfront payment (*see Credit Default Swaps* for further discussion).

Basket Default Swaps

Basket default derivatives or swaps are more sophisticated credit derivatives that are linked to several underlying credits. The standard product is an insurance contract that offers protection against the event of the k th default on a basket of n , $n \geq k$, underlying names. It is similar to a plain credit default swap (CDS) but the credit event to insure against is the event of the k th default, and it is not specified to a particular name in the basket. A premium, or spread, s is paid as an insurance fee until maturity or the event of k th default. We denote by $s^{k\text{th}}$ the fair spread in a k th-to-default swap, that is, the spread making the value of this swap equal to zero at inception. For the basic product description, we refer, for example, to [2, 3, 12].

If the n underlying credits in the basket default swap are independent, the fair spread $s^{1\text{st}}$ of a first-to-default swap (FtD) is expected to be close to the sum of the fair individual default swap spreads s_i over all underlying credits $i = 1, \dots, n$. For exponential waiting times, this follows since the minimum of exponentially distributed waiting times has itself an exponential distribution with an intensity that equals the sum of the intensities of the individual waiting times. If, on the other hand, the underlying credits are in some sense “totally” dependent the first default will be the one with the worst spread; therefore $s^{1\text{st}} = \max_i(s_i)$.

For the exact determination of the fair spread of basket default swaps, multivariate modeling of the default times of the credits in the basket is necessary. This dependency modeling can be classified into three different approaches, which are also used in collateralized debt obligations (CDO)-modeling (*see Collateralized Debt Obligations (CDO)*):

- Copula approach (*see Default Time Copulas; Gaussian Copula Model; Copulas: Estimation*)
- Asset-value approach (*see Structural Default Risk Models; also Merton, Robert C.*)
- Reduced-form, spread-based approach (*see Multiname Reduced Form Models; Hazard Rate; Intensity-based Credit Risk Models; Duffie–Singleton Model; Jarrow–Lando–Turnbull Model*)

Modeling Approaches

Copula Approach

As contingent payments are only triggered in case of default, copula modeling focuses on the multivariate distribution of default times.

The copula approach was first applied in this context in [13, 14]. The challenge is to specify a function C such that with given marginal distribution F_i , we have that

$$\begin{aligned} \text{Prob}\{\tau_1 \leq t_1, \dots, \tau_n \leq t_n\} &= F(t_1, \dots, t_n) \\ &= C(F_1(t_1), \dots, F_n(t_n)) \end{aligned} \quad (1)$$

Basically, the set of Copula functions coincides with the set of all multivariate distribution functions whose marginal distributions are uniform distributions on $[0, 1]$, since under certain regularity assumptions

$$C(u_1, \dots, u_n) = F(F_1^{-1}(u_1), \dots, F_n^{-1}(u_n)) \quad (2)$$

One of the most elementary copula functions is the normal copula (or Gauss copula), which is derived by this approach from the multivariate normal distribution (*see Gaussian Copula Model*). Clearly, there are various different copulas generating all kinds of dependencies, for example, in [3, 12]. The advantage of the normal copula, however, is that it relates to the one period version of certain asset-value models used in credit portfolio risk modeling. But note that since the asset-value approach can only model defaults up to a single time horizon T , the calibration between the two models can only be done for one fixed horizon. Dynamic extensions of this in the asset-value context are exit time models.

Asset-value Models

In asset-value models we are looking for stochastic processes (Y_t^i) called *ability-to-pay processes* and (nonstochastic) barriers $K_i(t)$ such that the default time τ_i for credit i can be modeled as the first hitting time of the barrier $K_i(t)$ by the process (Y_t^i) :

$$\tau_i = \inf\{t \geq 0 : Y_t^i \leq K_i(t)\} \quad (3)$$

First, successful models of this class are reached when Y^i are either Brownian motions with drift or time changed Brownian motions; see [9, 15], where also some numerical calibration results are shown. Exit times of more general stochastic processes, including stochastic volatility models, are applied to default modeling in [8].

Reduced-form Modeling

Here we start from the classical single-name CDS approach, where the default time is a double stochastic Poisson process (or Cox-process); see **Hazard Rate; Multiname Reduced Form Models** and [5, 6, 11]. In this approach, it is assumed that conditional on a realization of a path of the default intensity, the default time is distributed like the time of the first jump of a time-inhomogeneous Poisson process with this intensity. Typically, the dynamics of resulting credit spreads are closely tied to the dynamics of the default intensity in this approach.

The main challenge here is the incorporation of default dependence. One either has to model common jumps in the spread processes or applies the copula approach exogenously to the default times given from the spread and hazard rates [4, 17]. Recently, an even more reduced approach was developed [1, 7, 18, 19] in which the accumulated losses $(L_t)_{t \geq 0}$ are modeled directly as a stochastic process. The

most general construction (as e.g., in [7]) is to view L as an increasing cadlag pure Jump process with absolute continuous compensator $\nu(dt, dx) = g(t, dx)dt$; see, for example, [10] for the underlying stochastic analysis. This is particularly useful, if one considers options on the spread s^{kth} of a basket swap. Here, the modeling attempt is on L and the single-name modeling is not considered.

Pricing

In order to price basket default swaps, we need the distribution $F_{(k:n)}(t)$ of the time τ^{kth} of the k th default. The k th default time is, in fact, the order statistic $\tau_{(k:n)}$, $k \leq n$, and, in general, we can derive the distribution of the k th order statistics from the multivariate distribution functions [3]. For pricing we also need the survival function:

$$S_{(k:n)}(t) = 1 - F_{(k:n)}(t) \quad (4)$$

The fair spread s^{kth} for maturity T_m is then given by

$$s^{kth} \sum_{i=1}^m \Delta_i B(T_0, T_i) S_{(k:n)}(T_i) = \sum_{i=1}^n (1 - REC_i) \int_{T_0}^{T_m} B(T_0, u) F_{(k:n)}^{kth=i}(du) \quad (5)$$

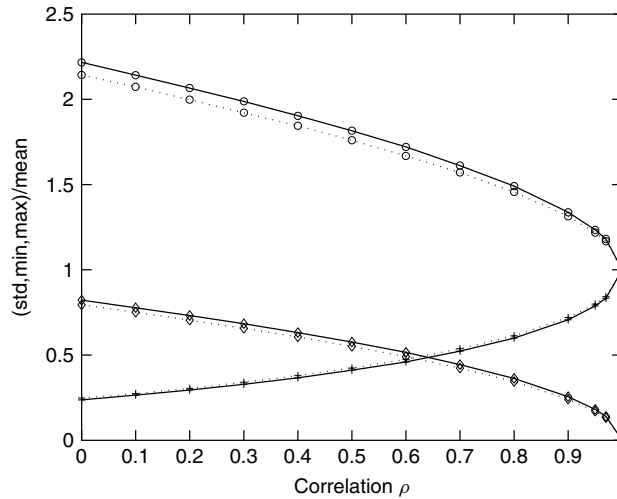

Figure 1 k th-to-default spread versus correlation for a basket with three underlyings: (solid) s^{1st} , (dashed) s^{2nd} , (dashed-dotted) s^{3rd}

The first part is the present value of the spread payments, which stops at τ^{kth} . The second part is the present value of the payment at the time of the k th default. Since the recovery rates might be different for the n underlying names, we have to sum up over all names and weigh with the probability that the k th default happens around u and that the k th defaulted name is just i (we assume that there are no joint defaults at exactly the same time). So $F_{(k:n)}^{kth=i}$ is the probability distribution of the k th order statistic of the default times and that $kth = i$. Figure 1 [3] shows the k th-to-default spreads for a basket of three underlyings with fair spreads $s_1 = 0.009$, $s_2 = 0.010$, and $s_3 = 0.011$, and pairwise equal normal copula correlation on the x -axis. In [16], it was already observed that the sum of the k th-to-default swap spreads is greater than the sum of the individual spreads, that is, $\sum_{k=1}^n s^{kth} > \sum_{i=1}^n s_i$. Both sides insure exactly the same risk, so this discrepancy is due to a windfall effect of the first-to default swap. At the time of the first default, one stops paying the huge spread s^{1st} on the one side but on the plain-vanilla side one stops just paying the spread s_i of the first defaulted obligor i .

LUDGER OVERBECK

Collateralized Debt Obligations (CDO)

Collateralized debt obligations (CDOs) can be generically defined as structured products using tranching^a and securitization technology to repackage and redistribute credit risks. Figure 1 symbolically depicts the mechanics of a CDO.

The first forms of CDOs appeared during the 1980s with the repackaging of high-yield bonds such as collateralized bond obligations (CBOs), following hot on the heels of the first collateralized mortgage obligations (CMOs) pioneered by First Boston in the United States in 1983. This technique was later extended to other asset classes such as bank loans (especially leveraged loans). With the advent of the credit derivatives market and the surge in credit default swap (CDS) trading at the beginning of the decade, CDOs became one of the fastest growing segments of the credit market (the so-called structured credit market) and a crucible of financial innovation. In the limited time frame of a few years (2001–2007), CDOs and structured credit arguably became the hottest areas in capital markets and among the greatest fee and trading income generators for investment banks, asset managers, and hedge funds, until the 2007 subprime crisis marked the (temporary?) end of the party.

This article first provides definitions and a typology of CDOs, based on their main characteristics. The second section deals with the main modeling techniques for CDOs. We then dwell upon the impact of the 2007 subprime crisis on the CDO business and look at the evolution of the market and structures in the aftermath of this watershed. Our concluding remarks deal with the future for CDOs in a post-credit crisis world.

Definitions and Typology of CDOs

CDOs cover a large variety of products and structures. The following parameters can be used to define the different types of CDOs.

The Nature of Collateral Assets

The common denominator of CDO transactions was, until 2002–2003, the application of securitization techniques to (credit) assets sourced in the financial markets, such as bonds (CBOs), or from financial institution balance sheets, such as bank loans (collateralized loan obligations (CLOs)). Theoretically, any asset generating recurrent cash flows can be securitized and therefore be used as a collateral to a CDO transaction. What distinguishes CDOs from securitization transactions (asset-backed securities (ABSs)),^b which deal with extended pools of small credit exposures, is that CDO underlying assets can be construed as unitary credit risks and analyzed as such (each CDO underlying asset usually carries an individual credit rating).

In this decade, the range of instruments used as CDO collateral has considerably increased, including securitization issues (CDOs of ABS), other CDOs (CDOs of CDOs), trust-preferred securities (TRUPs), and going as far as hedge funds^c or private equity participations.

In parallel, the rise of credit derivatives (CDSs) has led to the emergence of a new type of products, the synthetic CDOs.^d Instead of “cash” securities, these instruments reference a pool of CDSs, which replicate the risk and cash-flow profile of a bond portfolio. The credit risk is transferred to the special-purpose vehicle (SPV) using CDS technology, which then issues securities backed by this “synthetic” portfolio. What makes synthetic CDOs attractive to structurers and managers is that they avoid the logistics and financial risk of buying in and warehousing securities while a CDO is being constructed and sold to investors. The use of CDSs as reference “assets” for CDOs opened the door to innovative structures and management techniques, which led part of the structured credit business away from traditional securitization and closer to exotic derivative trading as discussed later.

Risk Transfer Mechanism

One must first distinguish credit risk transfer from the collateral portfolio to SPV and, second, from the SPV to capital market investors.

Credit risk transfer from the collateral portfolio to the SPV may happen *via* the following:

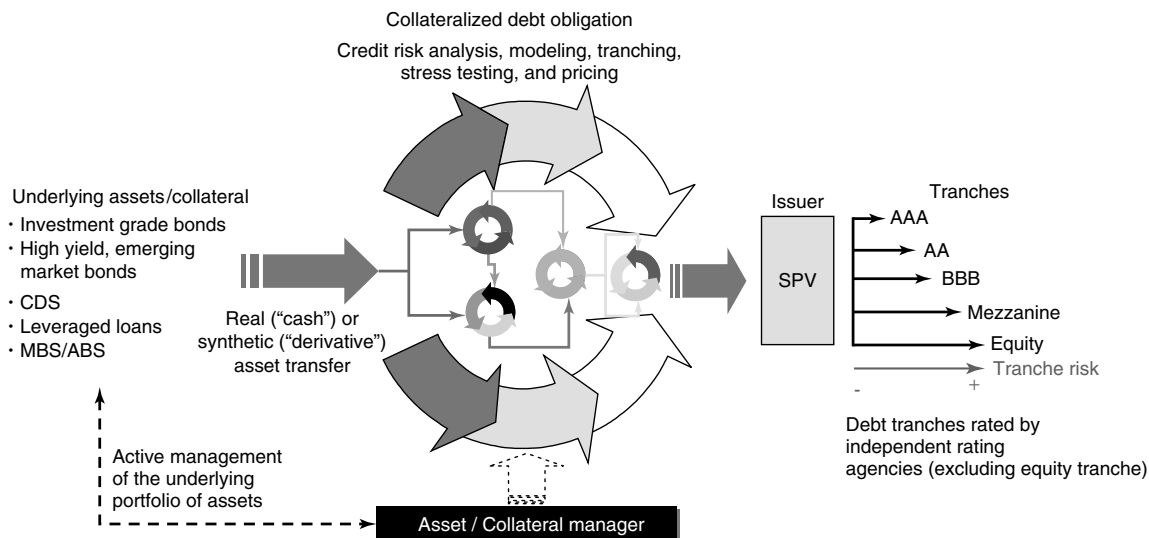

Figure 1 Mechanics of a CDO (Bruyere *et al.* 2005)

- “real” asset acquisition (true sale): “cash CDO” or
- credit derivative technology (or other, e.g., insurance): “synthetic CDO” or collateralized synthetic obligation (CSO).

Risk transfer from the SPV to capital market investors can take the following forms:

- SPV credit-linked note issuance: “funded CDO”;
- credit derivatives (CDSs) sold by the investor to the SPV: “unfunded CDO”; and
- a combination of the above-mentioned: “partially funded CDO”. Most whole capital structure CDOs fall into that category.

Objective of the Transaction

Most CDOs are structured for arbitrage purposes. Arbitrage CDOs are tailor-made investment products, using cash or synthetic technology, created for the benefit of capital market investors. In these transactions, collateral assets are usually sourced in the fixed-income cash or credit derivative markets.

However, a significant part of the CDO market was also driven with the purpose of bank balance sheet management. In such a transaction, the

objective for the sponsor bank is to obtain regulatory or economic capital relief using CDO technology to transfer credit risk to investors. In these transactions, assets or credit risk exposures are typically sourced from the sponsor bank’s own balance sheet.

Static or Managed CDOs

“Static CDOs” are characterized by the fact that the composition of the reference portfolio does not change over the life of the transaction (but for substitutions in a limited number of cases).

At the opposite end of the spectrum, “managed CDOs” (*see Managed CDO*) allow for the dynamic management of the portfolio of collateral assets within a predetermined set of constraints. CDOs are usually managed by a third-party asset manager with credit management expertise. In a managed arbitrage CDO, the asset manager’s objective may be the following:

- to avoid default and ensure timely payment of interest and repayment of principal (“cash-flow CDO”) or
- to optimize the market value of the underlying collateral pool through active management (“market-value CDO”).

“Self-managed CDOs” enable investors themselves to manage the reference portfolio of the CDO they have underwritten.

The following section provides an analysis of the main CDO modeling techniques.

Analysis of CDO Modelling Techniques

Cash-flow CDOs

On the basis of securitization techniques, cash-flow CDOs usually aim at exploiting an arbitrage opportunity between the yield generated by a portfolio of credit assets and that required by investors on the securitized debt, the great majority of which (80–90%) is rated investment grade due to the various credit enhancement mechanisms:

- *Tranching and waterfall*
The creation of several layers of risk (“tranches”) and the sequential allocation of income generated by the collateral portfolio in order of tranche seniority.
- *Subordination*
Losses are absorbed by all junior tranches to a given tranche, thus providing a protection “cushion” (when the CDO is liquidated, the senior creditors have priority over the mezzanine investors, who have priority over the equity holders).
- *Overcollateralization (O/C) and interest cover (I/C) tests*
These act as CDO covenants, leading to the diversification of cash flows toward the early repayment of the most senior tranche if they are breached, thus strengthening the level of subordination.
- *Diversification*
Reference portfolios are diversified in terms of obligor geography and sector, thus limiting the risk of correlated defaults.

Risks and sources of performance in cash-flow CDOs include the following:

- *Default risk*
Underperformance of the underlying portfolio (defaults) leads to a decrease in the amount of assets (and therefore the amount of capital, the equivalent of a write-off in accounting terms) and

in future income streams (since the coupon is no longer being paid on the asset in default) and therefore in the dividend amounts ultimately paid to the equity tranche investors.

- *Portfolio management*
Active trading by the CDO manager may generate losses (which have the same impact as a default) or gains (which are then paid out in dividends or incorporated into the CDO capital, thereby, increasing the subordination level). Generally, the CDO manager is only able to modify the portfolio for a given period (5–7 years, the so-called reinvestment period). He/she must comply with a set of criteria (quality of the portfolio, sector diversification, maturity profile, maximum annual trading allowance, etc.) defined in accordance with the rating agencies.
- *Ramp-up risk*
When a cash CDO is launched, the underlying portfolio cannot be immediately constituted by the manager (essentially to avoid disturbing market liquidity). The portfolio is, therefore, built up over 3–6 months (the ramp-up period). During that time, asset prices may go up and the initial average coupon target for the portfolio might not be attained. In addition, the bank arranging the transaction carries the credit risk of the collateral during the ramp-up period (the so-called “warehousing” risk). To avoid taking too much risk on their balance sheets and allocate capital, banks have been using off-balance sheet vehicles (such as conduits and structured investment vehicles (SIVs)) to park the assets during the ramp-up period. However, as witnessed during the 2007 credit crisis, these defense structures backfired as liquidity dried up and banks were forced to consolidate the vehicles and the security warehouses on their balance sheets.
- *Reinvestment risk*
During the life of the transaction, the manager is regularly led to replace assets and therefore to reinvest part of the portfolio. Market conditions may change and the average coupon level might not be attained. To manage this risk, the manager and the other equity investors usually have an early termination option on the CDO.

Synthetic CDOs: Correlation Products

In the synthetic space, tranching and securitization techniques can also be applied to a portfolio of

CDSs (the so-called whole capital structure (WCS) synthetic CDOs).

However, a watershed appeared with the creation of single-tranche technology, fed by the rise in CDS trading liquidity and advances in credit-modeling expertise. For an investor, any CDO tranche can be considered as a “put spread”^e on the losses of the reference portfolio (the attachment and the detachment points of the CDO tranche being equivalent to the two strike prices of this option combination). Thus, the pricing of a CDO tranche ($x\%$ to $y\%$) can be deduced from the value of the portfolio (i.e., the losses from 0 to 100%) from which the value of the equity tranche (0% to $x\%$) and that of the senior tranche ($y\%$ to 100%) are subtracted. These techniques led to the development of the exotic credit market, which trades on the basis of “correlation”, not unlike the equity derivative market, and volatility.

In a bespoke single-tranche CDO, the arranger usually retains the unsold tranches on its books and dynamically manages their credit risk by selling a fragment (delta) of the notional amount determined for each reference credit entity in the portfolio. This delta must then be readjusted dynamically depending on the changes in the credit spreads. The objective of delta hedging is to neutralize the price variations in the tranche that are linked to changes in the spread of the entities in the underlying portfolio. The delta of a tranche depends upon its seniority and residual maturity. Since deltas are being determined using marginal spread variations, a significant change in spreads will lead to a profit or loss depending upon the convexity of the tranche price (“gamma” in option language). Synthetic CDO arrangers, therefore, not only manage first-order risk levels but also need to monitor their convexity positions.

These hedging mechanisms, however, are not perfect, since they do not deal with second-order risks:

- *Recovery rate in the event of default*
This parameter cannot be inferred from market data. Thus, it is necessary for the dealers to set aside appropriate levels of reserves^f to cover this risk.
- *P&L in the event of default*
Tranche convexity properties are magnified in the event of default and bank positions must be managed accordingly.

- *Correlation (“rho”)*

The pricing and risk management of CDOs are based on correlation rate assumptions. Correlation is determined on the basis of a smile (or skew), which depends mainly on the subordination of the tranche considered. Different correlation rates can thus be given to the attachment and detachment points x and y . This approach by “correlation pairs” is commonly referred to as *base correlation*.

- With the rise of the credit index market,^g CDO arrangers have benefited from new methods for managing their correlation books. Standard tranches are now traded on the main indices in the interbank market, thus providing a benchmark level for the correlation parameters. Until the 2007 credit crisis, liquidity had significantly increased in the CDO tranche market, enabling arrangers to rebalance their books with credit hedge funds and other sophisticated investors.

The Impact of the Subprime Crisis on the Evolution of the CDO Market

With the 2007 subprime and credit crisis, CDOs have come to epitomize the evil of financial innovation. The credit-risk-dispatching mechanism implicit in CDO structures has been broadly accused of fostering the wide spread of poorly understood risks among mainstream capital market investors lured by attractive yields in a low interest-rate environment. To what extent does that charge stand?

ABS CDOs and Subprime Crisis: How Did It Happen?

A key driver for the subprime residential mortgage-backed securities (RMBS) market was the strong demand for subordinated bonds (aka mezzanine tranches, in particular, BBB and BB) from ABS CDO managers.

The reason these bonds were so attractive is that the rating agencies assumed that a portfolio of subordinate mezzanine bonds from various ABS issues would not be highly correlated (much as they assume that corporate bonds from various industries are not highly correlated). Because of this low-correlation assumption, pooling subprime mezzanine bonds into

a CDO structure enabled the CDO manager to create, in essence, new AAA-rated CDO bonds, using only BBB subprime RMBS.

The assumed diversification benefit drove the capital structure of the CDO and explains a large of part of the enormous “misrating” of subprime CDO risk by rating agencies (let alone the rating of the underlying subprime RMBS risk itself).

ABS CDO—A Key Driver of the “Subprime” Demand. The demand from ABS CDOs allowed RMBS originators to lay off a significant portion of the risk. We estimate that \$70 billion of mezzanine subprime RMBS were issued in 2005–2007 *versus* \$200 billion of mezzanine ABS CDOs over the same period. Such notional amount of mezzanine ABS CDOs roughly represents an implied capacity of \$90 billion for mezzanine subprime RMBS investments (over the vintages 2005–2007).^h

This excess demand was filled by synthetic risk (CDS) buckets. The creation of the ABS CDS market multiplied credit risk in the system, allowing for the creation of far more CDOs than the available cash “CDOable” assets. For example, one tranche of a subprime RMBS securitization (nominal \$15.2 million) was referenced in at least 31 mezzanine ABS CDOs (total notional of \$240.5 million).

High-grade ABS CDOs also need to be taken into account. Although the “subprime” demand from these CDOs (roughly \$85 billion) was lower than the nominal of high-grade subprime actually issued (\$230 billion), they fueled the issuance of mezzanine ABS CDOs through the feature of the “inner CDO bucket”. Such a bucket typically had an average size of 20%, allowing CDO arrangers to channel a significant portion of ABS CDO risk. Such “resecuritization” was also facilitated by the existence of CDS on CDOs, further multiplying the credit risk in the system: one tranche of a mezzanine ABS CDO (\$7.5 million nominal) was referenced in at least 17 high-grade ABS CDOs (\$154 million total notional).

At first sight, it would, therefore, be fair to conclude that, since 2005, ABS CDOs have globally absorbed almost every cash-subordinated bond created in the subprime world (and have sold significant protection in synthetic form as well), while traditional cash buyers were largely absent. However, does this mean that the credit risk was effectively transferred to “mainstream” capital market investors?

Anatomy of the ABS CDO Market: Where Did It All Go?. About \$430 billion of ABS CDOs were issued between 2005 and 2007. However, the amount of risk transferred outside the banking system was actually limited because of the following factors:

- investment banks retaining a significant part of super-senior risk, either directly (\$85 billion for the most affected: Citigroup, UBS, Merrill Lynch, Morgan Stanley) or indirectly (by taking on counterparty risk on monoline insurers; \$120 billion notional amounts);
- resecuritization effect though CDO bucket (\$40 billion notional);
- off-balance sheet vehicles, for which banks retained all potential losses (conduits) or part of the losses (SIV, ~\$15 billion of ABS CDO investments); and
- “quasi-”off-balance sheet vehicles, such as money market funds that were subsequently supported by bank capital.

Outside the main banking sector, the most notable “CDO” casualties were either sophisticated insurers (such as AIG) or medium-sized banks (IKB, SachsenLB, and other German Landesbanken).

As a result, it appears that CDOs were primarily a repackaging tool. The main roots of the “subprime” demand stem from abusive off-balance sheet structures (SIVs, conduits) and regulatory capital arbitrages (negative basis trades, long/short badly captured by Value-at-Risk (VaR) models, etc.), both of which resulted in maintaining most of the risk within the banking system while “masking” its true price/value.

One could argue that there was no “real” CDO market for RMBS where rational investors could have sent earlier warning signals (by reducing demand, refusing incestuous features such as CDO buckets within ABS CDOs) and acted as stabilization agents (long-term demand, different investor base than in the underlying RMBS market).

In addition, the derivative market did not perform up to its objectives, as it was created too late (the ABX index, which effectively introduced a greater price transparency) and actually magnified the effects of the mispricing/misrating of RMBS risk.

In conclusion, if the ABS CDO market effectively drove the demand for mezzanine subprime RMBS, its impact on mainstream investors has been limited. In

that respect, it is worth noting that the vast majority of RMBS risk (approximately 82 cents on the dollar) ended up being rated AAA and acquired not by CDOs but by institutions taking advantage of very cheap funding.

How did Other CDO Markets Fare?

Leveraged Loan CLOs. CLOs have suffered from pressure on both the asset and the liabilities sides. Prices of leveraged loans fell in line with the overall credit market, due to technical factors (significant loan overhang resulting from warehouses at the major investment banks) and fundamental fears (increase in default rates, weakly structured leveraged buy-out (LBO) deals). On the liability side, we estimate that negative basis buyers represented 50% of the AAA CLO buyer base, while banks and SIVs/CDOs accounted for 25% and 15%, respectively. The CLO market suffered from the disappearance of such “cheap funding”.

Even though we witnessed an LBO “bubble” (private equity houses taking advantage of the strong CLO bid), the impact of the burst has not been as significant as for the ABS CDO market:

- CLOs were not the sole buyer of leveraged loans.
- They did not suffer from misrating.
- New AAA CLO buyers stepped in (Asian institutions, unaffected banks, insurance companies).

Most of the CLO deals issued in 2008 have been balance sheet driven (cleaning up of warehouses), with simple two-tier structures (AAA and equity), where the AAA tranche (or the equity) is retained by the originating bank.

As the full capital structure execution is challenging and as the sourcing of cash asset is difficult (illiquidity, no warehouse providers for ramp up), the development of single-tranche synthetic CLOs, supported by the growth of the Loan CDS market (ISDA documentation, launch of LCDX and LevX indices), is a key feature of the forthcoming years.

Corporate Synthetic CDOs. With the huge growth in synthetic CDOs, what is commonly referred to as the *structured bid* became a dominant driver of credit spreads. While a combination of mark-to-market losses, rating downgrade risk, and headline risk could have caused investors to unwind positions

in synthetic CDOs, this market segment actually held up well in line with the underlying asset quality (corporate earnings) further supported by the liquidity provided by banks (correlation desks).

Even though the market avoided the “great unwind”, the buying base for these products has essentially gone away, and while some prop desks and hedge funds are still active, the institutional money that provided the liquidity backbone has vanished.

Conclusion: Where Next for CDOs?

The postcrisis CDO market will probably be characterized by a convergence trend toward the mechanics of the corporate synthetic market, which has proved more efficient and resilient for the distribution of credit risk:

- the development of index and index tranches (transparent and traded correlation) fueling liquidity;
- less reliance on rating agencies and more in-house due diligence on assets; and
- a return to balance-sheet-driven transactions.

The main challenges for the CDO market include the following:

- restoring investor confidence in the benefit of structured products by providing better transparency and liquidity;
- addressing the AAA funding issue (now that SIVs and conduits have been dissolved); and
- overcoming the discrepancies in accounting treatment.¹

Once the dust has settled, we expect securitization and CDO transactions to come back on the basis of more transparent and rational fundamentals.

End Notes

^aTranching is the operation by which the cash flows from a portfolio of assets are allocated by order of priority to create various layers (“tranches”), from the less risky (“senior” tranche) to the most risky (“first loss” or “equity” tranche). Tranching technology is usually performed using rating agency guidelines in order to ensure that the senior tranche attracts the most favorable rating (triple-A).

^b Asset-backed securities are securities representing a securitization issue. The ABS market covers mortgage-backed securities (residential and commercial), consumer (credit card, student loans, auto loans), and commercial loans (trade receivables, leases, small business loans, etc.).

^c Collateralized fund obligations.

^d “Synthetic” in as far as the mechanism for transferring risk is synthetic, using a derivative.

^e Combination of two put options on the same underlying asset, at two different strike prices.

^f Usually in the form of bid–ask spreads.

^g iTraxx for the European market and CDX.NA for the US market.

^h On the basis of the following assumptions: 50% of the portfolio allocated to subprime, of which 60% to the precedent vintage.

ⁱ While a cash CDO (or any cash bond) can be accounted for as “available for sale” by banks and insurers (meaning that its price volatility will directly impact the equity base of the investor), the valuation of an equivalent synthetic products impacts the income (P&L) of the investor.

Forward-starting CDO Tranche

At the core of any CDO pricing model is a mechanism for generating dependent defaults. If a simple factor structure is used to join their marginal distributions, the default times of the underlying credits are independent conditionally on the realization of the common factor(s). This conditional independence of defaults is very useful because it allows one to use quasi-analytical algorithms to compute the term structure of expected tranche losses, which is the fundamental ingredient for the valuation of a synthetic CDO.

Because of their analytical tractability, conditionally independent models have become a standard in the synthetic CDO market. In the next section, we review the one-factor Gaussian-copula model, which has played a dominant role since the early days of single-tranche trading.

The Gaussian-copula Model

In the one-factor Gaussian-copula framework, the dependence of the default times is Gaussian, and is therefore completely specified by their correlations. In this model, given a particular realization of a normally distributed common factor Y , the probability that the j th credit defaults by time t is equal to

$$\pi_{j,t}(Y) = N\left(\frac{D_{j,t} - \beta_j \cdot Y}{\sqrt{1 - \beta_j^2}}\right), \quad j = 1, 2, \dots, M \quad (1)$$

where $N(\cdot)$ denotes the standard Gaussian distribution function, the vector $\{\beta_j\}$ determines the correlations of the default times, $\{D_{j,t}\}$ are free parameters chosen to satisfy

$$p_{j,t} = \int_Y \pi_{j,t}(Y) dN(Y) \quad (2)$$

and $p_{j,t}$ are the (unconditional) probabilities that name j defaults by time t . Importantly, for the CDO model to price the underlying credit default swap (CDS) correctly, $p_{j,t}$ must be backed out from the term structure of observable CDS spreads.

Given a realization of the Gaussian factor Y , the M individual credits are independent, and a simple recursive procedure [2] can then be employed to recover the conditional loss distribution of the underlying portfolio, as well as the loss distribution of any particular tranche of interest. Once we know how to compute the loss distribution of a tranche for a given realization of the common factor, it is straightforward to take a probability-weighted average across all possible realizations of Y and thus recover the unconditional loss distribution of the tranche.

Repeating this procedure for a grid of horizon dates and interpreting the expected percentage loss up to time t as a “cumulative default probability”, we can price the tranche using exactly the same analytics that we would use for pricing a CDS. More precisely, we can define the “tranche curve” as the term structure of expected surviving percentage notional of the tranche, that is,

$$Q(t) = 1 - E\left[\frac{[L_t - U]^+ - [L_t - (U + V)]^+}{V}\right] \quad (3)$$

where L_t is the number of loss units experienced by the reference portfolio by time t , U is the number of loss units that the tranche can withstand (attachment), and V is the number of loss units protected by the tranche investor. Then the two legs of the swap can be priced using

$$\text{Premium} = cN \sum_{i=1}^T \Delta_i Q(t_i) B(t_i) \quad (4)$$

$$\text{Protection} = N \sum_{i=1}^T B(t_i) (Q(t_{i-1}) - Q(t_i)) \quad (5)$$

where c is the annual coupon paid on the tranche, N is the notional of the tranche, t_i , $i = 1, 2, \dots, T$ are the coupon dates, Δ_i , $i = 1, 2, \dots, T$ are accrual factors, and $B(t)$ is the risk-free discount factor for time t . Notice that, for ease of notation, we have used the coupon dates t_i , $i = 1, 2, \dots, T$ to discretize the timeline for the valuation of the protection leg.

Pricing of Reset Tranches

Let us define a reset tranche as a path-dependent tranche whose attachment and/or width are reset at

a predetermined time (the reset date) as deterministic functions of the random amount of losses incurred by the reference portfolio up to that time. Notice that forward-starting tranches and tranches whose attachment point resets at a future date both belong to this class.

Pricing a Reset Tranche

Let t_s denote the reset date, λ_j , $j = 1, 2, \dots, M$, the number of loss units produced by the default of the j th name, $\lambda = \sum \lambda_j$ the maximum number of loss units that the portfolio can suffer, $p(\omega)$ the probability today that the reference portfolio incurs exactly ω loss units by the reset date t_s .

A reset tranche can be defined by the vector $\{t_T, t_s, U, V, U(\omega), V(\omega)\}$ where $U(\omega) \geq \omega$ is the attachment point of the tranche (in loss units) after the reset date, and $V(\omega)$ is the number of loss units protected by the tranche investor after the reset date. We can price the two legs of this swap as follows:

Premium

$$= cN \sum_{\omega=0}^{\lambda} p(\omega) \sum_{i=1}^T \Delta_i Q(t_i; \omega) B(t_i) \quad (6)$$

Protection

$$= N \sum_{\omega=0}^{\lambda} p(\omega) \sum_{i=1}^T B(t_i) (Q(t_{i-1}; \omega) - Q(t_i; \omega)) \quad (7)$$

where we have defined the *conditional* tranche curve $Q(t; \omega)$, $t_0 \leq t \leq t_T$, as

In words, the conditional tranche curve $Q(t; \omega)$ represents the (risk-neutral) expected percentage surviving notional of the tranche at time t , conditional on the event that the reference portfolio experiences a cumulative loss of ω units up to the reset date.

Equally, we can write down the valuation in terms of the *unconditional* tranche curve

$$Q(t) = \sum_{\omega=0}^{\lambda} p(\omega) \cdot Q(t; \omega) \quad (9)$$

and thus obtain the familiar equations

$$\text{Premium} = cN \sum_{i=1}^T \Delta_i Q(t_i) B(t_i) \quad (10)$$

$$\text{Protection} = N \sum_{i=1}^T B(t_i) (Q(t_{i-1}) - Q(t_i)) \quad (11)$$

However, while the unconditional tranche curve for $t_0 \leq t \leq t_s$ reduces to the standard tranche curve defined in the section The Gaussian-copula Model,

$$\begin{aligned} Q(t) &= \sum_{\omega=0}^{\lambda} p(\omega) \cdot Q(t; \omega) = 1 - \sum_{\omega=0}^{\lambda} p(\omega) \\ &\times E \left[\frac{[L_t - U]^+ - [L_t - (U + V)]^+}{V} \middle| L_{t_s} = \omega \right] \\ &= 1 - E \left[\frac{[L_t - U]^+ - [L_t - (U + V)]^+}{V} \right] \end{aligned} \quad (12)$$

$$\begin{aligned} Q(t; \omega) &= T(t, \omega) \cdot \left(1 - E \left[\frac{[L_t - U(t; \omega)]^+ - [L_t - (U(t; \omega) + V(t; \omega))]^+}{V(t; \omega)} \middle| L_{t_s} = \omega \right] \right), \\ T(t, \omega) &= 1 - 1_{\{t > t_s\}} \frac{[\omega - U]^+ - [\omega - (U + V)]^+}{V}, \\ U(t; \omega) &= \begin{cases} U, & t \leq t_s \\ U(\omega), & t > t_s \end{cases}, \\ V(t; \omega) &= \begin{cases} V, & t \leq t_s \\ V(\omega), & t > t_s \end{cases} \end{aligned} \quad (8)$$

the unconditional tranche curve for $t_s < t \leq t_T$

$$Z_{v_1, v_2}^0 = 0 \text{ otherwise} \quad (15)$$

$$\begin{aligned} Q(t) &= \sum_{\omega=0}^{\lambda} p(\omega) \cdot Q(t; \omega) \\ &= \sum_{\omega=0}^{\lambda} p(\omega) \cdot T(t, \omega) \cdot \left(1 - E \left[\frac{[L_t - U(\omega)]^+ - [L_t - (U(\omega) + V(\omega))]^+}{V(\omega)} \middle| L_{t_s} = \omega \right] \right) \end{aligned} \quad (13)$$

incorporates the added complexity of the path-dependent valuation.

Deriving the Conditional Tranche Curve

Our discussion so far leaves open the problem of constructing the conditional tranche curve. From the previous discussion, it should be clear that to achieve this goal we need to be able to compute conditional expectations of the form $E[f(L_{t_u}, \omega) | L_{t_s} = \omega]$ for some function f . In this section, we present a two-dimensional recursive algorithm for computing the joint distribution of cumulative losses at two different horizons, which in turn allows us to compute the conditional expectations that we need. The methodology is conceptually similar to the one introduced by Baheti *et al.* [3] for pricing “squared” products.

As anticipated, we assume that the underlying default model exhibits the property of conditional independence. We exploit this by conditioning our procedure on a particular realization of a common factor Y . We first discretize losses in the event of default by associating each credit with the number of loss units that its default would produce: we indicate by λ_j the integer number of loss units that would result from the default of name j . Next, we construct a square matrix (Z_{v_1, v_2}) whose sides consist of all possible loss levels for the reference portfolio, that is, $(0, 1, \dots, \lambda)$. In this matrix, we store the joint probabilities that the reference portfolio incurs v_1 loss units up to time t_s and v_2 loss units up to time t_u , with $t_u \geq t_s$. By definition of cumulative loss, the matrix must be upper triangular, that is,

$$Z_{v_1, v_2} = 0 \text{ if } v_2 < v_1 \quad (14)$$

For the nontrivial elements where $v_2 \geq v_1$, we set up the following recursion. We first initiate each state (recursion step $j = 0$) by setting

$$Z_{v_1, v_2}^0 = 1, \text{ if } v_1 = 0 \text{ and } v_2 = 0$$

We preserve the notation adopted during our description of the Gaussian-copula model and denote by $\pi_{j,t}(Y)$ the probability that name j defaults by time t , conditional on the market factor taking value Y . Now we feed one credit at a time into the recursion and update each element according to the following:

If $v_1 \geq \lambda_j$, then

$$\begin{aligned} Z_{v_1, v_2}^j &= (1 - \pi_{j,u}(Y)) \cdot Z_{v_1, v_2}^{j-1} \\ &\quad + \pi_{j,s}(Y) \cdot Z_{(v_1 - \lambda_j), (v_2 - \lambda_j)}^{j-1} \\ &\quad + (\pi_{j,u}(Y) - \pi_{j,s}(Y)) \cdot Z_{(v_1), (v_2 - \lambda_j)}^{j-1} \end{aligned} \quad (16)$$

If $v_2 < \lambda_j$, then

$$Z_{v_1, v_2}^j = (1 - \pi_{j,u}(Y)) \cdot Z_{v_1, v_2}^{j-1} \quad (17)$$

If $v_1 < \lambda_j \leq v_2$, then

$$\begin{aligned} Z_{v_1, v_2}^j &= (1 - \pi_{j,u}(Y)) \cdot Z_{v_1, v_2}^{j-1} \\ &\quad + (\pi_{j,u}(Y) - \pi_{j,s}(Y)) \cdot Z_{(v_1), (v_2 - \lambda_j)}^{j-1} \end{aligned} \quad (18)$$

After including all the issuers, we set

$$(Z_{v_1, v_2}) = (Z_{v_1, v_2}^M) \quad (19)$$

The matrix (Z_{v_1, v_2}) now holds the joint loss distribution of the reference portfolio at the two horizon dates t_s and t_u , conditional on the realization of the market factor Y , and we can numerically integrate over the common factor to recover the unconditional joint loss distribution. Using the joint distribution of losses at different horizons, it is then straightforward, for any function $f(\cdot)$, to compute conditional expectations of the form $E[f(L_{t_u}, \omega) | L_{t_s} = \omega]$, which is how we construct the conditional tranche curve.

Comments

We have presented a simple methodology for quasi-analytically pricing a class of default-path-dependent

tranches. The proposed methodology is general in the sense that it can be easily applied to any model with conditionally independent defaults, including “implied copula” models fitted to liquidly traded tranches as in the Hull–White [4] model. The algorithm is useful because fast pricing of reset tranches allows one to obtain a variety of Greeks that are essential for effective risk management.

As observed by Andersen [1], however, some caution is necessary when pricing instruments whose valuation is sensitive to the joint distribution of cumulative losses at different horizons. Liquidly traded tranches only contain information about marginal loss distributions and tell us nothing about their dependence. Implying a default time copula from these prices, therefore, implicitly contains an arbitrary assumption about intertemporal dependencies, and it is easy to verify that different implied copulae

that fit observable prices equally well may produce significantly different valuations for path-dependent instruments.

CDO Square

A CDO-of-CDO, or CDO square (CDO²), is a type of collateralized debt obligation (CDO) that has CDO tranches as reference assets. The CDO² market is a natural extension of the CDO market. The concept of CDO² was pioneered by the ZAIS group, when they launched ZING I in 1999, focusing on Euro CDO assets [2]. Recognizable growth of the CDO² market, particularly in the United States, was fueled by the excessive volume growth of the CDO market in the new millennium. In 2004, the situation of tightening credit spreads and a stable credit outlook shifted investor and dealer interest toward more structured credit basket products in the search for yield and tailored risk-return profiles. The repackaging of CDO tranches *via* the CDO² technology allows the dealer to manage the risk and capital cost of (residual) trading book positions. As in the case of CDOs, the dealer can exploit the rating alchemy, that is, the difference between traded and historical default probabilities as well as default correlations, to generate positive carry strategies. The investor will benefit from a more diversified reference portfolio, generally higher yield than similarly rated corporate debt, and the double-layer subordination effect.

We distinguish three main CDO² transaction types: cash CDO², synthetic CDO², and hybrid CDO². All transaction types can either refer to a static portfolio of CDOs or can be combined with an active management of the reference CDO portfolio. In a cash or cash-flow CDO², the reference assets are existing cash CDOs, which typically provide the funds to pay CDO² investors. In a synthetic CDO², the credit risk is generated synthetically, for example, *via* unfunded CDO tranche swaps. Hybrid CDO²s appeared with the rise of the structured finance CDO market and comprise both elements. Typically, in such transactions, the major portion (ca. 80–90%) of the reference portfolio is cash asset-backed security (ABS) exposure and the remainder is synthetic CDOs. It is quite common to use a special purpose vehicle (SPV) overlay for cash CDO² and hybrid CDO².

Mechanics of a Synthetic CDO²

A synthetic CDO² tranche follows the same mechanics as an ordinary CDO tranche (*see Collateralized Debt Obligations (CDO)*), with the only difference that its reference portfolio is made up of CDO tranches. This portfolio is called the *outer or master portfolio*. CDO tranches are determined by their corresponding reference portfolio plus an attachment (or subordination) level and detachment (or exhaustion) level with regard to aggregated credit losses. Hence, we refer to the loss attachment and detachment of the outer portfolio as *outer attachment* and *outer detachment*. Similarly, each CDO tranche of the outer portfolio is described by a corresponding inner reference portfolio and an inner attachment and detachment level (compare with Figure 1 for a schematic description). The inner reference portfolios often overlap and include some of the same reference assets.

Inner attachment and detachment levels as well as the reference notional of assets in inner portfolios are quite often of comparable size. Typically, we find ca. 50–150 assets per inner portfolio and ca. 5–10 inner CDO tranches, which generally translate into a total of ca. 250–500 different reference assets.

CDO² investors benefit from two layers of subordination. First, we must have a considerable number of default events with associated loss rates to exceed the subordination of at least one inner CDO tranche. This will trigger losses on the outer portfolio. However, only if the subordination of the outer CDO tranche is exhausted, we will recognize CDO² losses. The mathematical description of the aggregated CDO² loss $L_{\text{out}}(t)$ for any future date t during the contract term reflects the double-layer effect.

First, the inner portfolio losses $L_j(t)$ have to be determined *via*

$$L_j(t) = \sum_{i=1}^N N_{ij} \cdot (1 - R_i) \cdot 1_{\{\tau_i \leq t\}} \quad (1)$$

where N_{ij} is the notional of assets $i = 1, \dots, N$ in the inner reference portfolios $j = 1, \dots, M$, R_i denotes the asset-specific recovery rate and $1_{\{\tau_i \leq t\}}$ is the (stochastic) default indicator function for the default time τ_i of reference asset i . Second, the inner portfolio losses $L_j(t)$ have to be transformed into

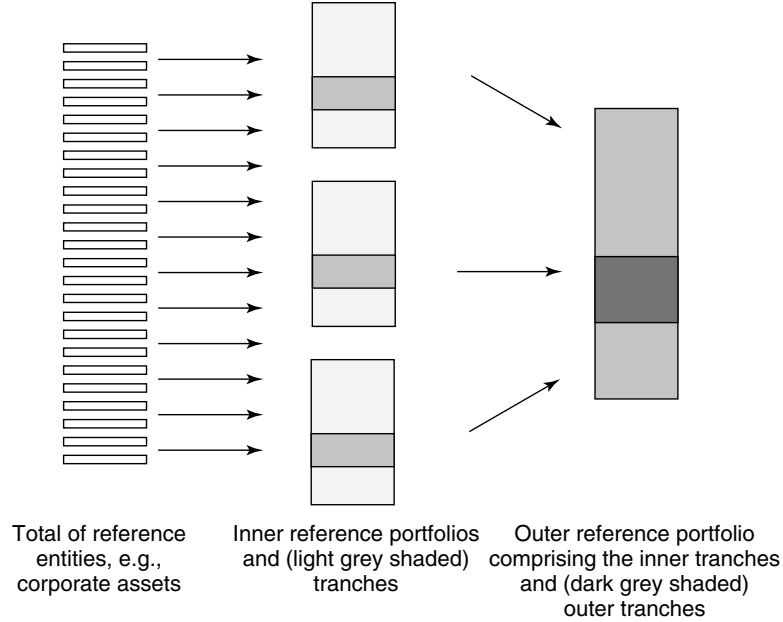

Figure 1 Schematic CDO² description

inner CDO tranche losses $L_{\text{inn},j}(t)$ (see **Collateralized Debt Obligations (CDO)**)

$$L_{\text{inn},j}(t) = \min[D_j - A_j, \max[L_j(t) - A_j, 0]] \quad (2)$$

where A_j and D_j denote the inner attachment and exhaustion level of the corresponding inner reference portfolio j . Third, the outer tranche or CDO² tranche loss can be computed as

$$L_{\text{out}}(t) = \min[D_{\text{out}} - A_{\text{out}}, \max[L_{\text{tot}}(t) - A_{\text{out}}, 0]] \quad (3)$$

where A_{out} and D_{out} denote the attachment and exhaustion points of the outer tranche and $L_{\text{tot}}(t) = \sum_{j=1}^M L_{\text{inn},j}(t)$ the sum of inner tranche losses.

Risk Analysis and Pricing

The limited universe of liquid and actively traded reference assets naturally yields overlaps in inner reference portfolios; in other words, reference assets tend to occur in more than one real-life inner reference portfolio. This causes the CDO² loss distribution to display fatter tails on both ends, since the

(non)occurrence of an isolated default event might simultaneously affect several inner reference portfolios, thereby displaying a leveraged effect [1]. This impact is even more pronounced in case of thin tranches and understood as cliff risk of CDO²s. Moreover, the double-layer tranche technology generally amplifies correlation sensitivities: an increase in the asset correlation yields a higher increase of correlation between affected inner CDO tranches. In summary, overlap and correlation are the main risk drivers of a CDO² tranche. In addition, the described effects considerably increase the impact of other risk drivers such as changing credit spreads (respectively, changing default probabilities) and changing recovery rates.

The key ingredient to pricing is the stochastic evaluation of the accumulated CDO² tranche loss $L_{\text{out}}(t)$ as determined in the previous paragraph. This requires the consistent use of a multivariate credit (default) model. Since no market standard has been developed yet owing to the lack of truly observable correlation information, the necessity and benefit of appropriate scenario models are highlighted in this article. The rating agencies Moody's, Standard & Poor's, and Fitch have consistently adapted their

CDO rating technology to the CDO² case. In particular, the rating technology comes with a look-through capability to underlying assets of inner reference portfolios. However, the look-through capacity stops with ABS-type assets that are modeled as a single asset.

Leveraged Super-senior Tranche

A leveraged super-senior (LSS) note is a structure that allows investors to take a leveraged exposure to the super-senior (SS) part of a collateralized debt obligation (CDO). This provides an enhanced level of return while typically maintaining a AAA rating. Leverage is achieved by posting an initial collateral amount that is less than the notional of the underlying SS tranche. All credit losses to the investor are capped at the collateral amount, but the coupon is paid on the full notional. Early unwind clauses are typically included in the trade to mitigate the risk to the issuer that losses exceed the collateral amount. Compared to a standard SS tranche the investor is exposed to mark-to-market (MTM) risk as well as credit risk, that is, for certain market moves his/her principal could be reduced even if no credit losses have occurred owing to a forced unwind. The issuer faces a so-called gap risk, the risk that the MTM of the tranche will fall below the initially posted collateral amount before a trade unwind can take place.

Super-senior Swap

In an (unleveraged) SS swap transaction an investor (protection seller) will take exposure to credit losses on the SS tranche of a CDO (see **Collateralized Debt Obligations (CDO)**). This means that in return for a regular fee (or coupon), the investor will make good all losses on the underlying reference portfolio that exceed the attachment amount, but are below the detachment amount. For an SS tranche the attachment point will be higher than what is required for achieving a AAA rating (see **Credit Rating**). The spread of the tranche is the fee that values the swap at 0.

Leveraged Super-senior (LSS) Swap

Since the risk of experiencing any losses on an SS tranche is remote, the spread for a standard SS tranche is low. In particular, it is lower than for other AAA-rated securities, which limits the attractiveness of the transaction to investors. LSS structures became

popular in 2005, when spreads on the 22–100%, 5-year, iTraxx index (see **Credit Default Swap (CDS) Indices**) tranche were around 5 bps.

Issuers of LSS notes are typically investment banks. When arranging a CDO transaction the issuer needs to be able to sell the entire capital structure, as otherwise he/she will be left with the remaining risk. For the reasons mentioned above, it can be harder to sell SS risk than risk on mezzanine and senior tranches. The LSS transaction allows the issuer to repackage the SS risk in a way that is attractive to the investor.

In an LSS transaction, the investor will invest in an SS tranche with notional N (referred to as the *reference tranche*). However, he/she will only post an initial collateral amount X (also referred to as the *participation amount*) that is less than the notional amount of the tranche. Any credit losses to the investor will reduce the collateral and losses are thus capped at the collateral amount, X . However, the investor still receives a coupon on the full notional, N , of the reference SS tranche. The ratio, N/X , is referred to as the *leverage*. If losses reach the collateral amount, the trade will terminate without any further cash flows. The typical structure of the LSS trade can be seen in Figure 1. We compare credit losses on the LSS and a standard SS in Figure 2.

The LSS structure provides an increased coupon to the investor compared to investing the collateral amount X in a standard SS tranche. The reason for this is that the investor takes on MTM risk over and above his/her credit risk as is described below.

The issuer of an LSS note (protection buyer) is only covered for losses up to the collateral amount X . However, he/she will typically hedge his/her position by selling protection on the corresponding standard SS tranche (cf. the section Hedging and Risks) where he/she is liable for all the losses on the tranche up to the full notional amount N . Thus, the issuer needs to mitigate the risk that losses exceed the collateral level. This is done *via* the inclusion of a trigger mechanism: As soon as a predefined trigger level is reached the trade will unwind at the MTM of the reference tranche capped at X . The trigger should thus be set such that the MTM on unwind will be less than X .

We note that in some transactions the investor has the option of posting more collateral upon trigger to avoid an unwind. In this case, the investor will continue to be paid the coupon of the original

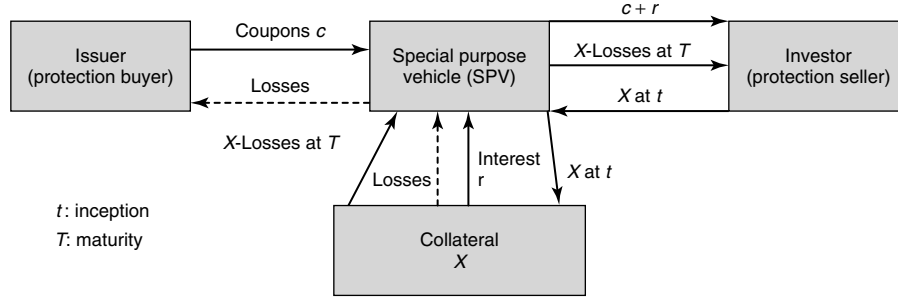

Figure 1 This figure shows the standard structure of cash flows in an LSS transaction

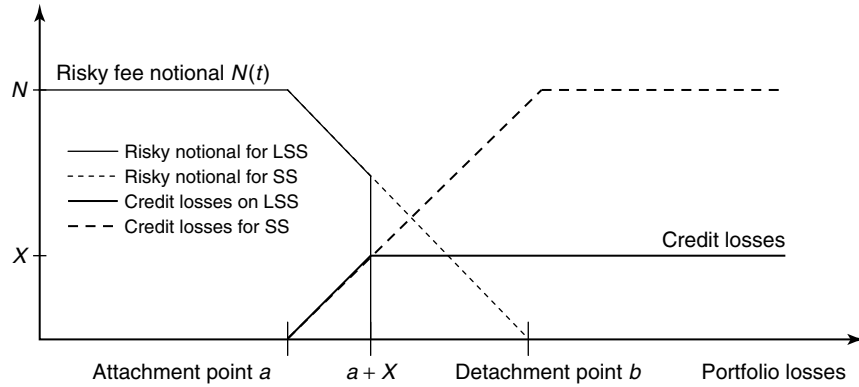

Figure 2 This figure shows the credit losses to the investor and the risky fee notional, $N(t)$, as a function of the portfolio losses. The coupon amount paid to the investor at a coupon date t_i is $s \cdot N(t_i)$, where s is the spread. For comparison we include both the behavior of the LSS and the reference unleveraged super-senior (SS)

transaction. This means that it is never optimal for the investor to deliver since after posting more collateral he/she will be liable for more losses without receiving a higher coupon in compensation. It is more favorable to reinvest in a new LSS transaction.

We describe the three main types of trigger mechanisms below. There is a trade-off between how well the trigger can approximate the MTM of the trade and how easy it is to objectively assess whether the trigger has been breached.

• Loss Trigger

A loss trigger is breached when the amount of portfolio notional lost owing to defaults exceeds the trigger level. This is the easiest trigger to monitor as the loss amounts can be objectively determined. However, the loss provides an imperfect approximation for the MTM of the tranche. In particular, if spreads

widen, the value of the LSS can drop severely from the point of view of the investor even in the absence of any defaults. This poses a risk to the issuer since at the time of trigger the MTM of the tranche could have dropped below the collateral amount.

• Spread Trigger

Spread triggers are based on the average spread of the underlying portfolio. Trigger levels can be defined as a function of the time to maturity and the level of losses in the portfolio. This provides a much better proxy to the MTM of the tranche than the loss trigger. For some standard portfolios, for example, iTraxx or CDX (*see Credit Default Swap (CDS) Indices*), the value of the average spread can also be assessed using publicly available information and is hence unambiguous. Often, however, the LSS is based on bespoke portfolios. In this case, the valuation of the

SS spreads will have to rely on models, for which there is no universally agreed methodology.

• Mark-to-market Trigger

The MTM trigger is based on the MTM of the reference (unleveraged) SS tranche. Clearly, if the MTM trigger is set below the collateral level the issuer ensures that the collateral will cover the unwind payment (up to gap risk, cf. the section Hedging and Risks). The disadvantage is that the MTM trigger is the hardest to assess objectively. Typically, the MTM for a tranche is not quoted, and hence one has to rely entirely on (complex) models for valuation.

Hedging and Risks

If the trigger mechanism guaranteed that upon unwind the issuer will receive the full MTM of the reference swap then this swap would provide a perfect hedge for the LSS. The coupon amount the investor would receive would be the same, as if he/she had invested the full notional amount N in an SS swap transaction.

However, there are two reasons why the trade can unwind without recovering the full MTM of the hedge:

- Typically, there will be a delay between a trigger breach and the actual unwind of the hedge. In this period, there is the risk that the MTM will drop below the collateral amount. The issuer then has to make good the difference ($MTM - X$). This is the so-called *gap risk*: The issuer is exposed to large and sudden increases in the value of SS protection or equivalently increases in the spread.
- Even in the absence of a trigger breach, the LSS will unwind if the SS tranche losses have wiped out the collateral. Since the collateral is 0 in this case, the issuer will have to pay the full MTM of the hedge to unwind his/her position. However, this scenario is unlikely, since the trigger should be set so that a trigger event occurs before the collateral has been reduced to 0.

The investor in an LSS transaction faces MTM risks as well as credit risks associated with SS tranche losses. In the case of a trigger event, the investor will be forced to unwind his/her position and will lose part or all of his/her principal as he/she realizes his/her

MTM losses (unless he/she posts more collateral). Unless dealing with a loss trigger, a trigger breach can happen even if the investor has not incurred any actual credit losses, for example, if there is a dramatic rise in spreads.

Valuation

The valuation of LSS transactions poses additional challenges to that of pricing a standard SS tranche. This is because the unwind feature means that we need to be able to value the risk of possible MTM losses to the investor and the issuer. Hence, we need to model the joint behavior of MTM and the portfolio losses. This is a dynamic problem that requires more than knowledge of the marginal loss distributions needed for standard tranche pricing.

There are two main candidates for dynamic credit models that can, in principle, be used to value an LSS transaction:

- low-dimensional models of the portfolio loss process;
- dynamic models of all single name spreads in the portfolio (*see Duffie–Singleton Model; Multiname Reduced Form Models*).

Modeling and valuation of the LSS product is not only important for the issuer and the investor but also for assessing the rating of the note. This depends not only on the probability of experiencing credit losses but also on the probability of having a trigger event. Rating agencies (*see Credit Rating*) use in-house models for this as described in, for example, [1, 2].

Model-independent Bounds

Some model-independent bounds for the value of the LSS can be derived. We discuss this from the perspective of the issuer who is long protection. Let us denote the spread of a standard tranche with attachment point a and detachment point b by $S_{a,b}$.

The spread of the corresponding leveraged tranche with collateral amount x will be denoted by $S_{a,b,x}$. Note that the leverage amount α is given by $\alpha = (b - a)/x$. The most basic bound we can then write down is

$$S_{a,b} \leq S_{a,b,x} \leq \alpha \cdot S_{a,b} \quad (1)$$

This means the following:

- The spread of the leveraged tranche is less than the leverage amount times the spread of the unleveraged tranche. This is because the issuer has additional unwind and gap risk. The difference

$$\alpha \cdot S_{a,b} - S_{a,b,x} \quad (2)$$
 is the *gap charge*.
- The spread of the leveraged tranche is greater than that of the unleveraged tranche. This is because of the trigger mechanism, which allows the issuer to recover the MTM of the unleveraged tranche up to the collateral amount.

We can also give a more stringent floor for the LSS value. To this, we introduce the fee leg value $F_{a,b}$ and contingent (or loss) leg value $C_{a,b}$ of a tranche (see **Collateralized Debt Obligations (CDO)**). The (positive) value of the fee leg is the expected value of all coupon payments paid on the risky notional. The contingent leg is the (positive) expected value of any loss payments. We now have the following bounds:

$$C_{a,a+x} \leq C_{a,b,x} \quad (3)$$

This is because on the contingent leg, the issuer will at least recover losses up to $a + x$. He can effectively recover more on unwind since he/she receives the MTM of the unleveraged tranche.

We also have

$$F_{a,b} \geq F_{a,b,x} \quad (4)$$

This corresponds to the fact that on the fee leg the issuer will at most pay the fees of the unleveraged reference tranche. He/she might effectively pay less if there is an unwind not due to the trigger such that no MTM exchange takes place.

For a more rigorous discussion we refer to [3].

MATTHIAS ARNSDORF

Managed CDO

General Definition

A managed (or “active”) *collateralized debt obligation* (CDO) is a large-scale securitization transaction that is actively arranged and administered to unbundle, transform, and diversify financial risks from a dynamic reference portfolio of one or more credit-sensitive asset classes (associated with different creditors, countries, and/or industry sectors). Although the type(s) of asset(s) in the reference portfolio are known and fixed through the life of the CDO, the underlying collateral of a managed CDO is variable.

Types of Managed CDOs

In general, CDO Managers operate under investment guidelines that are defined in the governing documents of the CDO transaction. Managers adjust the investment exposure over time to meet a pre-specified risk–return profile and/or achieve a certain degree of diversification in response to changes in risk sensitivity, market sentiment, and/or timing preferences. These guidelines specify parameters for the initial portfolio (during the “ramp-up phase”, see below) but not the exact composition, for example, a minimum average rating, a minimum average yield, a maximum average maturity, and a minimum degree of diversification. As opposed to a static CDO, managers monitor and, if necessary, trade assets within the reference portfolio in order to inform decisions about asset purchases and sales that protect the collateral value from impairment due to deterioration in credit quality [6]. For further references, see [1–3, 5, 7, 8]. “Lightly managed” reference portfolios allow for some substitution of assets in the context of a defensive management strategy, while a “fully managed” CDO suggests a more active role of managers subject to limits and investment guidelines that are determined by the issuers, rating agencies, and different levels of risk tolerance of investors at inception. In the event of the issuer’s insolvency or default, managers are charged with maximizing recoveries on behalf of investors. However, investors in managed CDOs do not know what specific assets CDO managers will invest in, recognizing that those assets will change over time as managers alter the composition

of the reference portfolio. Thus, investors face both credit risk and the risk of poor management.

The majority of CDOs are managed and, in many instances, involve compounded structured finance claims. While standard CDOs use the same off-balance sheet structuring technology as *asset-backed securities* (ABSs) (e.g., securities that are themselves repackaged obligations on mortgages, consumer loans, home equity lines of credit, and credit card receivables), their reference portfolios typically include a wider and more diverse range of assets, such as senior secured bank loans, high-yield bonds, and *credit default swaps* (CDSs). In particular, the variable portfolio structure of managed CDOs is particularly amenable to refinance ABSs, emerging market bonds, or even other CDOs (to produce CDOs of CDOs, also called *CDO*²), as collateral assets in the so-called “pools-of-pools” structures.

Managed CDOs Have an Arbitrage Proposition

Managed CDOs are structured for *arbitrage* purposes. As opposed to *balance sheet* CDOs, where issuers unload defined asset exposure to third parties in order to change their balance sheet composition or debt maturity structure, in *arbitrage* transactions, the ability to trade a dynamic reference portfolio helps managers focus on the pool’s prospects for appreciation with the view of realizing economic gains while limiting downside risks. These gains result from the pricing mismatch between investment returns from reference assets (in the case of a *cash flow* structure) or credit protection premia on exposures (in the case of a *synthetic* structure) and lower financing cost of generally higher rated liabilities in the form of issued CDO securities. While cash flow CDOs, the most common type of CDOs, pay off liabilities with the cash generated from interest and principal payments, synthetic CDOs sell credit protection (together with various third-party guarantees) to create partially funded and highly leveraged investment on the performance of designated credit exposures (without actually purchasing the reference assets).

The Life of a Managed CDO

The life of a managed CDO can be divided into three distinct phases (Figure 1). During the “ramp-up

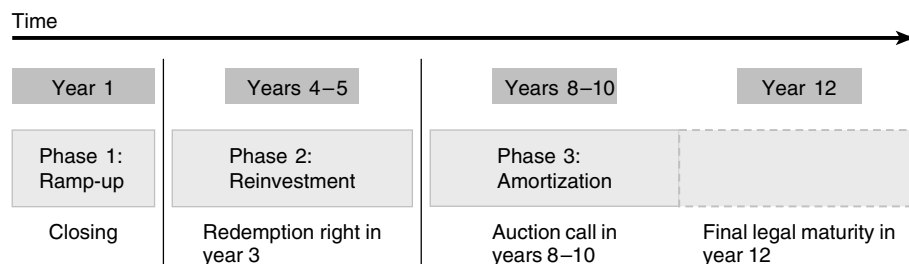

Figure 1 The phases in the life of a managed CDO

phase” (which lasts about one year), asset managers invest the proceeds from CDO placement (possibly after an initial warehousing period when the sponsor finances the buildup of the asset portfolio before securitizing). During the subsequent “reinvestment phase” (up to five years or longer), managers reinvest cash flows as well as trade the reference portfolio within the prescribed guidelines. Cash flows generated by the assets are used to pay back investors generally in sequential order from the senior investors, who hold the highest rated (typically “AAA”-rated) securities, to the “equity investors” who bear the first-loss risk and generally hold unrated securities. In transactions with *revolving* pools, portfolio assets can be replaced (e.g., credit card and trade receivables, corporate bonds) and balances are adjustable up to maximum limits without amortization schedule of principal. In contrast, managers of *substituting* pools incorporate new assets (within defined credit parameters) as original liabilities are paid down (e.g., corporate bonds, some residential mortgages, and consumer loans), but balances remain fixed. In the “amortization phase”, the reference portfolio matures (or is prepaid/sold) and investors receive some or all of their principal investment back according to the seniority of their claim.

Lessons from the Credit Crisis

Although rating agencies have developed stress tests to evaluate the resilience of dynamic portfolio structures, the 2007 subprime mortgage crisis demonstrated that managed CDOs might create incentive problems [4]. Existing quality and coverage tests on the underlying collaterals are designed to trigger amortization scenarios if asset performance deteriorates. However, CDO managers can manipulate these

tests to avoid early amortization. In response to a general repricing of risk, dwindling investor demand increased risk premia and curtailed the capacity of CDO managers to offset higher funding costs. Faced with rising liability pressures and without real buyers available, managers of “blind pools” could “double up” by opting for riskier positions and greater leverage to preserve own arbitrage gains within predefined investment guidelines, which were gradually undermined by the disassociation of ratings and structured asset performance. In principle, if transaction costs are ignored, risk-neutral managers would not benefit from dynamic asset allocation by substituting badly performing assets. Under worsening credit conditions, better asset performance comes at a premium, making it more expensive to weed out distressed assets. Therefore, CDO managers are no better off than before once they divert funds to safer but more costly assets (or accept higher hedging costs).

Collateralized Debt Obligation (CDO) Options

The synthetic collateralized debt obligation (CDO) tranche activity is still a relatively new business, which started in late 2000. Initially seen as an eccentricity in the securitization market, it finally got a life on its own. Contrary to the rest of the securitization market, it grew as an arbitrage business, where the bank will not gain from structuring fees (like for cash CDOs) but from an arbitrage between two different markets: single-name credit default swaps *versus* synthetic single-tranche CDO. Its evolution was then marked by multiple borrowings from equity derivatives market, using its terminology (single tranche viewed as call spread on credit losses) and its technology (correlation smiles and the type of derivatives on it). This helps explain why the article focuses exclusively on synthetic CDO tranches, because to our knowledge there do not exist derivatives based on cash CDO notes.^a

For a more comprehensive CDO framework, *see Collateralized Debt Obligations (CDO)*, and for an introduction to CDO tranche pricing, *see Intensity-based Credit Risk Models*. However, we introduce those two important notions that are used in this article:

- A credit default swap (CDS) is a bilateral contract where the protection buyer will pay a quarterly premium (expressed as a proportion of the CDS notional) and receive from the protection seller, if specific events took place (related to the default or bankruptcy of a specific corporate entity), a payment corresponding to one minus the price of a bond of the defaulted entity, that payment being called the *severity of default* or the *credit loss*.
- A synthetic CDO tranche is a bilateral contract where the protection buyer will pay a quarterly premium (the premium leg of the swap) and receive from the protection seller the increment in loss on the tranche (the loss leg of the swap), where the loss on the tranche is contractually defined as a function of the sum of credit losses on a portfolio of single-names CDS, or more accurately as $\min(d - a, \max(L_t - a))$ with the following:

- L_t represents cumulative credit losses on that portfolio up to date t , that is, the sum of different severities of defaulted entities that are in that portfolio;
- a is defined as the attachment point of the CDO tranche in proportion of the initial pool size; and
- d is defined as its detachment point.

Definitions

Here, we list the different derivatives that we have seen in the synthetic CDO markets created between 2001 and 2007. Those derivatives can be categorized in two groups: derivatives on CDO tranches where the behavior of the derivative is conditioned by losses realization, or default-path-dependent derivatives, and derivatives conditioned by a spread/market value evolution. Some derivatives like leveraged supersenior (LSS) (*see Leveraged Super-senior Tranche*) can be in the two categories depending on their variations.

The first category of default-path-dependent structure is also known as *reset tranches* (as defined in [4]): those are CDO tranches where the attachment point and/or the width of the tranche are modified at a future reset date as a predetermined function of the portfolio losses up to that date.

- *Forward-starting CDO* (*see Forward-starting CDO Tranche and* [2]): this is a CDO tranche where the contract becomes effective at a future date, where any entities defaulting between the entry into the forward and its effective date will be considered to have a recovery rate at 100%, or in other words at the effective date, the CDO tranche will have an attachment point equal to the sum of the cumulative losses up to that date t_1 and the pre-fixed initial attachment point (i.e., $a + L_{t_1}$), its width being unchanged in dollar amount (i.e., $d - a$). There is also a variation on that contract [7] where the forward CDO is the obligation to enter into a CDO tranche at a future date, taking into consideration the erosion of subordination due to losses up to the effective date, and the decrease in the width, but not the losses on the tranche, thus a subordination of $\max(0; a - L_{t_1})$ and width of $\min(d; \max(a; L_{t_1}))$.
- *Subordination step-up*: This is a standard CDO tranche except that at the reset date, if losses have

not started to touch the tranche the subordination will be increased by a fixed amount. Multiple variations of those contracts exist with several reset dates or increase in subordination linked to losses being in a specific band.

- *Leveraged supersenior* (see **Leveraged Supersenior Tranche**): This is a synthetic CDO tranche, with a large attachment point, thus its supersenior nature, which is initially partially collateralized by the protection seller. Owing to that partial collateralization, when a loss trigger or mark-to-market (MtM) trigger is breached, the protection seller has the obligation of either providing additional collateralization or unwinding its contract at market value. When the trigger is based on loss level, this can be viewed as a reset tranche.

The second category encompasses all derivatives in the classical sense, that is, derivatives based on the market value of the underlying asset.

- *Call on CDO tranches*: This is an option giving the option holder the possibility to buy protection on a synthetic CDO tranche at a predetermined spread on one of several future dates, being either European for one single date or Bermudan for a set of future dates. The strike is defined as a spread level (and not as a value of the tranche). The synthetic CDO tranche, that is, portfolio composition, attachment/detachment points, and maturity, is defined initially, and akin to the differentiation done on forward-starting CDO, losses up to the exercise date of the option may or may not affect the attachment point.
- *Put on CDO tranches*: Contrary to the call option, this gives the option holder the possibility to sell protection on a CDO tranche at a predetermined spread.
- *Callable structure*: This is an option that gives the protection seller (or the protection buyer) the right to terminate the transaction at no additional costs during its life. If the option is for the protection seller, this is, in fact, a Bermudan call on the CDO tranche itself with a strike equal to its initial spread level. Here the attachment point of the underlying synthetic CDO tranche will be eroded by losses up to the exercise date of the option.
- *Rating guarantee*: We know of one investment bank that worked on the possibility to issue a guarantee on the CDO tranche rating, giving the

option to investors to put their CDO tranche at par to the issuer of such guarantee if the rating was downgraded below a prespecified threshold. This is in effect a callable structure conditional on the tranche being downgraded by a rating agency.

Purpose and Market

The purpose of those innovations is, in most cases, related to issues encountered by the bank's desk working on synthetic CDO tranches. The innovations in that market were always caused not by a need of the investors but by potential arbitrages to exploit. Synthetic CDO tranche from 2001 to 2007 was a booming market with several success stories. However, this was a very competitive market, where the competitive advantage was due to the endless creation of new structural features. Indeed, as soon as an innovation was introduced to the market by one player, several others tried to imitate it, soon depleting the potential gains evidenced by such innovation (Figure 1).

Each innovation was triggered by either an arbitrage to exploit or a specific problem encountered by the desk:

- *Forward-starting CDO*: Those products were created to exploit discrepancies between the terms structure of spread as the five-year maturity spread was depleted because of the wave of five-year synthetic CDO tranches. Synthetic CDO tranches were starting to be structured at 10 years or even as forward starting 5–10 years to benefit from the tightening at 5 years. Indeed, a 5–10 years forward starting CDO can be seen as a combination of a 10 years synthetic tranche and a 5 years synthetic tranche, selling protection for 10 years but buying protection for the first 5 years.
- *Leveraged supersenior*: When the correlation desk sold synthetic CDO tranches, they sold mainly equity and mezzanine tranches, and thus either delta-hedged them or kept the most senior tranches on their book. The supersenior exposures were very hard to sell due to their low spreads compared to their notional amounts, that is, the amount of cash needed to invest in those tranches. The creation of LSS allowed those desks to buy protection on supersenior synthetic CDO tranches by broadening the investor base outside of its

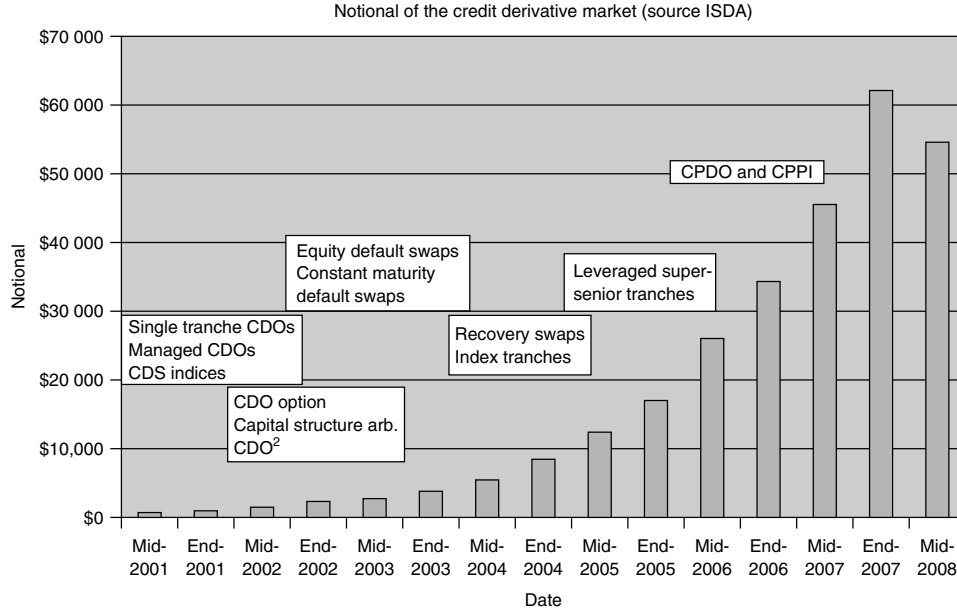

Figure 1 Evolution of the notional of the credit derivatives market with several innovations

initial clients (monolines or (re)insurance companies), the LSS having a higher spread for an “assumed” low credit risk.

Valuation

The valuation of a CDO tranche, whether initially or during its life, relies on the knowledge of the loss distribution of the underlying portfolio through time or, in other words on the law governing the random path L_t representing the cumulative losses up to t . The knowledge of the loss distribution at different future date (thus a loss distribution surface) is required^b to price a CDO tranche, that is, to value the two legs of that tranche swap: $P[L_T \leq l | \mathcal{F}_t]$ the probability that losses up to time T will exceed threshold l knowing the losses at time t .^c If the existing information in the market consists of the credit index tranches prices, in the arbitrage pricing theory framework, from those prices we will extract constraints on the “spot” loss distribution surface being $P[L_T \leq l | \mathcal{F}_0]$.

Some CDO derivatives can be valued with that “spot” loss distribution surface: the forward-starting CDO as described in [7] (the second variation as described above) can be understood as a long–short

position on maturities: long, the CDO tranche at the longest maturity and short, the same CDO tranche at the effective date. Indeed, on comparing the two positions—a t_1/t_2 forward-starting CDO tranche *versus* a long CDO tranche at t_2 and a short CDO tranche at t_1 with the same attachment/detachment points:

- if losses are always below the attachment point, no CDO tranches will be touched;
- if $L_{t_1} < a$ and $L_{t_2} > a$, the forward-starting CDO will lose $\min(d - a, L_{t_2} - a)$ and the long CDO tranche will lose the same amount; and
- if $L_{t_1} > a$ and $L_{t_2} > a$, the forward-starting CDO will lose $\min(d - L_{t_1}, L_{t_2} - L_{t_1})$ and the long–short CDO tranches will lose/gain $\min(d - a, L_{t_2} - a) / \min(d - a, L_{t_1} - a)$, which gives the same aggregate amount.^d

However, to value the other reset tranches, we need an additional information: the intertemporal dependence of losses, that is, the dependence between losses at different dates. For a forward-starting CDO—first variation—we need the law of (L_{t_1}, L_{t_2}) to be able to price it.

In addition, for options on tranche, dependent on future spreads, the knowledge of the “spot” loss

distribution surface is not sufficient to value those options. An additional assumption related to spread volatility is needed: this can be an *ad hoc* assumption directly on the volatility [7] or can be embedded into a stochastic deformation of the loss distribution surface $P[L_T \leq l | \mathcal{F}_t]$ through time. This leads researchers to introduce the class of models known as a *dynamic losses model*. The dynamic losses model defined so far relies on the standard CDO models, which are classified according to two broad categories [8]:

- *Top-down models*: The top-down approach will only look at the evolution of the losses on the portfolio and model its dynamics. The seminal paper describing a general framework for such dynamic of the “forward” loss distribution surface is [11], where the distribution of losses in the portfolio is represented as a Markov chain with stochastic transition rates. Andersen *et al.* [3] explore the same road in a less general manner. Those approaches are tractable, flexible but they do not capture information from the single-names CDS market.
- *Bottom-up models*: The approach starts with a representation of the credit risk of the underlying single names in order to build a loss distribution surface. Starting from the modeling of individual defaults, they use classical credit modeling:
- *Structural models (see Default Barrier Models)*: A structural model computes the default as the breaching by a random process of a barrier (in the initial Merton seminal article the first represents the assets of a company and the second its indebtedness). That class of model incorporates a dynamic for the probabilities of losses naturally, introducing default dependencies through the random process, with linear combination of random process (Brownian motion or Gamma process, see [9]). A related class of models looks at a discrete evolution of creditworthiness, generally with a Markov chain, where the use of stochastic transition rates can also be applied (a related example is in [1]).
- *Reduced-form models (see Intensity-based Credit Risk Models)*: A reduced-form model uses hazard rates to represent the risk of

default of individual companies; a portfolio can be analyzed with correlated hazard rates. A natural extension of those models to address dynamic losses is to use stochastic hazard rate for each company, which may be linked through common jumps (as first introduced by Duffie and Gârleanu [5]), correlated Brownian motion, or even introduction of stochastic time process mapping calendar time to business time [10].

Following the financial crisis of 2008, the landscape for synthetic CDO tranches has seen a change in paradigm. The default of Lehman Brothers in September 2008 and the demise of the investment bank business model have exposed the shaky foundations of the CDO market: liquidity drying in stress period and lack of acknowledgment of the counterparty risk in the CDS market. However, the initiatives that are currently discussed (standardization of that market, central clearing house) will, on the long term, expand the scope of that market and ultimately be beneficial for the development of those instruments.

End Notes

^a. Apart from rare guarantees offered by structuring desks or call optionality for the equity tranche of cash CDOs.

^b. In reality as pointed out in [6], the knowledge of the expected loss on the CDO tranche is sufficient to price it.

^c. The filtration $\mathcal{F}_t$ may embed more information than the cumulative losses up to that time.

^d. Taking into account even the timing of payment of losses, the two positions are the same.

Credit Default Swap Index Options

Portfolio credit default swaps (CDSs) referencing indices such as CDX and iTraxx are the most liquid instruments in today's credit market and options on these have become mainstream. A CDS index option (also called a *portfolio swaption*) is an option to enter into a portfolio swap as a protection buyer or a protection seller. A portfolio swap (also called a *CDS index swap*) is similar to a portfolio of single-name CDS all with the same coupon (for details, *see Credit Default Swap (CDS) Indices*).

Both portfolio swaps and swaptions are traded over the counter but are standardized. The conventions for how portfolio swaps are quoted and traded are important for properly valuing portfolio swaptions.

In this article, we outline the basic conventions and terminology for portfolio swaptions, explain the standard model used by most market participants, and briefly discuss other models and approaches.

Conventions and Terminology

A portfolio swaption is an option to enter into a portfolio swap as a protection buyer (payer swaption) or a protection seller (receiver swaption). The swaption is defined by the underlying portfolio swap, for example, 5-year CDX.IG.11, the expiration date, and the strike spread or strike price. For investment grade portfolios, it is a convention to specify a strike spread, whereas for high yield portfolios a strike price is usually specified. Trading is primarily in options on 5-year portfolio swaps. Option maturities are less than 1 year, with most liquidity in 1–3 months maturities. The standard option expiration dates are the 20th of each month.

The strike, whether it is specified as a spread or as a price, must be converted by a simple calculation to determine the cash amount to be exchanged between the swaption counterparties upon exercise. The calculation is easiest when a strike price is specified:

$$\begin{aligned}\text{Cash amount} &= \text{Notional} \cdot (\text{Strike price} - 100\%) \\ &\quad - \text{Accrued coupon}\end{aligned}\quad (1)$$

The cash amount is paid by the protection buyer. The accrued coupon enters the calculation because portfolio swaps, by convention trade with accrued coupon, similar to the way bonds trade with accrued interest. To simplify the exposition, we ignore accrued coupon in the remainder of the article.

When a strike spread is specified, the cash amount is calculated using the standard CDS valuation model, for example, as implemented in the Bloomberg CDSW screen:

$$\begin{aligned}\text{Cash amount} &= \text{Notional} \cdot \text{PV01} \cdot \\ &\quad (\text{Strike spread} - \text{Coupon})\end{aligned}\quad (2)$$

The coupon is the fixed premium rate for the underlying portfolio swap. When valuing a portfolio swaption, it is important to respect the exact market convention for calculating the PV01 such as the flat spread curve convention (*see Credit Default Swap (CDS) Indices*).

Another important market convention is that if the swaption is exercised, the option holder will buy or sell protection on all names in the portfolio including those that may have defaulted before option expiration.

The Standard Model

Now, suppose that V is the value at option expiration of owning protection on all names in the portfolio including those that have already defaulted. Option payoff at exercise is then

$$\begin{aligned}\text{Payer swaption payoff at exercise} \\ &= \max\{V - \text{Cash amount}, 0\} \\ \text{Receiver swaption payoff at exercise} \\ &= \max\{\text{Cash amount} - V, 0\}\end{aligned}\quad (3)$$

where the cash amount is calculated from the strike price as in equation (1) or from the strike spread using a CDS valuation model as in equation (2). The cash amount is not affected by defaults. In fact, if a strike price is specified, the cash amount is known with certainty before option expiration. If a strike spread is specified, the only uncertainty about the cash amount derives from uncertainty about the interest rate curve. However, when pricing portfolio swaptions, it is standard to assume that forward rates are realized.

To price a swaption, we must specify a stochastic model for V . In addition to assuming that risk-neutral valuation is proper [1, 3], the standard model is based on two minimal assumptions that are clarified further:

1. the spread of the underlying portfolio swap is lognormally distributed and
2. the model correctly prices a synthetic forward contract constructed by combining a long payer and a short receiver with the same strikes.

The standard model assumes that V is a function, $V(X)$, of a hypothetical spread:

$$X = E(X) \exp(-0.5\sigma^2 T + \sigma \text{Normal}(0, T)) \quad (4)$$

where $\text{Normal}(0, T)$ is random normal variable with mean 0 and variance T (the time, in years, to option expiration), and σ is the free parameter that we interpret as the spread volatility. $E(X)$ is the expected value of X . The function $V(X)$ is the one found in equation (2) when the cash amount is seen as a function of the strike spread.

The swaptions are priced by discounting their expected terminal payoff (risk-neutral valuation). To understand where $E(X)$ comes from, consider a payer and a receiver swaption both with a strike price of 100% or equivalently strike spreads equal to the coupon in the underlying portfolio swap. In this case, the cash amount in equation (1) or (2) is zero and the terminal payoff from a position that is long the payer and short the receiver is V . The value of this position is therefore

$$V_0 = D(T)E(V(X)) \quad (5)$$

where $D(T)$ is the discount factor to time T (option expiration).

The value of a position that pays V , that is, V_0 , can also be determined from the credit curve of the underlying portfolio (potentially using the credit curves of all the names in the portfolio) since it is simply the value of owning protection on all names in the portfolio but only having to pay premium from option expiration onward. Once we have a value for V_0 , $E(V(X))$ can be found as $V_0/D(T)$ and $E(X)$ can be implied from this value. We can then price the swaptions using σ as the only additional parameter.

It is recommended to solve the model numerically to get the most accurate pricing. However, by making a few simple approximations (such as simplifying the expression for the PV01 in equation (2)) it is possible to derive approximate closed-form solutions that look like Black formulas.

See [2] for details on the model outlined above.

Other Models and Approaches

The standard model is a simple approach to what could be a very complicated problem. Instead of trying to model the credit curves and default of each of the names in the portfolio, the approach in the standard model is to model the hypothetical spread on the aggregate portfolio that also includes defaulted names. Thereby the model has only one free parameter, the aggregate spread volatility, and the approach becomes similar to using Black–Scholes for S&P 500 options. This analogy to the equity world suggests paths to the next generation of models such as introducing stochastic volatility and jumps or creating a model that starts from the individual credits by modeling their default, spread volatility, and spread correlation.

Hazard Rate

Consider a *credit default swap* (CDS) (see **Credit Default Swaps**), where the premium payments are periodic and the terminal payment is a digital cash settlement of recovery rate $1 - \bar{\ell}$. For simplicity, we assume that the current time is normalized to $t = 0$, the risk-free rate r is constant throughout the maturity of the contract, and spreads are already given at standard interperiod rates (allowing us to ignore day-count fractions and division by period length). The cash flows of a CDS can be decomposed into the default leg and the premium leg. The default leg is a single lump sum compensation for the loss $\bar{\ell}$ on the face value of the reference asset made at the default time by the protection seller to the protection buyer, given that the default is before the expiration date T of the contract. The premium leg consists of the fees, called the *CDS spread*, paid by the protection buyer at dates t_m (assumed to be equidistant e.g., quarterly) until the default event or T , whichever is first. The spread S is given as a fraction of the unit notional.

A concise mathematical expression for both legs can be obtained *via* a point process representation. Suppose we have a filtered probability space $(\Omega, \mathcal{F}, \mathbb{Q})$ satisfying the usual conditions. We model the default time as a random time τ in $[0, \infty]$ with an associated single jump point process

$$N_t = \mathbf{1}_{\{\tau \leq t\}} = \begin{cases} 1 & \text{if } \tau \leq t \\ 0 & \text{if } \tau > t \end{cases} \quad (1)$$

The default leg D_0 and premium leg $P_0(S)$ can now be expressed in terms of N as

$$D_0 = \mathbb{E}_0 \left[\bar{\ell} e^{-r\tau} N_\tau \right] = \mathbb{E}_0 \left[\int_0^T \bar{\ell} e^{-rs} dN_s \right] \quad (2)$$

$$P_0(S) = \mathbb{E}_0 \left[S \sum_{t_m} e^{-rt_m} (1 - N_{t_m}) \right] \quad (3)$$

where $\mathbb{E}_t[\cdot] = \mathbb{E}[\cdot | \mathcal{F}_t]$ is the conditional expectation with respect to time t , information $\mathcal{F}_t$, and the integral of equation (2) is defined in the Stieltjes sense. Finally, by an application of Fubini's theorem and integration by parts, equations (2) and (3) can be

expressed as

$$D_0 = \bar{\ell} e^{-rT} \mathbb{Q}_0[\tau \leq T] + \bar{\ell} r \int_0^T e^{-rs} \mathbb{Q}_0[\tau \leq s] ds \quad (4)$$

$$P_0(S) = S \sum_{t_m} e^{-rt_m} \mathbb{Q}_0[\tau > t_m] \quad (5)$$

The fair spread is the spread S^* for which $P_0(S^*) = D_0$, making the value of the contract at initiation 0. This simple expositional formulation shows that the modeling of survival probabilities under the pricing measure of the form $\mathbb{Q}_0[\tau > s]$ is the essence of CDS pricing. These quantities can be modeled in a unified way using the concept of *hazard rate*.

Hazard Rate and Default Intensity

Suppose that we have a filtered probability space $(\Omega, \mathcal{F}, \mathbb{Q})$ satisfying the usual conditions and that the default time of a firm is modeled by a random time τ , where $\mathbb{Q}[\tau = 0] = 0$ and $\mathbb{Q}[\tau > t] > 0$ for all $t \in \mathbb{R}_+$. We start under the assumption, which will be relaxed later, that the evolution of information only involves observations of whether or not default has occurred up to time t . In other words, we are dealing with the natural filtration $\mathcal{F}_t = \mathcal{N}_t = \sigma(N_s, s \leq t)$ of the right continuous, increasing process N , introduced earlier, completed to include the $\mathbb{Q}$ -negligible sets. Let $F(t) = \mathbb{Q}[\tau \leq t]$ be the cumulative distribution function of τ . Then, the *hazard function* of τ is defined by the increasing function $H : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ given as

$$H(t) = -\ln(1 - F(t)) \quad \forall t \in \mathbb{R}_+ \quad (6)$$

Suppose, furthermore, that F is absolutely continuous, admitting a density representation of $F(t) = \int_0^t f(s) ds$. The *hazard rate* of τ is defined by the nonnegative function $h : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ given as

$$h(t) = \frac{f(t)}{1 - F(t)} \quad (7)$$

under which we have

$$F(t) = 1 - e^{-H(t)} = 1 - e^{-\int_0^t h(s) ds} \quad \forall t \in \mathbb{R}_+ \quad (8)$$

Naturally, the component probabilities of equations (4) and (5) can be expressed in terms of the

hazard rate as

$$\begin{aligned} \mathbb{Q}[\tau > s | \mathcal{N}_t] \\ = \mathbf{1}_{\{\tau > t\}} e^{H(t) - H(s)} = \mathbf{1}_{\{\tau > t\}} e^{-\int_t^s h(u) du} \end{aligned} \quad (9)$$

$$\begin{aligned} \mathbb{Q}[t < \tau \leq s | \mathcal{N}_t] &= \mathbf{1}_{\{\tau > t\}} (1 - e^{H(t) - H(s)}) \\ &= \mathbf{1}_{\{\tau > t\}} \left(1 - e^{-\int_t^s h(u) du} \right) \end{aligned} \quad (10)$$

where $s \geq t$. Note that for a continuous h , $h(t)\Delta$ represents the first-order approximation of the probability of default between t and $t + \Delta$, given survival up to t . The term *hazard rate* stems from the fact that $h(t)$ can be thought of as the instantaneous ($\Delta \rightarrow 0$) rate of failure (in our case default arrival) at time t conditional on survival up to time t . Because of this conceptualization, the hazard rate is often referred to as the *forward default rate* in financial literature. While the term *default intensity* is also frequently used interchangeably with *hazard rate* [3], some authors [5] elect to distinguish between the two terms, where *intensity* is used to refer to the arrival rate conditioned on all observable information, and not only on survival. If survival is the only observable information, as in our current setting, the two terms are equivalent even under this distinction.

A useful alternate characterization of the hazard rate is possible using the martingale theory of point processes highlighted in [2]. As an increasing process, N has an obvious upward trend. The conditional probability of default by time $s \geq t$ is always greater than or equal to N_t itself, and hence N is a submartingale. It follows that N admits the Doob–Meyer decomposition [4] $N = M + A$, where M is an $\mathbb{F}$ -martingale and A is a right-continuous, $\mathbb{F}$ -predictable, increasing process starting from 0, both unique up to indistinguishability. A compensates for the upward trend such that $N - A$ is an $\mathbb{F}$ -martingale, and hence the popular terminology ($\mathbb{F}$ -)compensator (see **Compensators**). Compensators are interesting constructs in and of themselves, as their analytical properties correspond to probabilistic properties of the underlying random time. For instance, the almost sure continuity of sample paths of A is equivalent to the total inaccessibility of τ . Giesecke [6] outlines these properties and provides a direct compensator-based pricing application. As shown in [7], the connection between the compensator A and the hazard function H is that $A(t) = H(t \wedge \tau)$, if and

only if the cumulative distribution function $F(t)$ is continuous. Furthermore, if $F(t)$ is absolutely continuous we have $A(t) = \int_0^{t \wedge \tau} h(s) ds$, where h is the hazard rate. Therefore, under the continuity (absolute continuity) of $F(t)$, we can say that the hazard function H (hazard rate h) is the unique function such that $N(t) - H(t \wedge \tau)$ ($= N(t) - \int_0^{t \wedge \tau} h(s) ds$) is an $\mathbb{F}$ -martingale. However, the martingale/compensator characterization and the standard hazard function definition no longer coincide when $F(t)$ is not continuous.

In financial literature, we are also interested in cases where the current information filtration models not only survival but the observation of other processes as well. Let the total flow of information be modeled by $\mathbb{F} = \mathbb{N} \vee \mathbb{G}$, where $\mathbb{N}$ is once again the natural filtration of N (and all filtrations considered are right-continuous completions). Under certain conditions the previous concepts can be extended in a straightforward fashion. Let $F(t) = \mathbb{Q}[\tau \leq t | \mathcal{F}_t]$. First, we assume that τ is not a $\mathbb{G}$ -stopping time (while it is trivially an $\mathbb{F}$ -stopping time) such that the $\mathbb{G}$ -hazard process $H(t) = -\ln(1 - F(t))$ is well-defined. If H is absolutely continuous, admitting the $\mathbb{G}$ -progressive density representation $H(t) = \int_0^t h(s) ds$, then the process

$$M(t) := N(t) - H(t \wedge \tau) = N(t) - \int_0^{t \wedge \tau} h(s) ds \quad (11)$$

is an $\mathbb{F}$ -martingale, and the analogs of equations (9) and (10) are given by

$$\begin{aligned} \mathbb{Q}[\tau > s | \mathcal{F}_t] &= \mathbf{1}_{\{\tau > t\}} \mathbb{E} \left[e^{H(t) - H(s)} | \mathcal{F}_t \right] \\ &= \mathbf{1}_{\{\tau > t\}} \mathbb{E} \left[e^{-\int_t^s h(u) du} | \mathcal{F}_t \right] \end{aligned} \quad (12)$$

$$\begin{aligned} \mathbb{Q}[t < \tau \leq s | \mathcal{F}_t] &= \mathbf{1}_{\{\tau > t\}} \mathbb{E} \left[1 - e^{H(t) - H(s)} | \mathcal{F}_t \right] \\ &= \mathbf{1}_{\{\tau > t\}} \mathbb{E} \left[1 - e^{-\int_t^s h(u) du} | \mathcal{F}_t \right] \end{aligned} \quad (13)$$

In this setting, h is deemed the $\mathbb{G}$ -intensity or $\mathbb{G}$ -hazard rate. Even, in the case where τ is a $\mathbb{G}$ -stopping time ($\mathbb{D} \subset \mathbb{G}$) and thus the $\mathbb{G}$ -hazard function is not well defined, similar results can be obtained under certain conditions. Under certain restrictions on the

distributional properties of τ , we can still use point process martingale theory (see **Point Processes**) to find an increasing $\mathbb{F}$ -predictable process Λ for which the conditional survival probabilities are given by

$$\mathbb{Q}[\tau > s | \mathcal{F}_t] = \mathbf{1}_{\{\tau > t\}} \mathbb{E} \left[e^{\Lambda(t) - \Lambda(s)} | \mathcal{F}_t \right] \quad (14)$$

Routinely, if Λ is absolutely continuous then, $\Lambda(t) - \Lambda(s)$ in equation (14) can be replaced by its density representation $-\int_t^s \lambda(u) du$. The details of such conditions and results, as well as a general theory of hazard processes, are summarized in [1, 7].

Reduced-form Modeling and Other Issues

The importance of the concept of hazard rates (or intensities) lies in the fact that their direct modeling and parametrization is the prevalent industry practice in evaluating credit derivatives. Now that the CDS market has grown to one of great volume and liquidity, the realm of CDS spread modeling has become less of a pricing issue and more of a calibration one. *Reduced-form* modeling (see **Intensity-based Credit Risk Models**) refers to valuation methods in which one exogenously specifies the dynamics of an intensity model, much like we would for spot rates, and then calibrates the model parameters to fit the market spread data *via* a pricing formulation such as equations (4)–(5). A full-fledged model could incorporate features such as premium accrual, dependence of intensity with stochastic spot rates and the loss rate, and interaction/contagion effects with other names, which were ignored in our expositional formulation.

The assumptions, the underlying informational assumptions in particular, implied by the mere existence of a hazard rate are a nontrivial issue. Not all models admit an intensity process in their given information filtrations. For instance, in the classical first passage structural model under perfect information (see **Default Barrier Models**) the forward default rate (hazard rate with survival information only) exists, but the intensity process (hazard rate with all available information i.e. the firm value process) does not. Conceptually, the existence of a positive instantaneous default arrival rate implies a certain imperfection in the observable information, modeled either explicitly through a noisy filtration or implicitly through a totally inaccessible stopping time in the complete filtration. This underlines one of

the many issues surrounding the divergence of opinions and efforts for convergence in the reduced-form versus structural literature. Duffie and Singleton [5, 8] both provide a comprehensive overview of different credit models, while Giesecke [6] specifically outlines the different informational assumptions and their implications in intensity formulations.

Duffie–Singleton Model

The credit risk modeling approach of Duffie and Singleton [8, 9] falls into the class of *reduced-form* (see **Reduced Form Credit Risk Models**; **Intensity-based Credit Risk Models**) or intensity-based models in the sense that default is directly modeled as being triggered by a point process, as opposed to structural models (see **Structural Default Risk Models**) attempting to explain default through the dynamics of the firm’s capital structure, and the intensity of this process under a risk-neutral probability measure is related to an appropriately defined instantaneous credit spread. In its original construction, it is set out as an econometric model, that is, a model the parameters of which are estimated from the time series of market data, such as the weekly data of swap yields used in [8]. To this end, the model is driven by a set of state variables following a Markov process under the risk-neutral measure, and defaultable zero-coupon bond prices are exponentially affine functions of the state variables along the lines of the results derived by Duffie and Kan [6] for default-free models of the term structure of interest rates (see **Affine Models**). Duffie and Singleton [9] show that the model framework can be made specific in a way that also allows default intensities and default-free interest rates to be negatively correlated in a manner that is more consistent theoretically than in prior attempts in the literature.

A key assumption of Duffie–Singleton is the modeling of recovery in the event of default as an exogenously given fraction of the market value of the defaultable claim immediately prior to default. Under this assumption, the possibility of default on a claim can be priced by default-adjusting the interest rate with which the future cash flow (or payoff) from the claim is discounted. That is to say that today’s ($t = 0$) value V_0 of a claim with the (possibly random) payoff X at time $t = T$ can be calculated as the expectation under the spot risk-neutral measure Q ,

$$V_0 = E_0^Q \left[\exp \left\{ - \int_0^T R_t dt \right\} X \right] \quad (1)$$

where the discounting is given in terms of the default-adjusted short-rate process $R_t = r_t + h_t L_t$, with r_t the default-free continuously compounded short rate,

h_t the default hazard rate, and L_t the fraction of market value lost in the event of default. $\lambda_t = h_t L_t$ can be interpreted as a “risk-neutral mean-loss rate of the instrument due to default.” As a consequence, credit spread data alone (be it corporate bond yields, swap to treasury spreads, or credit default swap spreads) are insufficient to separate the “risk-neutral mean-loss rate” λ_t into its hazard rate h_t and loss fraction L_t .

The representation (1) lends the model considerable tractability, particularly for applications that do not require the separation of R_t into its components r_t , h_t , and L_t , since R_t could then be modeled directly as a function $\rho(Y_t)$ of a state variable process Y that is Markovian under Q . If the payoff of the claim is also Markovian in Y , say $X = g(Y_T)$, then the value of the claim at any time t (assuming that default has not occurred by time t) can be written as the conditional expectation

$$V_t = E^Q \left[\exp \left\{ - \int_t^T \rho(Y_s) ds \right\} g(Y_T) \middle| Y_t \right] \quad (2)$$

$\rho(Y_s)$ can be modeled analogously to any one of a number of tractable default-free interest rate term structure models. One possible choice of making the Markovian model specific is along the lines of a multifactor affine term structure model as studied by Dai and Singleton [3], in which r_t and λ_t are affine functions of the vector Y_t ,

$$r_t = \delta_0 + \sum_{i=1}^N \delta_i Y_t^{(i)} = \delta_0 + \delta_Y^\top Y_t \quad (3)$$

$$\lambda_t = \gamma_0 + \sum_{i=1}^N \gamma_i Y_t^{(i)} = \gamma_0 + \gamma_Y^\top Y_t \quad (4)$$

and Y_t follows an “affine diffusion”

$$dY_t = \mathcal{K}(\Theta - Y_t) dt + \Sigma \sqrt{S(t)} dW(t) \quad (5)$$

where W is an N -dimensional standard Brownian motion under Q , $\mathcal{K}$ and Σ are $N \times N$ matrices (which may, in general, be nondiagonal and asymmetric), and $S(t)$ is a diagonal matrix with the i th diagonal element given by

$$[S(t)]_{ii} = \alpha_i + \beta_i^\top Y_t \quad (6)$$

If certain admissibility conditions on the model parameters are satisfied [3], it follows from [6] that

default-free and defaultable zero-coupon bond prices are exponential affine functions of the state variables.

Duffie and Singleton [9] highlight that modeling Y as a vector of independent components following [2] “square-root diffusions” constrains the joint conditional distribution of r_t and λ_t in a manner inconsistent with empirical findings. In particular, the [3] conditions on admissible model parameters imply that such a model cannot produce negative correlation between the default-free interest rate and the default hazard rate. Duffie–Singleton instead propose to use a more flexible specification, which does not suffer from this disadvantage. In its three-factor form, it is given by

$$\alpha = \begin{pmatrix} 0 \\ 0 \\ \beta_3 \end{pmatrix} \quad \beta_1 = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \quad \beta_2 = \begin{pmatrix} 0 \\ \beta_{22} \\ 0 \end{pmatrix}$$

$$\beta_3 = \begin{pmatrix} \beta_{31} \\ \beta_{32} \\ 0 \end{pmatrix} \quad \delta_Y = \begin{pmatrix} \delta_1 \\ 1 \\ 1 \end{pmatrix} \quad \gamma_Y = \begin{pmatrix} \gamma \\ \gamma \\ 0 \end{pmatrix} \quad (7)$$

with all coefficients (including δ_0 and γ_0 in equations (3) and (4)) strictly positive. Furthermore,

$$\mathcal{K} = \begin{bmatrix} \kappa_{11} & \kappa_{12} & 0 \\ \kappa_{21} & \kappa_{22} & 0 \\ 0 & 0 & \kappa_{33} \end{bmatrix} \quad \Sigma = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \sigma_{31} & \sigma_{32} & 1 \end{bmatrix} \quad (8)$$

with the off-diagonal elements of $\mathcal{K}$ being nonpositive. This specification ensures strictly positive credit spreads λ_t and can represent negative correlation between the increments of r and λ .

The “recovery-of-market-value” assumption at the core of the Duffie–Singleton framework is in line with market practice for defaultable derivative financial instruments such as swaps. For defaultable bonds, it is arguably more realistic to model the loss in the event of default as a fraction of the par value. However, Duffie and Singleton [9] provide evidence that par yield spreads implied by reduced-form models are relatively robust with respect to different recovery assumptions, and suggest that for bonds trading substantially away from par, pricing differences due to different recovery assumptions can be largely compensated by changes in the recovery parameters. The computational tractability gained through the “recovery-of-market-value” assumption may thus

justify accepting its slight inconsistency with legal and market practice.

The parallels of equation (1) to the valuation of contingent claims in default-free interest rate term structure models also extend to the methodology of Heath *et al.* [10] (HJM). Defining a term structure of “defaultable instantaneous forward rates” $\bar{f}(t, T)$ in terms of defaultable zero-coupon bond prices $\bar{B}(t, T)$ (i.e., the time t price of a bond maturing in T) by

$$\bar{B}(t, T) = \exp \left\{ - \int_t^T \bar{f}(t, u) du \right\} \quad (9)$$

the model can be written in terms of the dynamics of the $\bar{f}(t, T)$, the drift of which under the risk-neutral measure must obey the no-arbitrage restrictions, derived by Heath, Jarrow, and Morton (HJM) in the default-free case. Note that the $\bar{f}$ are “forward rates” only in the sense that equation (9) is analogous to the definition of instantaneous forward rates in the default-free case and their relationship to forward bond prices is less straightforward than for default-free forward rates. That is to say that typically for the forward price $\bar{F}(t, T_1, T_2) = \bar{B}(t, T_2)/\bar{B}(t, T_1)$ (where $B(t, T)$ is a default-free zero-coupon bond), one has

$$\bar{F}(t, T_1, T_2) \neq \frac{\bar{B}(t, T_2)}{\bar{B}(t, T_1)} = \exp \left\{ - \int_{T_1}^{T_2} \bar{f}(t, u) du \right\} \quad (10)$$

For the continuously compounded defaultable short rate $\bar{r}(t) = \bar{f}(t, t)$, the no-arbitrage restrictions imply

$$\bar{f}(t, t) = r_t + h_t L_t = R_t \quad (11)$$

which is equal to the default-adjusted short rate given in equation (1). In this sense, the risk-neutral mean-loss rate $h_t L_t$ is equal to the instantaneous credit spread $\bar{r}(t) - r_t$.

Cast in terms of HJM, the model is automatically calibrated to an initial term structure of defaultable discount factors $\bar{B}(t, T)$. This type of straightforward “cross-sectional” calibration makes the model useful not only for the econometric estimation followed by Duffie and Singleton [8] and others such as Duffee [4] and Collin-Dufresne and Solnik [1] but also for the relative pricing of credit derivatives.

The model can be extended in a number of directions, several of which are discussed in [9]. “Liquidity” effects can be modeled by defining a fractional

carrying cost ℓ of defaultable instruments, in which case the relevant discount rate $R_t = r_t + h_t L_t + \ell_t$ is adjusted for default and liquidity. The assumption of exogenous default intensity and recovery rate can be lifted, as in [5], by allowing intensities/recovery rates to differ for the counterparties in an over-the-counter (OTC) derivative transaction, with the intensity/recovery rate relevant for discounting determined by which counterparty is in the money. Jumps in the default-adjusted rate can be introduced along the lines of [6] while preserving the tractability of an affine term structure model. The model of single-obligor default considered by Duffie and Singleton [8, 9] can also be extended to the portfolio level using the copula function approach of Schönbucher and Schubert [11], since introducing default correlation through correlated diffusive dynamics of the default intensities h_t for different obligors is typically insufficient, resulting only in very mild correlation of defaults.

Historically, reduced-form models like Duffie–Singleton have been considered to be following a different paradigm than the more fundamental structural models where default is triggered when the value of the firm falls below a barrier taken to represent the firm’s liabilities. However, the two approaches have been reconciled by Duffie and Lando [7], who show that models based on a default intensity can be underpinned by a structural model in which bondholders are imperfectly informed about the firm’s value.

Jarrow–Lando–Turnbull Model

The credit-risk model of Jarrow, Lando, and Turnbull is based on a Markov chain with finite state space, modeled in discrete or continuous time. Economically, it relies on the appealing interpretation of using different rating classes, which are represented by the states of the Markov chain. Presumably, it is the first credit-risk model that incorporates rating information into the valuation of defaultable bonds and credit derivatives. An advantage of modeling the credit-rating process is that the resulting bond prices explicitly depend on the issuer's initial rating and possible rating transitions in the future. Moreover, the model allows to price derivatives whose payoffs depend on the credit rating of some reference bond, an application that is not straightforward in intensity-based models or structural-default models.

Technically, the model is formulated on a filtered probability space with a money-market account $B = \{B(t)\}_{0 \leq t \leq T}$ as numéraire. The state space of the underlying Markov chain is denoted by $S = \{1, \dots, K\}$, where state K represents default. The other states are identified with rating classes that are ordered according to increasing default risk, that is, state 1 represents the best rating. Transition probabilities from one state to another are specified *via* a probability matrix $\mathbf{Q}$ in discrete time and using a generator matrix $\mathbf{\Lambda}$ in continuous time. Multiple defaults are excluded by making the default state absorbing, which corresponds to specific choices of the last rows of $\mathbf{Q}$ and $\mathbf{\Lambda}$, respectively. The original model achieves a high level of tractability by imposing the following assumptions: existence of a unique equivalent martingale measure, independence of risk-free interest rates and credit migrations under the martingale measure, and a constant recovery R paid at the maturity of the defaulted bonds. It is further suggested in [8] that historical transition probabilities could be adjusted by some deterministic, time-dependent, proportional risk premium to derive the required transition matrix $\tilde{\mathbf{Q}}$ or generator matrix $\tilde{\mathbf{\Lambda}}$ under the martingale measure. Then, T -year survival probabilities are expressed in terms of this martingale measure, under which defaultable bonds, futures, and derivatives on risky bonds are priced by computing their expected discounted payoff. To be more precise, let us briefly

describe the discrete-time case. Denoting the matrix of risk premiums at time t by the $K \times K$ -dimensional diagonal matrix $\mathbf{\Pi}(t) = \text{diag}(\pi_1(t), \dots, \pi_{K-1}(t), 1)$, it is assumed that

$$\tilde{\mathbf{Q}}(t, t+1) - \mathbf{I} = \mathbf{\Pi}(t)(\mathbf{Q} - \mathbf{I}) \quad (1)$$

where $\mathbf{I}$ denotes the K -dimensional identity matrix and with assumptions ensuring that $\tilde{\mathbf{Q}}(t, t+1)$ is a probability matrix with absorbing state K . It is well known that the n -step transition matrix at time t under the martingale measure is given by

$$\tilde{\mathbf{Q}}(t, t+n) = \prod_{i=0}^{n-1} \tilde{\mathbf{Q}}(t+i, t+i+1), \quad \forall n \in \mathbb{N} \quad (2)$$

Let τ denote the random default time and $C(T)$ the random payoff at time T of a credit-risky claim. Then the value $C(t)$ at time t of this contingent claim is given by

$$C(t) = B(t) \cdot \tilde{\mathbb{E}}_t[C(T)/B(T)] \quad (3)$$

with $\tilde{\mathbb{E}}_t$ denoting the conditional expectation, with respect to the information at time t under the martingale measure. Under these assumptions, the price $P(t, T)$ of a default-free zero-coupon bond at time t , maturing at time T , is given by

$$P(t, T) = B(t) \cdot \tilde{\mathbb{E}}_t[1/B(T)] \quad (4)$$

The corresponding price $P_i^d(t, T)$ of a defaultable zero-coupon bond rated i at time t is given by

$$P_i^d(t, T) = P(t, T) \cdot \left(R + (1 - R) \cdot \tilde{Q}_i^i(\tau > T) \right) \quad (5)$$

with $\tilde{Q}_i(\tau > T) = (\tilde{Q}_i^1(\tau > T), \dots, \tilde{Q}_i^{K-1}(\tau > T), 0)$ denoting the time T survival probabilities for firms in the different rating classes at time t under the martingale measure. These survival probabilities are given by

$$\tilde{Q}_i^i(\tau > T) = 1 - \tilde{q}_{i,K}(t, T), \quad i = 1, \dots, K \quad (6)$$

where $\tilde{q}_{i,K}(t, T)$ denotes the respective element of $\tilde{\mathbf{Q}}(t, T)$. Further applications of the model include the construction of hedging strategies against rating changes and the pricing of options on risky debt.

Most results derived in the discrete model find their analog in the continuous version of the model. More complicated in a continuous framework is the derivation of martingale probabilities, specified by the generator matrix $\tilde{\Lambda}$. For the construction of this matrix, [8] presents an implicit calibration method that starts with a historical estimation of Λ . On the basis of the paradigm of choosing $\tilde{\Lambda}$ close to the historical Λ , a proportional risk premium is introduced, which is calibrated to observed bond prices.

The original references of the presented methodology are [9] and [8], and an excellent textbook summary is Chapter 12 of [4]. An introduction to Markov chains is given in [1] and [3]. Estimation procedures of the historical intensity matrix are studied in [10] and [7]. Considering generalizations of the model, let us mention [5] for stochastic recovery rates, [2, 12], and [13], for transition probabilities explained by state variables, and [11] for a different risk premium. Finally, a multifirm extension using a stochastic time change is presented in [6].

Intensity-based Credit Risk Models

Reduced-form credit risk models have become standard tools for pricing credit derivatives and for providing a link between credit spreads and default probabilities. In structural models, following the Merton approach [1, 12], default is defined by a firm value hitting a certain barrier. In such an approach, the concept of credit spread is rather abstract since it is not modeled explicitly and therefore is not directly accessible and may also have dynamics that are not completely pleasing. Reduced-form models, however, concentrate on modeling the hazard rate or intensity of default, which is directly linked to the credit spread process. In contrast to a structural approach, the event of default in a reduced-form model comes about as a sudden unanticipated event (although the likelihood of this event may have been changing).

Deterministic Hazard Rates

Risk-neutral Default Probability

The basic idea around pricing default sensitive products is that of considering a risky zero-coupon bond of unit notional and maturity T . We write the payoff at maturity as

$$C(T, T) = \begin{cases} 1 & \text{default} \\ \delta & \text{no default} \end{cases} \quad (1)$$

where δ is an assumed recovery fraction paid immediately in the event of default. The price of a risky cash flow due at time T is then

$$C(t, T) = [S(t, T) + [1 - S(t, T)]\delta]B(t, T) \quad (2)$$

with $B(t, T)$ denoting the risk-free discount factor for time T as seen from time t , $S(t, T)$ is the risk-neutral survival (no default) probability (*see Hazard Rate*) in the interval $[t, T]$ or, equivalently, $1 - S(t, T)$ is the risk-neutral default probability. This style of approach was developed by Jarrow and Turnbull [8, 9].

Pricing a Credit Default Swap (CDS)

A credit default swap (CDS) (*see Credit Default Swaps*) has become a benchmark product for trading

credit risk and hence we base most of our analysis around CDS pricing. Standard assumptions used in pricing CDS include deterministic default probabilities, interest rates, and recovery values (or at least independence between these three quantities). In a CDS contract, the protection buyer will typically pay a fixed periodic premium, X_{CDS} , to the protection seller until the maturity date or the default (credit event) time (T). The present value of these premiums at time t can be written as

$$V_{\text{premium}}(t, T) = \sum_{i=1}^m S(t, t_i) B(t, t_i) \Delta_{i-1, i} X_{\text{CDS}} \quad (3)$$

where m is the number of premium payments and $\Delta_{i-1, i}$ represents the day count fraction.

The protection seller in a CDS contract will undertake in the event of a default to compensate the buyer for the loss of notional less some recovery value, δ . The value of the default component obtained by integrating over all possible default times is given by

$$V_{\text{default}}(t, T) = (1 - \delta) \int_t^T B(t, u) dS(t, u) \quad (4)$$

Note that due to the required negative slope of $S(t, u)$, this term will be negative; hence, the sum of equations (3) and (4) defines the value of a CDS from a protection provider's point of view.

Defining the Hazard Rate

In pricing a CDS, the main issue is to define $S(t, u)$ for all relevant times in the future, $t \leq u \leq T$. If we consider default to be a Poisson process driven by a constant intensity of default, then the survival probability is

$$S(t, u) = \exp[-h(u - t)] \quad (5)$$

where h is the intensity of default, often described as the hazard rate. We can interpret h as a forward instantaneous default probability; the probability of default in a small period dt conditional on no prior default is $h dt$. Default is a sudden unanticipated event (although it may, of course, have been partly anticipated due to a high value of h).

Link from Hazard Rate to Credit Spread

If we assume that CDS premiums are paid continuously,^a then the value of the premium

payments can be written as

$$V_{\text{premium}}(t, T) \approx X_{\text{CDS}} \int_t^T B(t, u) S(t, u) du \quad (6)$$

Under the assumption of a constant hazard rate of default, we can write $dS(t, u) = -hS(t, u) du$ and the default payment leg becomes

$$V_{\text{default}}(t, T) = -(1 - \delta)h \int_t^T B(t, u) S(t, u) du \quad (7)$$

The CDS spread will be such that the total value of these components is zero. Hence from $V_{\text{premium}}(t, T) + V_{\text{default}}(t, T) = 0$ we have the simple relationship

$$h \approx \frac{X_{\text{CDS}}}{(1 - \delta)} \quad (8)$$

The above close relationship between the hazard rate and CDS premium (credit spread) is important in that the underlying variable in our model is directly linked to credit spreads observed in the market. This is a key advantage over structural models whose underlying variables are rather abstract and hard to observe.

Simple Formulas

Suppose we define the risk-free discount factors *via* a constant continuously compounded interest rate $B(t, u) = \exp[-r(u - t)]$. We then have closed-form expressions for quantities such as

$$\begin{aligned} & V_{\text{premium}}(t, T) / X_{\text{CDS}} \\ & \approx \int_t^T \exp[-(r + h)(u - t)] du \\ & = \frac{1 - \exp[-(r + h)(T - t)]}{r + h} \end{aligned} \quad (9)$$

The above expression and equation (8) allow a quick calculation for the value of a CDS, or equivalently a risky annuity or DV01 for a particular credit.

Incorporating Term Structure

For a nonconstant intensity of default, the survival probability is given by

$$S(t, u) = \exp \left[- \int_t^u h(x) dx \right] \quad (10)$$

To allow for a term structure of credit (e.g., CDS premia at different maturities) and indeed a term structure of interest rates, we must choose some functional form for h . Such an approach is the credit equivalent of yield curve stripping, although due to the illiquidity of credit spreads much less refined, and was first suggested by Li [10]. The single-name CDS market is mainly based around 5-year instruments and other maturities will be rather illiquid. A standard approach is to choose a piecewise constant representation of the hazard rate to coincide with the maturity dates of the individual CDS quotes.

Extensions

Bonds and Basis Issues

Within a reduced-form framework, bonds can be priced in a similar way to CDS:

$$\begin{aligned} V_{\text{bond}}(t, T) = & \sum_{i=1}^m S(t, t_i) B(t, t_i) \Delta_{i-1, i} X_{\text{bond}} \\ & + S(t, T) B(t, T) - \delta \int_t^T B(t, u) dS(t, u) \end{aligned} \quad (11)$$

The first term above is similar to the default payment on a CDS but the assumption here is that the bond will be worth a fraction δ in default. The second and third terms represent the coupon and principal payments on the bond, respectively. It is therefore possible to price bonds *via* the CDS market (or *vice versa*) and indeed to calibrate a credit curve *via* bonds of different maturities from the same issuer. However, the treatment of bonds and CDS within the same modeling framework must be done with caution. Components such as funding, the CDS delivery option, delivery squeezes, and counterparty risk mean that CDS and bonds of the same issuer will trade with a basis representing nonequal risk-neutral default probabilities. In the context of the

formulas, the components creating such a basis would represent different recovery values as well as discount factors when pricing CDS and bonds of the same issuer.

Stochastic Default Intensity

The deterministic reduced-form approach can be extended to accommodate stochastic hazard rates and leads to the following expression for survival probabilities:-

$$S(t, u) = E^Q \left[\exp \left[- \int_t^u h(x) dx \right] \right] \quad (12)$$

This has led to various specifications for modeling a hazard rate process with parallels with interest-rate models for modeling products sensitive to credit spread volatility with examples to be found in [4, 5, 11]. Jarrow *et al.* [7] (see **Jarrow-Lando-Turnbull Model**) have extended such an approach to have a Markovian structure to model credit migration or discrete changes in credit quality that would lead to jump in the credit spread. Furthermore, credit hybrid models with hazard rates correlated to other market variables, such as interest rates, have been introduced. For example, see [13].

Portfolio Approaches

The first attempts at modeling portfolio credit products, such as basket default swaps and CDOs, involved multidimensional hazard rate models. However, it was soon realized that introducing the level of default correlation required to price such products realistically was far from trivial. This point is easily understood by considering that two perfectly correlated hazard rates will not produce perfectly correlated default events and more complex dynamics are required such as those considered by Duffie [3]. Most portfolio credit models have instead followed structural approaches (commonly referred to as *copula models* with the so-called Gaussian copula model becoming the market standard for pricing CDOs; see **Gaussian Copula Model**) for reasons of simplicity. Schonbucher and Schubert [14] have shown how to combine intensity and copula models. More recently, the search for

more sophisticated portfolio credit risk modeling approaches is largely based around reduced-form models as in [2] and [6] (see **Multiname Reduced Form Models**).

Conclusions

We have outlined the specification and usage of reduced-form models for modeling a default process and described the link between the underlying in such a model and market observed credit spreads. We have described the application of such models to vanilla credit derivative structures such as CDS and also more sophisticated structures such as credit spread options, credit hybrid instrument, and portfolio credit products.

End Notes

^aCDS premiums are typically paid quarterly in arrears but an accrued premium is paid in the event of default to compensate the protection seller for the period for which a premium has been paid. Hence the continuous premium assumption is only a mild approximation.

Default Barrier Models

The modeling of default from an economic point of view is a great challenge due to the binary and low probability nature of such an event. Default barrier models provide an elegant solution to this challenge since they link the default event to the point at which some continuously evolving quantity hits a known barrier. In structural models of credit risk (*see Structural Default Risk Models*) the process and the barrier are interpreted in terms of capital structure of the firm as the value of the firm and its liabilities. More generally, one can view the process and the barrier as state variables that need not necessarily be observable.

Single-name Models

In the classic Merton framework [12], the value of a firm (asset value) is considered to be stochastic and default is modeled as the point where the firm is unable to pay its outstanding liabilities when they mature. The asset value is modeled as a geometric Brownian motion:

$$\frac{dV_t}{V_t} = \mu dt + \sigma dW \quad (1)$$

where μ and σ represent the drift and volatility of the asset, respectively, and dW is a standard Brownian motion. The original Merton model assumes that a firm has issued only a zero-coupon bond and will not therefore default prior to the maturity of this debt as illustrated in Figure 1. Denoting the maturity and face value of the debt by T and D respectively, the default condition can then be written as $V_T < D$. Through option pricing arguments, Merton then provides a link between corporate debt and equity *via* pricing formulae based on the value of the firm and its volatility (analogously to options being valued from spot prices and volatility). The problem of modeling default is transformed into that of assessing the future distribution of firm value and the barrier where default would occur. Such quantities can be estimated nontrivially from equity data and capital structure information. This is then the key contribution of Merton approach in that low-frequency binary events can be modeling *via* a continuous process and calibrated using high-frequency data.

Practical Extensions of the Merton Approach

The classic Merton approach has been extended by many authors such as Black and Cox [2] and Leland [10]. Commercially, it has been developed by KMV™ (now Moody's KMV) with the aim of predicting default *via* the assessment of 1-year default probability defined as EDF™ (expected default frequency). A more recent and related, although simpler, approach is CreditGrades™.

Moody's KMV Approach. This approach [8, 9] was inspired by the Merton approach to default modeling and aimed to lift many of the stylized assumptions and model the evolution and future default of a company in a realistic fashion. A key aspect of this is to account for the fact that a firm may default at any time but will not necessarily default immediately when they are bankruptcy insolvent (when $V_t < D$). Hence a challenge is to work out exactly where the default barrier is. KMV do this *via* considering both the short-term and long-term liabilities of the firm. Their approach can be broadly summarized in three stages:

- estimation of the market value and volatility of a firm's assets;
- calculation of the distance to default which is an index measure of default risk; and
- scaling of the distance to default to the actual probability of default using a default database.

The distance to default (DD) measure, representing a standardized distance from which a firm is above its default threshold, is defined by^a

$$DD = \frac{\ln(V/D) + (\mu - 0.5\sigma^2)T}{\sigma\sqrt{T}} \quad (2)$$

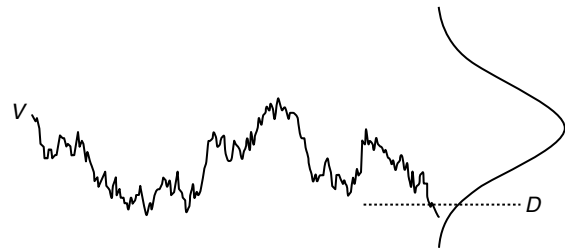

Figure 1 Illustration of the traditional Merton approach to modeling default based on the value of the firm being below the face value of debt at maturity

The default probability would then be given by $p_d = \Phi(-DD)$. A key element of the approach is to recognize the model risk inherent in this approach and rather to estimate the default probability empirically from many years of default history (and the calculated DD variables). We therefore ask ourselves the following question: for a firm with a DD of 4.0 (say), how often have firms with the same DD defaulted historically? The answer is likely to be considerably higher than the theoretical result of $\Phi(-4.0) = 0.003\%$. This mapping of DD to actual default probability could be thought of as an empirical correction for the non-Gaussian behavior of firm value.

CreditGrades Approach. The aim of CreditGrades is rather similar to that of KMV except that the modeling framework [3] is rather simpler, in particular without using empirical data in order to map to an eventual default probability. In the Credit Grades approach, the default barrier is given by

$$LD = \bar{L}De^{\lambda Z - \lambda^2/2} \quad (3)$$

where Z is a standard normal variable, D is the “debt per share”, $\bar{L}$ is an average recovery level, and λ creates an uncertainty in the default barrier. The level of the default barrier and the asset return are independent. Hence the main differences between the traditional Merton approach and CreditGrades is that the latter approach assumes that default can occur at any time when the asset process has dropped to a level of LD , whereas the Merton framework assumes $\bar{L} = 1$ and $\lambda = 0$ and no default prior to the maturity of the debt. CreditGrades recommends values of $\bar{L} = 0.5$ and $\lambda = 0.3$. A sensitivity analysis of these parameters should give the user a very clear understanding of the uncertainties inherent in estimating default probability.

Portfolio Models

While default barrier models have proved very useful for assessing single-name default probability and supporting trading strategies such as capital structure arbitrage, arguably an even more significant development has been their application in credit portfolio models. The basic strength of the default barrier approach is to provide the transformation necessary to

model default events *via* a multivariate normal distribution driven by asset correlations. The intuition of the approach makes it possible to add complexities such as credit migrations and stochastic recovery rates into the model.

Default Correlation

Consider modeling the joint default probability of two entities. Using the standard definition of a correlation coefficient, we can write the joint default probability as

$$p_{AB} = p_A p_B + \rho_{AB} \sqrt{p_A(1-p_A)p_B(1-p_B)} \quad (4)$$

where p_A and p_B are the individual default probabilities and ρ_{AB} is the default correlation. Assuming, without loss of generality, that $p_A \leq p_B$ and since the joint default probability can be no greater than the smaller of the individual default probabilities, we have

$$\begin{aligned} \rho_{AB} &= \frac{p_{AB} - p_A p_B}{\sqrt{p_A(1-p_A)p_B(1-p_B)}} \\ &\leq \frac{p_A - p_A p_B}{\sqrt{p_A(1-p_A)p_B(1-p_B)}} \\ &= \sqrt{\frac{p_A(1-p_B)}{p_B(1-p_A)}} \end{aligned} \quad (5)$$

This shows that the default correlation cannot be +1 (or indeed *via* a similar argument -1) unless the individual default probabilities are equal. There is therefore a maximum (and minimum) possible default correlation that changes with the underlying default probabilities. This suggests a need for more economic structure to model joint default probability.

Default Barrier Approach

Suppose that we write default as being driven by a standard Gaussian variable X_i being below a certain level $k = \Phi^{-1}(p)$. We can interpret X as being an asset return in the classic Merton sense, with k being a default barrier. Now joint default probability is readily defined *via* a bivariate Gaussian distribution:

$$p_{AB} = \Phi_2(\Phi^{-1}(p_A), \Phi^{-1}(p_B); \lambda_{AB}) \quad (6)$$

where Φ_2 is a cumulative bivariate cumulative distribution function and λ_{AB} is the “asset correlation”.

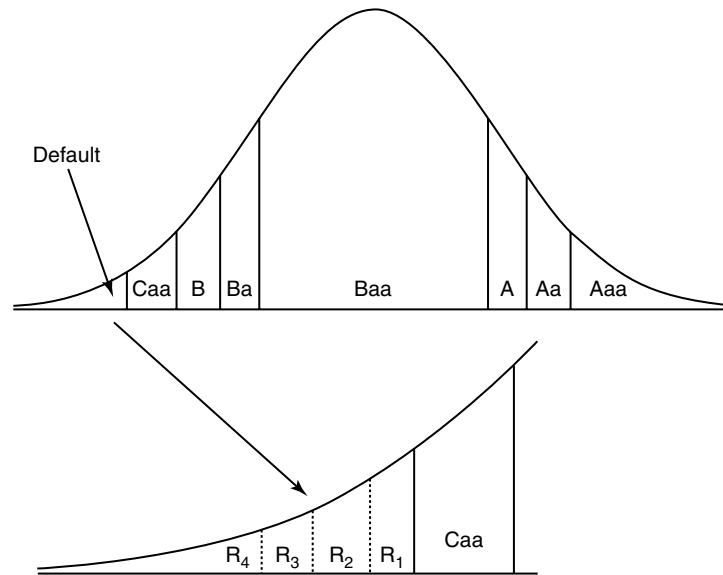

Figure 2 Illustration of the mapping of default and credit migrations thresholds as used in the CreditMetrics approach. The default region is also shown with additional thresholds corresponding to different recovery values with $R_1 < R_2 < R_3 < R_4$

Multiple names can be handled *via* a multivariate Gaussian distribution^b with Monte Carlo simulation or various factor-type approaches used for the calculation of multiple defaults and/or losses.

Although there is a clear link between this simple approach and the multidimensional Merton model, we have ignored the full path of the asset value process and linked default to just a single variable X_i . A more rigorous time-dependent approach can be found in [7], which is much more complex and time consuming to implement. In practice, the one-period approach is rather similar to the full approach for relative small default probabilities.

CreditMetrics

CreditMetrics [6], first published in 1997, is a credit portfolio model based on the multivariate normal default barrier approach. This framework assumes a default barrier as described above and also considers the mapping of credit migration probabilities onto the same normal variable. A downgrade can therefore be seen as a less extreme move not causing default. In addition to credit migrations, one can also superimpose different recovery rates onto the same mapping so that there is more than one default barrier with lower barriers representing more severe default

and therefore a lower recovery value; for example, see [1]. An illustration of the mapping is shown in Figure 2.

Regulatory Approaches

Basel 2. A key strength of the above framework is that defaults, credit migrations, and recovery rates can be modeled within a single intuitive framework with correlation parameters estimated from equity data. While other credit portfolio modeling frameworks have been proposed, the CreditMetrics style approach has been the most popular. Indeed, the Basel 2 formula [4] can be seen as arising from a simplified version of this approach with the following assumptions:

- no credit migration or stochastic recovery and
- infinitely large homogeneous portfolio.

Rating Agency Approaches to Structured Finance.

With the massive growth of the collateralized debt obligation (CDO) came a need for rating agencies (*see Structured Finance Rating Methodologies*) to model the risk inherent in a CDO structure with a view to assigning a rating to some or all of the tranches of the CDO capital structure. Rating a

tranche of a CDO is essentially the same problem as estimating capital on a credit portfolio and hence it may come as no surprise that the rating agencies models were based on default barrier approaches. The rating agencies models can be thought of as therefore heavily following the CreditMetrics approach. The credit crisis of 2007 brought very swift criticism of rating agency modeling approaches to rating all types of structure finance and CDO structures. This was related largely to poor assessment of the model parameters (specifically rather optimistic default probabilities and correlation assumptions) rather than a failure of the model itself.

CDO Pricing

A final and perhaps most exciting (although not for necessarily positive reasons) application of the default barrier approach is in the pricing of synthetic CDO structures. The market standard approach for pricing CDOs follows the work of Li [11] (*see Gaussian Copula Model*) who models time of default in a multivariate normal framework:

$$\begin{aligned} \Pr(T_A < 1, T_B < 1) \\ = \Phi_2(\Phi^{-1}(F_A(T_A)), \Phi^{-1}(F_B(T_B)); \gamma) \end{aligned} \quad (7)$$

where F_A and F_B are the distribution functions for the survival times T_B and T_B and γ is a correlation parameter. At first glance, although this uses the same multivariate distribution, or copula^c, this approach initially does not seem to be a default barrier model. However, as noted in [11], for a single period, the approaches are identical. Furthermore, as shown by Laurent and Gregory [5], the pricing of a synthetic CDO requires just the knowledge of loss distributions at each date up to the contractual maturity date (and not any further dynamical information). Hence, we can think of the Li approach as being again similar^d to the traditional framework of credit portfolio modeling, following CreditMetrics and ultimately inspired by the Merton approach to modeling default *via* the hitting time of a barrier. The recent strong criticism linking the model in [11] to the credit crisis [13] does not fairly consider the rather naïve calibration use of the model that has caused many of the problems in structured finance.

Conclusions

We have described the range of default barrier models used in default probability estimation, capital structure trading, credit portfolio management, regulatory capital calculations, and pricing and rating CDO products. The intuition that default can be modeled as a hitting of a barrier has been crucial to the rapid development of credit risk models. For credit portfolio risk in particular, the default barrier approach has been key to the development of models for many different purposes, driven from the same underlying structural framework. Given that some applications of the approach (most notably rating agency models and CDO pricing) have received large criticism, it is worth pointing out that one can only discredit the entire framework (including any multidimensional Merton approach) or realize that it is a misuse of the model rather than the model itself that lies at the heart of the problems.

End Notes

^aIn the proprietary Moody's KMV implementation, the default point is not the face value of debt but the current book value of their liabilities. This is often computed as short-term liabilities plus half long-term liabilities.

^bIt should be noted that alternatives to a Gaussian distribution (e.g., student-*t*) can and have been considered although the Gaussian approach has remained most common.

^cThis approach has become known as the *Gaussian copula model* which is perhaps confusing since the key point of the approach is the representation of the joint distribution of default times and not the choice of a Gaussian copula or multivariate distribution.

^dLi was at the time working at JP Morgan and so this is not surprising.

Multiname Reduced Form Models

Currently, there are three established approaches for describing the default of a single credit: (i) reduced-form; (ii) structural; and (iii) hybrid. It has been an outstanding goal for many researchers to extend these approaches to baskets of several (potentially many) credits. In this article, we concentrate on the reduced-form approach and show how it works in single-name and multiname settings.

Single-name Intensity Models

For a single name, the main assumptions of the reduced-form model are as follows [8, 9, 12]. The name defaults at the first time a Cox process jumps from 0 to 1. The default intensity (hazard rate) $X(t)$ of this process is governed by a mean-reverting nonnegative jump-diffusion process

$$dX(t) = f(t, X(t)) dt + g(t, X(t)) dW(t) + J dN(t), \quad X(0) = X_0 \quad (1)$$

where $W(t)$ is a standard Wiener process, $N(t)$ is a Poisson process with intensity $\lambda(t)$, and J is a positive jump distribution; W, N, J are mutually independent. It is clear that we have to impose the following constraints:

$$f(t, 0) \geq 0, \quad f(t, \infty) < 0, \quad g(t, 0) = 0 \quad (2)$$

plus a number of other technical conditions to ensure that $X(t)$ stays nonnegative and is mean reverting.

For analytical convenience (rather than for stronger reasons), it is customary to assume that X is governed by the square-root stochastic differential equation (SDE):

$$dX(t) = \kappa(\theta(t) - X(t)) dt + \sigma\sqrt{X(t)} dW(t) + J dN(t), \quad X(0) = X_0 \quad (3)$$

with exponential (or hyperexponential) jump distribution [4]. However, for practical purposes it is more convenient to consider discrete jump distributions with jump values $J_m > 0$, $1 \leq m \leq M$, occurring with probabilities $\pi_m > 0$; such distributions are more flexible than parametric ones because they allow one to place jumps where they are needed.

In this framework, the survival probability of the name from time 0 to time T has the form

$$q(0, T) = \mathbb{E}_0 \left\{ e^{-\int_0^T X(t') dt'} \right\} = \mathbb{E}_0 \{ e^{-Y(T)} \} \quad (4)$$

where $Y(t)$ is governed by the following degenerate SDE:

$$dY(t) = X(t) dt, \quad Y(0) = 0 \quad (5)$$

More generally, the survival probability from time t to time T conditional on no default before time t has the form

$$\begin{aligned} q(t, T | X(t), Y(t)) &= \mathbb{I}_{(\tau > t)} \mathbb{E}_t \left\{ e^{-\int_t^T X(t') dt'} \middle| X(t), Y(t) \right\} \\ &= e^{Y(t)} \mathbb{I}_{(\tau > t)} \mathbb{E}_t \{ e^{-Y(T)} | X(t), Y(t) \} \end{aligned} \quad (6)$$

where τ is the default time and $\mathbb{I}_{(\tau > t)}$ is the corresponding indicator function. This expectation, and, more generally, expectations of the form $\mathbb{E}_t \{ e^{-\xi Y(T)} | X(t), Y(t) \}$, can be computed by solving the following augmented partial differential equation (PDE) (see [10], Chapter 13):

$$\mathcal{L}V(t, T, X, Y) + X V_Y(t, T, X, Y) = 0 \quad (7)$$

$$V(T, T, X, Y) = e^{-\xi Y} \quad (8)$$

where

$$\begin{aligned} \mathcal{L}V &\equiv V_t + \kappa(\theta(t) - X) V_X + \frac{1}{2} \sigma^2 X V_{XX} \\ &\quad + \lambda \sum_m \pi_m [V(X + J_m) - V(X)] \end{aligned} \quad (9)$$

Specifically, the following relation holds:

$$\mathbb{E}_t \{ e^{-\xi Y(T)} | X(t), Y(t) \} = V(t, T, X(t), Y(t)) \quad (10)$$

The corresponding solution can be written in the so-called affine form:

$$V(t, T, X, Y) = e^{a(t, T, \xi) + b(t, T, \xi)X - \xi Y} \quad (11)$$

where a, b are functions of time governed by the following system of ordinary differential equations (ODEs):

$$\begin{cases} \frac{da(t, T, \xi)}{dt} = -\kappa \theta(t) b(t, T, \xi) \\ \quad - \lambda \sum_m \pi_m [e^{J_m b(t, T, \xi)} - 1] \\ \frac{db(t, T, \xi)}{dt} = \xi + \kappa b(t, T, \xi) \\ \quad - \frac{1}{2} \sigma^2 b^2(t, T, \xi) \end{cases} \quad (12)$$

$$a(T, T, \xi) = 0, \quad b(T, T, \xi) = 0 \quad (13)$$

While in the presence of discrete jumps this system cannot be solved analytically, it is very easy to solve it numerically *via* the standard Runge–Kutta method. The survival probability $q(0, T)$ and default probability $p(0, T)$ have the form

$$\begin{aligned} q(0, T) &= e^{a(0, T, 1) + b(0, T, 1)X_0} \\ p(0, T) &= 1 - q(0, T) = 1 - e^{a(0, T, 1) + b(0, T, 1)X_0} \end{aligned} \quad (14)$$

Assuming for simplicity that the short interest rate $r(t)$ is deterministic and the protection payments are made continuously, we can write the value U of a credit default swap (CDS) paying an up-front amount v and a coupon s in exchange for receiving $1 - R$

(where R is the default recovery) on default as follows:

$$U = -v + V(0, X_0) \quad (15)$$

Here, $V(t, X)$ solves the following pricing problem:

$$\mathcal{L}V(t, X) - (r + X)V(t, X) = s - (1 - R)X \quad (16)$$

$$V(T, X) = 0 \quad (17)$$

where $\mathcal{L}$ is given by expression (9). Using Duhamel's principle, we obtain the following expression for V :

$$\begin{aligned} V(t, X) &= -s \int_t^T D(t, t') e^{a(t, t', 1) + b(t, t', 1)X} dt' \\ &\quad - (1 - R) \int_t^T D(t, t') d[e^{a(t, t', 1) + b(t, t', 1)X}] \end{aligned} \quad (18)$$

where

$$D(t, t') = e^{-\int_t^{t'} r(t'') dt''} \quad (19)$$

is the discount factor between two times t and t' . Accordingly,

$$\begin{aligned} U &= -v - s \int_0^T D(0, t') (1 - p(0, t')) dt' \\ &\quad + (1 - R) \int_0^T D(0, t') dp(0, t') \end{aligned} \quad (20)$$

For a given up-front payment v , we can represent the corresponding par spread $\hat{s}$ (i.e., the spread that makes the value of the corresponding CDS zero) as follows:

$$\hat{s}(T) = \frac{-v + (1 - R) \int_0^T D(0, t') dp(0, t')}{\int_0^T D(0, t') (1 - p(0, t')) dt'} \quad (21)$$

It is clear that the numerator represents the payout in the case of default, while the denominator represents the risky DV_{01} . Conversely, for a given

spread we can represent the par up-front payment in the form

$$\begin{aligned} \hat{v} = & -s(T) \int_0^T D(0, t') (1 - p(0, t')) dt' \\ & + (1 - R) \int_0^T D(0, t') dp(0, t') \end{aligned} \quad (22)$$

In these formulas, we implicitly assume that the corresponding CDS is fully collateralized, so that in the event of default $1 - R$ is readily available. Shortly, we will evaluate CDS spreads in the presence of the counterparty risk.

In general, there is not enough market information to calibrate the diffusion and jump parts. So, typically, they are viewed as given constants, and the mean-reversion level $\theta(t)$ is calibrated in such a way that the whole par spread curve is matched.

Multiname Intensity Models

The Two-name Case

It is very tempting to extend the above framework to cover several correlated names. For example, consider two credits, A, B and assume for simplicity that their default intensities coincide,

$$X_A(t) = X_B(t) = X(t) \quad (23)$$

and both names have the same recovery $R_A = R_B = R$. For a given maturity T , the default event correlation ρ is defined as follows:

It is clear that

$$\begin{aligned} p_A(0, T) &= p_B(0, T) = p(0, T) \\ &= 1 - e^{a(0, T, 1) + b(0, T, 1)X_0} \end{aligned} \quad (27)$$

Simple calculation yields

$$\begin{aligned} p_{AB}(0, T) &= \mathbb{E}_0 \left\{ e^{-\int_0^T (X_A(t') + X_B(t')) dt'} \right\} \\ &\quad + p_A(0, T) + p_B(0, T) - 1 \\ &= \mathbb{E}_0 \left\{ e^{-2 \int_0^T X(t') dt'} \right\} + 2p(0, T) - 1 \end{aligned} \quad (28)$$

so that

$$\begin{aligned} \rho(0, T) &= \frac{\mathbb{E}_0 \left\{ e^{-2 \int_0^T X(t') dt'} \right\} - (1 - p(0, T))^2}{p(0, T)(1 - p(0, T))} \\ &= \frac{e^{a(0, T, 2) + b(0, T, 2)X_0} - e^{2a(0, T, 1) + 2b(0, T, 1)X_0}}{(1 - e^{a(0, T, 1) + b(0, T, 1)X_0}) e^{a(0, T, 1) + b(0, T, 1)X_0}} \end{aligned} \quad (29)$$

It turns out that in the absence of jumps, the corresponding event correlation is very low [12]. However, if large positive jumps are added (while overall survival probability is preserved), then correlation can increase all the way to one. Assuming that

$$\rho(0, T) = \frac{P(\tau_A \leq T, \tau_B \leq T) - P(\tau_A \leq T)P(\tau_B \leq T)}{\sqrt{P(\tau_A \leq T)(1 - P(\tau_A \leq T))P(\tau_B \leq T)(1 - P(\tau_B \leq T))}} \quad (24)$$

$$\rho(0, T) = \frac{p_{AB}(0, T) - p_A(0, T)p_B(0, T)}{\sqrt{p_A(0, T)(1 - p_A(0, T))p_B(0, T)(1 - p_B(0, T))}} \quad (25)$$

where τ_A, τ_B are the default times, and

$$\begin{aligned} p_A(0, T) &= P(\tau_A \leq T), \quad p_B(0, T) = P(\tau_B \leq T) \\ p_{AB}(0, T) &= P(\tau_A \leq T, \tau_B \leq T) \end{aligned} \quad (26)$$

$T = 5y, \kappa = 0.5, \sigma = 7\%$, and $J = 5.0$, we illustrate this observation in Figure 1.

In the two-name portfolio, we can define two types of CDSs which depend on the correlation: (i) the first-to-default (FTD) swap; (ii) the

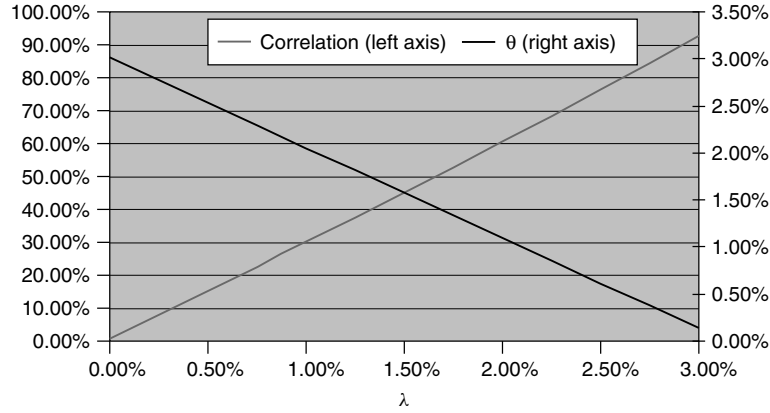

Figure 1 Correlation ρ and mean-reversion level $\theta = X_0$ as functions of jump intensity λ . Other parameters are as follows: $T = 5y$, $\kappa = 0.5$, $\sigma = 7\%$, and $J = 5.0$

second-to-default (STD) swap. The corresponding par spreads (assuming that there are no up-front payments) are

where V is the value of a fully collateralized CDS on name B with spread s , and $V_+ = \max\{V, 0\}$, $V_- = \min\{V, 0\}$. It is clear that the discount rate

$$\hat{s}_1(T) = \frac{(1-R) \int_0^T D(0, t') d \left[1 - e^{a(0, t') + b(0, t') X_0} \right]}{\int_0^T D(0, t') e^{a(0, t') + b(0, t') X_0} dt'} \quad (30)$$

$$\hat{s}_2(T) = \frac{(1-R) \int_0^T D(0, t') d \left[1 - \left(2e^{a(t', 1) + b(t', 1) X_0} - e^{a(t', 2) + b(t', 2) X_0} \right) \right]}{\int_0^T D(0, t') \left(2e^{a(t', 1) + b(t', 1) X_0} - e^{a(t', 2) + b(t', 2) X_0} \right) dt'} \quad (31)$$

It is clear that the relative values of $\hat{s}_1, \hat{s}_2$ very strongly depend on whether or not jumps are present in the model (see Figure 2).

However, an even more important application of the above model is the evaluation of counterparty effects on fair CDS spreads. Let us assume that name A has written a CDS on reference name B . It is clear that the pricing problem for the value of the uncollateralized CDS $\tilde{V}$ can be written as follows:

$$\begin{aligned} \mathcal{L}\tilde{V}(t, X) - (r + 2X) \tilde{V}(t, X) \\ = s - (1-R)X - (RV_+(t, X) + V_-(t, X))X \end{aligned} \quad (32)$$

is increased from $r + X$, in equation (16), to $r + 2X$, in equation (32), since there are two cases when the uncollateralized CDS can be terminated due to default: when the reference name B defaults and when the issuer A defaults. The terms on the right represent a continuous stream of coupon payments, the amount received if B defaults before A , and the amount received (or paid) in case when A defaults before B . Although equation (32) is no longer analytically solvable, it can be solved numerically *via*, say, an appropriate modification of the classical Crank–Nicholson method. It turns out that in the presence of jumps the value of the fair par spread goes down dramatically.

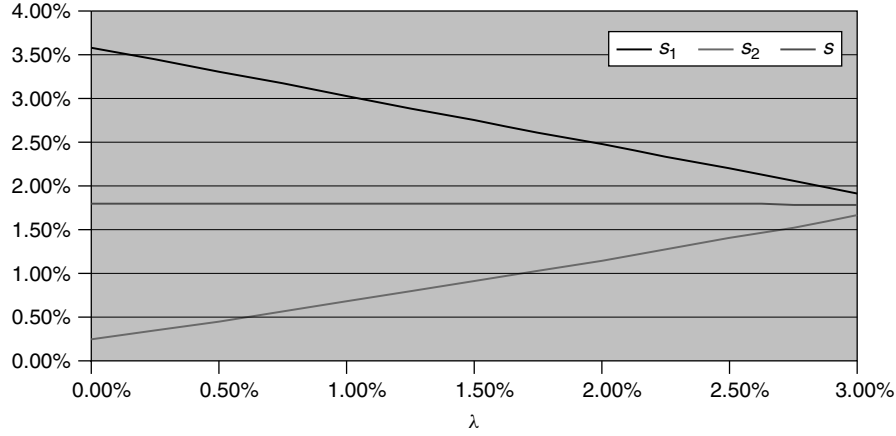

Figure 2 FTD spread $\hat{s}_1$, STD spread $\hat{s}_2$, and single-name CDS spread $\hat{s}$ as functions of jump intensity λ . Other parameters are the same as in Figure 1. It is clear that jumps are necessary to have $\hat{s}_1$ and $\hat{s}_2$ of similar magnitudes

The Multiname Case

The above modeling framework has been expanded in various directions and used as a basis for several coherent intensity-based models for credit baskets; see [2, 3, 6, 7, 11].

To start, we briefly summarize the affine jump-diffusion model of Duffie–Garleanu [3] and Mortensen [11]. Consider a basket of N names with equal unit notionals and equal recoveries R . Let us assume that the corresponding default intensities can be decomposed as follows:

$$X_i(t) = \beta_i X_c(t) + \tilde{X}_i(t) \quad (33)$$

where X_c is the common intensity driven by the following SDE:

$$\begin{aligned} dX_c(t) &= \kappa_c (\theta_c - X_c(t)) dt + \sigma_c \sqrt{X_c(t)} dW_c(t) \\ &\quad + J_c dN_c(t) \\ X_c(0) &= X_{c0} \end{aligned} \quad (34)$$

while $\tilde{X}_i$ are idiosyncratic intensities driven by similar SDEs:

$$\begin{aligned} d\tilde{X}_i(t) &= \kappa_i (\theta_i - \tilde{X}_i(t)) dt + \sigma_i \sqrt{\tilde{X}_i(t)} dW_i(t) \\ &\quad + \tilde{J}_i dN_i(t) \\ \tilde{X}_i(0) &= \tilde{X}_{i0} \end{aligned} \quad (35)$$

Here, $1 \leq i \leq N$. The processes $\tilde{X}_i(t)$, $X_c(t)$ are assumed to be independent. In this formulation, β_i are similar to the β_i appearing in the capital asset pricing model (CAPM). We note that θ_c, θ_i are assumed to be constant. In the original Duffie–Garleanu formulation, it was assumed that all $\beta_i = 1$. However, this assumption is very restrictive since it limits the magnitude of the common factor by the size of the lowest spread X_i , so that, in general, high correlation cannot be achieved. It was lifted in the subsequent paper by Mortensen. Of course, to preserve analyticity, one needs to impose very rigid conditions on the coefficients of the corresponding SDEs, since, in general, the sum of two affine processes is not an affine process. Specifically, the following should hold:

$$\kappa_i = \kappa_c = \kappa, \quad \sigma_i = \sqrt{\beta_i} \sigma_c, \quad \lambda_i = \lambda, \quad J_{im} = \beta_i J_{cm} \quad (36)$$

Even when the above constraints are satisfied, there are too many free parameters in the model. A reduction in their number is achieved by imposing the following constraints:

$$\frac{\beta_i \theta_c}{\beta_i \theta_c + \theta_i} = \frac{\lambda_c}{\lambda_c + \lambda} = \frac{X_c(0)}{X_c(0) + X_{ave}(0)} = \omega \quad (37)$$

where ω is a correlation-like parameter representing the systematic share of intensities, and $X_{ave}(0)$ is the average of $X_i(0)$. When ω is low, the dynamics of intensities is predominantly idiosyncratic, and it is systemic when ω is close to one.

Provided that equation (36) is true, the affine ansatz still holds, so that survival probabilities of individual names can be written in the form

$$\begin{aligned}
q_i(t, T | X_i(t)) &= \mathbb{I}_{(\tau_i > t)} \mathbb{E}_t \left\{ e^{-\int_t^T X_i(t') dt'} \middle| X_i(t) \right\} \\
&= \mathbb{I}_{(\tau_i > t)} \mathbb{E}_t \left\{ e^{-\beta_i [Y_c(T) - Y_c(t)]} \middle| X_c(t) \right\} \\
&\quad \times \mathbb{E}_t \left\{ e^{-[\tilde{Y}_i(T) - \tilde{Y}_i(t)]} \middle| \tilde{X}_i(t) \right\} \\
&= \mathbb{I}_{(\tau_i > t)} e^{a_c(t, T, \beta_i) + b_c(t, T, \beta_i) X_c(t) + a_i(t, T, 1) + b_i(t, T, 1) \tilde{X}_i(t)}
\end{aligned} \tag{38}$$

Moreover, conditioning the dynamics of spreads on the common factor $Y_c(T)$, we can write idiosyncratic survival probabilities as follows:

$$\begin{aligned}
q_i(t, T | \tilde{X}_i(t), Y_c(T)) &= \mathbb{I}_{(\tau_i > t)} e^{-\beta_i [Y_c(T) - Y_c(t)] + a_i(t, T, 1) + b_i(t, T, 1) \tilde{X}_i(t)}
\end{aligned} \tag{39}$$

$$\begin{aligned}
q_i(0, T | \tilde{X}_{i0}, Y_c(T)) &= e^{-\beta_i Y_c(T) + a_i(0, T, 1) + b_i(0, T, 1) \tilde{X}_{i0}}
\end{aligned} \tag{40}$$

First, we perform the calibration of the model parameters to fit 1y and 5y CDS spreads for individual names. Once this calibration is performed, we can apply the usual recursion and calculate the conditional probability of loss of exactly n names, $0 \leq n \leq N$, in the corresponding portfolio, or, equivalently, of the loss of size $(1 - R)n$, which we denote as $p(0, T, n | Y)$.

For a tranche of the portfolio which covers losses from the attachment point α to the detachment point δ , $0 \leq \alpha < \delta \leq 1$, the relative tranche loss is defined as follows:

$$\Lambda_{\alpha, \delta}(L) = \frac{\max\{\min\{L, \delta N\} - \alpha N, 0\}}{(\delta - \alpha) N} \tag{41}$$

Its conditional expectation has the form

$$p_{\alpha, \delta}(0, T | Y) = \sum_{n=0}^N \Lambda_{\alpha, \delta}((1 - R)n) p(0, T, n | Y) \tag{42}$$

In order to find the unconditional expectation, we have to integrate $p_{\alpha, \delta}(0, T | Y)$ with respect to the distribution $f(Y)$ of the common factor Y . The latter distribution can be found *via* the inverse Laplace transform of the function

$$\phi(\xi) = \int_0^\infty e^{-\xi Y} f(Y) dY = e^{a_c(0, T, \xi) + b_c(0, T, \xi) X_{c0}} \tag{43}$$

by numerically calculating the Bromwich integral in the complex plane

$$\begin{aligned}
f(Y) &= \frac{1}{2\pi i} \int_{\gamma - i\infty}^{\gamma + i\infty} e^{\xi Y} \phi(\xi) d\xi \\
&= \frac{1}{2\pi i} \int_{\gamma - i\infty}^{\gamma + i\infty} e^{\xi Y + a_c(0, T, \xi) + b_c(0, T, \xi) X_{c0}} d\xi
\end{aligned} \tag{44}$$

Both standard and more recent methods allow one to calculate the inverse transform without too much difficulty; see, for example, [1]. Finally, we calculate the unconditional expectation of the tranche loss by performing integration over the common factor:

$$p_{\alpha, \delta}(0, T) = \int_0^\infty p_{\alpha, \delta}(0, T | Y) f(Y) dY \tag{45}$$

Knowing this expectation, we can represent par spread and par up-front for the tranche in question by slightly generalizing formulas (21) and (22). In other words,

$$s_{\alpha, \delta}(T) = \frac{-v + \int_0^T D(0, t') dp_{\alpha, \delta}(0, t')}{\int_0^T D(0, t') (1 - p_{\alpha, \delta}(0, t')) dt'} \tag{46}$$

$$\begin{aligned}
v &= -s_{\alpha, \delta}(T) \int_0^T D(0, t') (1 - p_{\alpha, \delta}(0, t')) dt' \\
&\quad + \int_0^T D(0, t') dp_{\alpha, \delta}(0, t')
\end{aligned} \tag{47}$$

Equity tranches with $\alpha = 0$, $\delta < 1$ (and, in some cases, other junior tranches) are traded with a fixed spread, say $s = 5\%$, and an up-front determined by formula (47); more senior tranches are traded with zero up-front and spread determined by formula (46).

Treatment of super-senior tranches with $\delta = 1$ has to be slightly modified, but we do not discuss the corresponding details for the sake of brevity.

The affine jump-diffusion model allows one to price tranches of standard on-the-run indices, such as CDX and iTraxx with reasonable (but not spectacular) accuracy, and can be further used to price bespoke tranches; however, one can argue that the presence of the stochastic idiosyncratic components makes it unnecessarily complex. In any case, the very rigid relationships between the model parameters suggest that the choice of these components is fairly limited and rather artificial.

Two models without stochastic idiosyncratic components were independently proposed in the literature. The first one, due to Chapovsky *et al.* [2], assumes purely deterministic idiosyncratic components, and represents q_i as follows:

$$q_i(0, T | Y_c(T)) = e^{-\beta_i(T)Y_c(T) + \xi_i(T)} \quad (48)$$

where, X_c, Y_c are driven by SDEs (1) and (5), while $\xi_i(T)$ is calibrated to the survival probabilities of individual names. The second one, due to Inglis–Lipton [6], models conditional survival probabilities directly, and postulates that $q_i(0, T | Y_c)$ can be represented in the logit form

$$q_i(0, T | Y_c(T)) = \mathbb{E}_i \left\{ \frac{1}{1 + e^{Y_c(T) + \chi_i(T)}} \right\} \quad (49)$$

We now describe the Inglis–Lipton model in some detail. To calibrate the model to individual CDS spreads, we need to solve the following pricing problem:

$$\hat{\mathcal{L}}V(t, X, Y) + XV_Y(t, X, Y) = 0 \quad (50)$$

$$V(T, X, Y) = \frac{1}{1 + e^Y} \quad (51)$$

where

$$\begin{aligned} \hat{\mathcal{L}}V \equiv & V_t + f(t, X) V_X + \frac{1}{2} g^2(t, X) V_{XX} \\ & + \lambda \sum_m \pi_m [V(X + J_m) - V(X)] \end{aligned} \quad (52)$$

and determine $\chi_i(T)$ from the following algebraic equation (rather than a PDE):

$$V(0, 0, \chi_i(T)) = q_i(0, T), \quad 1 \leq i \leq N \quad (53)$$

As before, we can easily calculate the probability of loss of exactly n names, $0 \leq n \leq N$, $p(0, T, n | Y)$, conditional on Y . We can then solve the pricing equation (50) with the terminal condition

$$V_{\alpha, \delta}(T, X, Y) = p_{\alpha, \delta}(0, T | Y) \quad (54)$$

and find the expected losses for an individual tranche at time 0:

$$p_{\alpha, \delta}(0, T) = V_{\alpha, \delta}(0, X_0, 0) \quad (55)$$

Here, $p_{\alpha, \delta}(0, T | Y)$, $p_{\alpha, \delta}(0, T)$ have the same meaning as in equations (42) and (45). In order to price senior tranches rare but large jumps are necessary. Since, as a rule, we need to analyze several tranches with different attachments, detachments, and maturities at once, it is more convenient to solve the forward version of equation (50) and find $p_{\alpha, \delta}(0, T)$ by integration. Thus, we are in a paradoxical situation when it is more efficient to perform calibration to individual names backward and calibration to tranches forward, rather than the other way round.

When derivatives explicitly depending on the number of defaults, such as leveraged super-senior (LSS) tranches, are considered, the X, Y dynamics requires augmentation with the dynamics of the number of defaulted names n . Since we are dealing with a “pure birth” process, we can use the well-known results due to Feller [5] and others and obtain the following expression for the one-step transition probability:

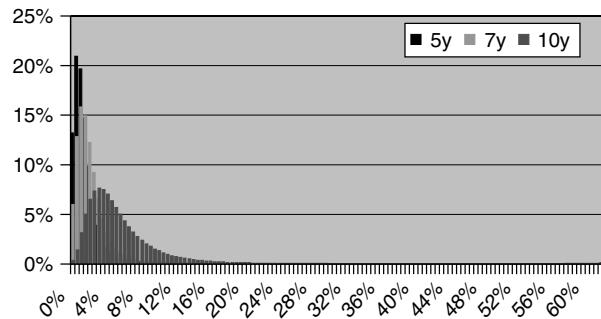

$$\begin{aligned} h(t, X, Y, n) &= \frac{-\sum_{n'=0}^n [p_t(t, T, n' | Y) + X p_Y(t, T, n' | Y)]}{p(t, T, n | Y)} \\ &= \frac{\sum_{n'=n+1}^N [p_t(t, T, n' | Y) + X p_Y(t, T, n' | Y)]}{p(t, T, n | Y)} \end{aligned} \quad (56)$$

The corresponding backward Kolmogoroff equation has the following form:

$$\begin{aligned} \hat{\mathcal{L}}V(t, X, Y, n) + XV_Y(t, X, Y, n) + h(t, X, Y, n) \\ \times [V(t, X, Y, n+1) - V(t, X, Y, n)] = 0 \end{aligned} \quad (57)$$

Table 1 Market quotes and full dynamic model calibration results. We quote par up-front payments with 5% spread for equity tranches, and par spreads for all other tranches^a

α	δ	5y	5y	7y	7y	10y	10y

^aadapted from [7]**Figure 3** Loss distributions for 5y, 7y, 10y implied by the calibrated dynamic model (adapted from [7])

If need occurs, a multifactor extension of the above model can be considered.

Table 1 shows the quality of calibration achievable in the above framework for the on-the-run iTraxx index on November 9, 2007. We show the corresponding loss distributions in Figure 3.

This model can naturally be used to price bespoke baskets (as long as an appropriate standard basket is determined). It does not suffer from any of the drawbacks of the standard mapping approaches used for this purpose.

We note in passing that Inglis–Lipton [6] describe a static version of their model which is perfectly adequate for the purposes of pricing standard and bespoke tranches, even under the current extreme market conditions.

Conclusion

In general, multiname intensity models have many attractive features. They are naturally connected to single-name intensity models. In order to account for the observed tranche spreads in the market, they have to postulate periods of very high intensities which

gradually mean-revert to moderate and low levels. Mean-reversion of the default intensities serves as a useful mechanism which allows one to price tranches with different maturities in a coherent fashion. Of course, due to the presence of large jumps, it is very difficult to provide convincing hedging mechanisms in such models. However, since we assume that jumps are discrete, it is possible in principle to hedge a given bespoke tranche with a *portfolio* of standard tranches. This is a topic of active research and experimentation at the moment, and we hope to present the outcome of this research in the near future.

Acknowledgments

I am grateful to my colleagues S. Inglis, J. Manzano, A. Rennie, A. Sepp, and D. Shelton for illuminating discussions of the subject matter.

ALEXANDER LIPTON

Default Time Copulas

Copulas are used in mathematical statistics to describe *multivariate distributions* in a way that separates the marginal distributions from the codependence structure. More precisely, any multivariate distribution can be “decomposed” into its *marginal distributions* and a multivariate distribution with uniform marginals. Suppose $X_1, \dots, X_n$ are real-valued stochastic variables with marginal distributions

$$f_i(x) = P(X_i \leq x), \quad i = 1, \dots, n \quad (1)$$

where the right-hand side denotes the probability that X_i takes a value less than or equal to x . Suppose further that C is a distribution function on the n -dimensional unit hypercube with uniform marginals.^a Then we can define a joint distribution of $(X_1, \dots, X_n)$ by

$$P(X_1 \leq x_1, \dots, X_n \leq x_n) = C(f_1(x_1), \dots, f_n(x_n)) \quad (2)$$

We say that C is the *copula function* of the joint distribution. Clearly, the copula function for a given distribution is unique. Existence, that is, the actual existence of a copula function for any joint distribution, is established by *Sklar’s Theorem* [3]. Given the definition of a copula, it is clear that a default time copula is a copula for the joint distribution of default times. Here, as in other applications in finance, the main advantage of using a copula formulation is that the marginal distributions are implied from the market, independent of information about mutual dependencies between default times. Specifically, the distribution of the time of default of a single firm can be implied^b from the par spread of the credit default swap (CDS) contracts on the debt of the firm. This distribution is represented by the “default curve”:

$$p_i(t) = P(\tau_i \leq t) \quad (3)$$

where τ_i is the stochastic default time of the i th firm.^c Once we have determined the marginal distributions of the default rates of single firms in this way, we may model mutual dependencies between these default times by choosing a suitable copula function

and writing the joint distribution of default times as in equation (2). From a practical point of view it is a great advantage that, by construction, the marginal distributions are unchanged under a change of copula. This allows us to preserve the calibration to market CDS quotes while adjusting the codependence structure.

Factor Copulas

In practice, copula functions are rarely specified directly for the default times. Instead, we introduce stochastic “default trigger variables” X_i such that we can identify events

$$\{X_i \leq h_i(t)\} \equiv \{\tau_i \leq t\} \quad (4)$$

for suitable nondecreasing functions $h_i : \mathbb{R}_+ \rightarrow \mathbb{R}$ such that

$$P(X_i \leq h_i(t)) = p_i(t) \quad (5)$$

We may regard the trigger variables as just a convenient mathematical device, but we may also follow Merton [2] and view X_i as the (return of the) value of the assets of the i th firm. With this interpretation, we may further interpret $h_i(T)$ for some fixed time horizon T as the face value of the firm’s debt maturing at T . In this picture, default coincides with insolvency.

One advantage of using default trigger variables rather than default times is that the codependency of firm values is more susceptible to economic reasoning. For example, we can think of asset values as being driven by a common factor representing general economic conditions. Then we would use a decomposition such as

$$X_i = f_i(Z) + \epsilon_i \quad (6)$$

where Z is the common factor, ϵ_i are idiosyncratic components independent of each other and of Z , and f_i are suitable “loading functions”. Note that, conditional on a given factor value, the trigger variables and, therefore, the default times, will be independent. The (unconditional) joint distribution is determined, for given distributions of Z and the ϵ_i s, by the loading functions f_i .

A default time copula specified by default triggers with the decomposition in equation (6) is called a *factor copula*. Most, if not all, copula models used in derivatives pricing are factor copulas.

Pricing with Copula Models

The generic application of default time copulas is in the pricing of CDO tranches, that is, tranches of a portfolio of debt instruments referencing a (large) number of issuers. Such a tranche is a special case of a security whose future cash flows is a function of the default times of the issuers. The present value of such a security is given by an expectation over the joint default time distribution, which, in the general case, has to be evaluated by Monte Carlo, that is, by random sampling from the distribution. However, as we shall now discuss, for certain types of securities, the expectation can be calculated by a much faster method if a factor copula is used.

Loss Distributions

Although it is true that a CDO tranche depends on the joint default time distribution, it does so in a rather special way since, in fact, it only depends on the total *loss* in the portfolio; in particular, it does not depend on the identity of the defaulted names, or on the order in which they default. More precisely, we can compute the value of a tranche if we know the distribution of the cumulated portfolio loss out to any time up to tranche maturity.^d As we shall now see, the computation of such loss distributions is particularly simple in a factor model.

We shall first show how to compute the distribution of portfolio loss to some fixed horizon t conditional on some given factor value z . To lighten the notation, we suppress the parameters z and t . Let p_i be the conditional probability that the i th issuer defaults and assume that the loss in default is given by some constant^e u . Further define

$$P_l^{(n)} = P(L^{(n)} = lu) \quad (7)$$

where $L^{(n)}$ is the default loss from the first n issuers (in some arbitrary order).

Then we have the following recursion relation (see [1])

$$P_l^{(n+1)} = (1 - p_{n+1})P_l^{(n)} + p_{n+1}P_{l-1}^{(n)} \quad (8)$$

which allows us to build the loss distribution for any portfolio from the trivial case of the empty portfolio

$$P_l^{(0)} = \delta_{l,0} \quad (9)$$

From the conditional loss distributions, we obtain the unconditional loss distribution by integration^f over z .

We remark that using equation (8) amounts to explicitly doing the convolution of the independent conditional loss distribution for each issuer in order to obtain the distribution of the portfolio loss. This convolution could also be done by Fourier techniques although this involves a somewhat greater computational burden. Note that by suitably inverting the convolution, one may compute the sensitivities of the tranche value to the parameters, for example, default probability, of each issuer. These are very important quantities in financial risk management.

Concluding Remarks

Models based on default time copulas are in widespread use for pricing and risk managing portfolio credit derivatives such as CDO tranches. The important special case of factor copulas combines the dual advantages of providing a clear economical interpretation of default time codependence and of allowing computationally efficient implementations.

The main practical limitation of copula models is that they are not *dynamic* models in the sense that they do not allow any conditioning on the future state of the world. This means that copula models cannot be reliably used, for example, in the pricing of options on tranches since here we have to be able to determine the distribution of the value of the underlying tranche conditioned on the state at option expiration time. To address such problems, we need a model that specifies the stochastic dynamics of a sufficient set of state variables. For example, we could specify the joint dynamics of all default intensities. Any such model would, of course, produce a joint default time distribution which would be describable by a copula and marginals. But this is not a one-to-one relationship since different dynamic models can produce the same copula. In this sense, the copula approach is more efficient for securities that depend only on the joint distribution of default times.

End Notes

^aThis simply means that $C : [0, 1]^n \rightarrow [0, 1]$ is nondecreasing in each argument, $C(0, \dots, 0) = 0$, $C(1, \dots, 1) = 1$, and that, for any i and any $y_i \in [0, 1]$,

$$\int_0^1 dy_1 \dots \int_0^1 dy_{i-1} \int_0^1 dy_{i+1} \dots \int_0^1 dy_n C(y_1, \dots, y_n) = y_i.$$

^bGiven suitable assumptions about *recovery* in default.

^cNote that this distribution is the so-called risk-neutral distribution, which differs from the real-world, or physical, distribution unless there is no *risk premium* associated with the risk of default.

^dIn practice, this is approximated by a finite set of times.

^eThis assumption is just for notational convenience; the extension to issuer specific, and possibly random, loss amounts is straightforward.

^fIf z has real dimension ≤ 3 , a quadrature scheme can be used, otherwise Monte Carlo integration is more efficient.

Gaussian Copula Model

Li [5] has introduced a copula function approach to credit portfolio modeling. In this approach, the author first introduces a random variable to denote the survival time for each credit and characterizes its properties using a density function or a hazard rate (see **Hazard Rate**). This allows us to move away from a one-period framework so that we could incorporate the term structure of default probabilities for each name in the portfolio. Then, the author introduces copula functions (see **Copulas: Estimation**) to combine information from all individual credits and further assumes a correlation structure among all credits. Mathematically, copula functions allow us to construct a joint distribution of survival times with given marginal distributions as specified by individual credit curves. This two-stage approach to forming a joint distribution of survival times has advantages. First, it incorporates all information on each individual credit. Second, we have more choices of different copula functions to form a good joint distribution to serve our purpose than if we assume a joint distribution of survival times from the start. While the normal copula function was used in [5] for illustration due to the simplicity of its economic interpretation of the correlation parameters and the relative ease of computation of its distribution function, the framework does allow use of other copula functions. We also discuss an efficient “one-step” simulation algorithm of survival times in the copula framework by exploring the mathematical property of copula functions in contrast to the period by period simulation as suggested earlier by others.

Default Information of a Single Name

To price any basket credit derivative structure, we first need to build a credit curve for each single credit in the portfolio, and then we need to have a default correlation model so that we can link all individual credits in the portfolio.

A credit curve for a company is a series of default probabilities to future dates. Traditionally, we use rating agency’s historical default experience to derive this information. From a relative value trading perspective, however, we rely more on market information from traded assets such as risky bond prices,

asset swap spreads, or, nowadays, directly the single-name term structure of default swap spreads to derive market implied default probabilities. These probabilities are usually called *risk neutral default probabilities*, which, in general, are much higher than the historical default probabilities for the rating class to which this company belongs. Mathematically, we use the distribution function of survival time to describe these probabilities. If we denote τ as an individual credit’s survival time which measures the length of time from today to the time of default, we use $F(t)$ as the distribution function defined as follows:

$$F(t) = \Pr[\tau \leq t] = 1 - S(t) \quad (1)$$

where $S(t)$ is called the *survival probability* up to time t . The marginal probabilities of defaults such as the ones over one-year periods, or hazard rates in continuous term, are usually called a *credit curve*. In general, for single-name default swap pricing, only a credit curve is needed in the same way as an interest rate curve is needed to price an interest rate swap.

Correlating Defaults through Copula Functions

Central to the valuation of the credit derivatives based on a credit portfolio is the default correlation. To put it in simple terms, default correlation measures the impact of one credit default on other credits. Intuitively, one would think of default correlation as being driven by some common macroeconomic factors. These factors tend to tie all industries into the common economic cycle, a sector-specific effect or a company-specific effect. From this angle, it is generally believed that default correlation is positive even between companies in different sectors. Within the same sector, we would expect companies to have an even higher default correlation since they have more commonalities. For example, overcapacity in the telecommunication industry after the internet/telecom bubble resulted in the default of numerous telecommunication and telephone companies. However, the sheer lack of default data means those assumptions are difficult to verify with any degree of certainty. Then we have to resort to an economic model to solve this problem.

From a mathematical point of view, we know the marginal distribution of survival time of each credit in the portfolio and we need to find a joint survival

time distribution function such that the marginal distributions are the same as the credit curves of individual credits. This problem cannot be solved uniquely. There exist a number of ways to construct a joint distribution with known marginals. Copula functions, used in multivariate statistics, provide a convenient way to specify any joint distribution with given marginal distributions.

A copula function (*see* **Copulas: Estimation**) is simply a specification of how to use the univariate marginal distributions to form a multivariate distribution. For example, if we have N -correlated uniform random variables $U_1, U_2, \dots, U_N$, then

$$\begin{aligned} C(u_1, u_2, \dots, u_N) \\ = \Pr\{U_1 < u_1, U_2 < u_2, \dots, U_N < u_N\} \quad (2) \end{aligned}$$

is the joint distribution function, which gives the probability that all of the uniforms are in the specified N -dimensional space cube. Using this joint distribution function C and N marginal distribution functions $F_i(t_i)$, which describe N credit curves, we form another function as follows: $C[F_1(t_1), F_2(t_2), \dots, F_N(t_N)]$. It can be shown that this function is a distribution function for the N -dimensional random vector of survival times where, as desired, the marginal distributions are $F_1(t_1), F_2(t_2), \dots, F_N(t_N)$; see [5]. So a copula function is nothing more than a joint distribution of uniform random variables from which we can build a joint distribution with a set of given marginals.

Then we need to solve two problems. First, which copula function should we use? Second, how do we calibrate the parameters in a copula function? Suppose we study a credit portfolio of two credits over a given period. The marginal default probabilities are given by the two credit curves constructed using market information or historical information. From an economic perspective, a company defaults when its asset falls below its liability. However, in the relative value trading environment, we know the default probability from the credit curve constructed using market information such as default swap spreads, asset swap spreads, or risky bond prices. Assume that there exists a standardized “asset return” X and a critical value x , and when $X \leq x$ the company would default, that is,

$$\begin{aligned} \Pr[X_1 \leq x_1] &= \Phi(x_1) = q_1 \\ \Pr[X_2 \leq x_2] &= \Phi(x_2) = q_2 \quad (3) \end{aligned}$$

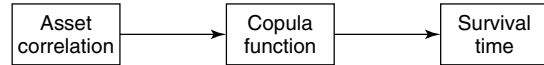

where Φ is the cumulative univariate standard normal distribution. We use Φ_n to denote the n -dimension cumulative normal distribution function. If we assume that the asset returns follow a bivariate normal distribution $\Phi_2(x, y, \rho)$ with correlation coefficient ρ , the joint default probability is given by

$$\begin{aligned} \Pr[X_1 \leq x_1, X_2 \leq x_2] \\ = \Pr[X_1 \leq \Phi^{-1}(q_1), X_2 \leq \Phi^{-1}(q_2)] \\ = \Phi_2[\Phi^{-1}(q_1), \Phi^{-1}(q_2), \rho] \quad (4) \end{aligned}$$

This expression suggests that we can use a Gaussian copula function with asset return correlations as parameters.

The above argument need not be associated with a normal copula. Any other copula function would be still able to give us a joint survival time distribution while preserving the individual credit curves. We have to use extra conditions in order to choose an appropriate copula function. When we compare two copula functions, we need to control the marginal distribution-free correlation parameter such as the rank correlation.

This approach gives a very flexible framework based on which we can value many basket structures. It can be expressed in the following graph:

We also present an efficient simulation algorithm here to implement our framework. To simulate correlated survival times, we introduce another sequence of random variables $X_1, X_2, \dots, X_n$ such that

$$X_i = \Phi^{-1}(F(\tau_i)) \quad (5)$$

where $\Phi^{-1}(\cdot)$ is a one-dimensional standard normal inverse function. $X_1, X_2, \dots, X_n$ follow a joint normal distribution with a given correlation matrix Σ . From this equation, we see that there is a one-to-one mapping between X_i and τ_i . Any problem associated with τ_i could be transformed into a problem associated with X_i , which follows a joint normal distribution. Then we could make use of an efficient calculation method of multivariate normal distribution function.

The correlation parameters, in the framework of our credit portfolio model, can be roughly interpreted

as the asset return correlation. However, in most practical uses of the current model, we either set the correlation matrix using one constant number or two numbers as the inter- and intraindustrial correlation for trading models. We could either use an economic model to asset correlation or we can calibrate the parameters using traded instruments involving correlation such as first-to-default or collateralized debt obligation (CDO) tranches.

The commonly used one or two correlation parameters are strongly associated with factor models for asset returns. For example, the one correlation parameter $\rho \geq 0$ corresponds to a one-factor asset return model where each asset return can be expressed as follows:

$$X_i = \sqrt{\rho} \cdot X_m + \sqrt{1 - \rho} \cdot \varepsilon_i \quad (6)$$

where X_m represents the common factor return and ε_i is the idiosyncratic risk associated with credit asset i . Vasicek [7] and Finger [3] use this one-factor copula for portfolio loss calculation. For a detailed discussion on this one-factor copula model, the reader is referred to these two references.

If we use two parameters, the interindustry correlation ρ_o and the intraindustrial correlation ρ_I , then for each credit of industry group $k = 1, 2, \dots, K$, we can express the asset return as follows [6]:

$$X_i = \sqrt{\rho_I - \rho_o} \cdot X_k + \sqrt{\rho_o} \cdot X_m + \varepsilon_i \quad (7)$$

Using these factor models, we can substantially reduce the dimensionality of the model. The number of independent factors then does not depend on the size of the portfolio. For example, for a portfolio whose credits belong to 10 industries, we just need to use 11 independent factors, one factor for each industry and one common factor for all credits. We could substantially improve the efficiency of our simulation or analytical approach once we exploit the property of the factor models embedded in the correlation structure. Some other orthogonal transformations such as the ones obtained by applying principal component analysis could also be used to reduce the dimension.

Loss Distribution

For a given credit portfolio, the first information investors would like to know is its loss distribution over a given time horizon in the future such as

1 year or 5 years. This would give the investor some idea about the possible default loss of his investment in the next few years. The information we need to use in our framework is as follows: the credit curve of each credit that characterizes the default property over the time horizon, the recovery assumption, and the asset correlation structures. Many useful risk measurements, such as the expected loss, the unexpected loss, or the standard deviation of loss, the maximum loss, Value-at-Risk (VaR) or the conditional shortfall, could be obtained easily once the total loss distribution is calculated.

Here we study the property of the loss distribution using a numerical example. The base case used is as given in Table 1.

Figure 1 shows the excess loss distribution where the x -axis is the loss amount and y -axis is the probability of loss more than a given amount in the x -axis. All excess loss functions would start from 1 and gradually go to zero. If we include the zero loss in the probability calculation, then the probability of having nonnegative losses is always 1. We purposely exclude the zero loss in the calculation so that we can see the probability of having zero loss in the graph explicitly. Let us define the excess loss more precisely. Suppose that L represents the total loss of the portfolio, which is a random variable, since we do not know for sure what value it takes. For a given set of loss amounts $l_0, l_1, \dots, l_n$, we can calculate the probability of excess loss $p_0, p_1, \dots, p_n$ as follows:

$$p_i = S(l_i) = \Pr[L > l_i] \quad (8)$$

The excess loss distribution essentially depicts (l_i, p_i) . The reason we use excess loss distribution instead of loss distribution, which is defined as $F(l_i) = 1 - S(l_i)$, is mainly due to the fact that many interesting properties of the loss distribution can be viewed more explicitly from the excess loss distribution graph than from the ordinary loss distribution

Table 1 Assumptions on a Credit Portfolio

Number of Assets	100
Credit spread	200 bps
Correlation	50%
Maturity	5 years
Recovery	30%

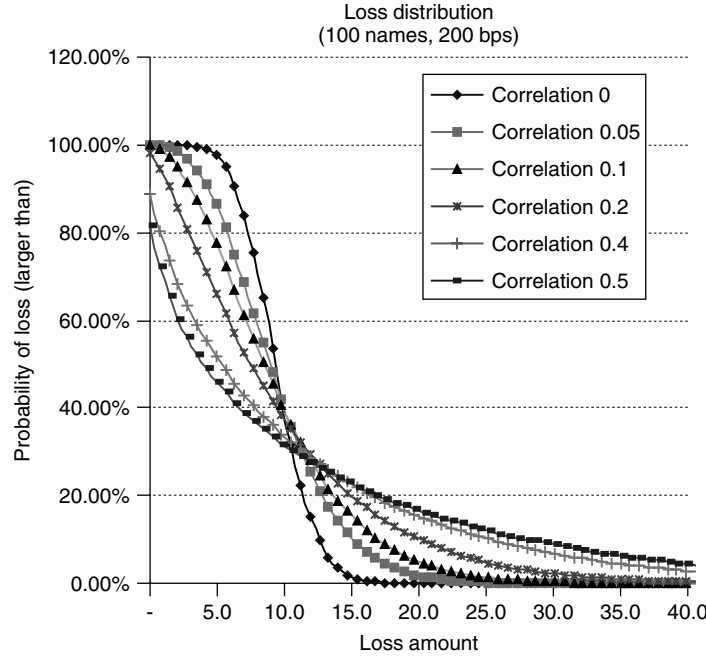

Figure 1 Excess Loss Distribution

graph. For example, the expected loss using the density function $f(l)$ of the loss distribution can be calculated as follows:

$$\mu_L = E(L) = \int_0^\infty l \cdot f(l) dl = \int_0^\infty S(l) dl \quad (9)$$

which is just the area below the excess loss distribution line. Some other quantity such as the expected loss of tranch securities (loss with a deductible and a ceiling) could also be more simply expressed if we use excess loss function. We discuss this point in the next section when we discuss about CDO pricing.

Figure 1 shows the impact of correlation on the total excess loss distribution. From the graph we see that the probability of having zero loss increases from almost 0 to about 20% when correlation changes from 0 to 50%. The default probability over 5 years for each name is $1 - e^{-5 \cdot 0.2 / (1 - 30\%)} = 13.31\%$, and the probability of having no default of a portfolio with 100 independent names is $(1 - 13.31\%)^{100}$, practically 0. However, when the correlation is high, default occurs more in bulk, which makes the probability of having zero loss go up to 20%. When correlation is high, more loss would be pushed to

the right, which makes the excess loss distribution tail much fatter since the expected total loss, the area below the excess loss function line, does not change along with the change in correlation. This can be shown using a credit VaR, which is defined as the excess loss, that probability of loss larger than this value is less than a given percentage such as 1%. The 1% credit VaR for various correlation values are given in Table 2.

In practice, it is very important to quickly obtain an accurate total excess loss distribution. There are a variety of methods that have been used for the total loss distribution. Here, we present the details on the recursive method in a one-factor Gaussian copula model and briefly summarize the conditional normal approximation approach.

Table 2 Correlation vs C-VaR

Correlation (%)	C-VaR
0	14.7
10	25.2
20	32.9
50	53.9
75	67.2%

We consider a credit portfolio consisting of n underlying credits whose notional amounts are N_i and fixed recovery rates are R_i , $i = 1, 2, \dots, n$. We consider the aggregate loss from today to time t as a fixed sum of random variables X_i :

$$L_n(t) = \sum_{i=1}^n l_i(t) = \sum_{i=1}^n (1 - R_i) \cdot N_i \cdot I_{(\tau_i < t)} \quad (10)$$

where τ_i is the survival time for the i th credit in the credit portfolio and I is the indicator function, which is 1 in the case $\tau_i \leq t$ and 0 otherwise. The distribution function of survival time c is denoted as $F_i(t) = \Pr[\tau_i \leq t]$. The specification of the survival time distribution $F_i(t)$ is usually called a *credit curve*, which can be derived from market credit default swap spreads.

From the above equation, we can calculate the total loss distribution as

$$\begin{aligned} F_{L(t)}(x) &= \Pr[L_n(t) \leq x] = \Pr\left[\sum_{i=1}^n X_i \leq x\right] \\ &= \int \Pr\left[\sum_{i=1}^n X_i \leq x | F\right] \cdot dF \end{aligned} \quad (11)$$

Conditional on the common factor F , all X_i are independent, and then we just need to calculate the convolution of n independent random variables, c . As discussed in the last section, we know that X_i are independent conditional on the common factor X_M in the one-factor model. Each X_i can take only two discrete values with constant recovery rate assumption as follows: the loss would be 0 if default does not occur or $B_i = (1 - R_i)N_i$ if default occurs.

$$f(x|F) = \begin{cases} 0, & 1 - q_i(t|F) \\ B_i, & q_i(t|F) \end{cases} \quad (12)$$

where $q_i(t|F)$ is the conditional default probability for credit i before time t .

The density of the conditional total loss distribution can be calculated recursively over the partial sum $L_j = L_{j-1} + X_j$. We then have the following recursive formula:

$$f_{L_j}(x|F) = \begin{cases} p_j \cdot f_{L_{j-1}}(x|F), & x < B_j \\ p_j \cdot f_{L_{j-1}}(x|F) + q_j \cdot f_{L_{j-1}}(x - B_j|F), & x \geq B_j \end{cases} \quad (13)$$

This has been described in [4] and also in [1]. The unconditional total loss distribution is obtained by simply integrating the conditional loss distribution over the common factor F . In the simple case of one-factor Gaussian copula model, we use a Gaussian quadrature for the integration over the one common factor. In the one-parameter case, the conditional default probability can be calculated directly as follows:

$$\begin{aligned} q_i(t|X_M) &= \Pr[\tau_i < t | X_M] \\ &= \Pr[F_i^{-1}(N(X_i)) < t | X_M] \\ &= \Pr[X_i < N^{-1}(F(t)) | X_M] \\ &= N\left(\frac{N^{-1}(q_i(t)) - \rho \cdot X_M}{\sqrt{1 - \rho}}\right) \end{aligned} \quad (14)$$

where $q_i(t)$ is the unconditional default probability of credit i before time t .

Another approach uses the conditional normal approximation. Conditional on the common factors, all credits are independent. On the basis of the law of large numbers, the total conditional loss distribution can be approximated by a normal distribution. The mean and variance of this normal distribution can be simply calculated similarly as we do in the above one-factor case. More details are given as follows.

Conditioning on the common factor X_M , we can compute the mean and variance of the total loss variable, $L|X_M$,

$$\begin{aligned} M_v &= \sum_{i=1}^n N_i \cdot (1 - R_i) \cdot q_i(t|X_M) \\ \sigma_v^2 &= \sum_{i=1}^n N_i^2 \cdot (1 - R_i)^2 \cdot q_i(t|X_M)(1 - q_i(t|X_M)) \end{aligned} \quad (15)$$

The conditional normal approach uses normal distributions to approximate the conditional loss distribution. The normal distribution has the same mean and variance as computed above. In general, other distributions, such as inverse normal or Student- t , can be used. The normal distribution is chosen because of the central limit theorem, which states that the

sum of independent distributions (but not identical distribution) approaches a normal distribution as the number of the independent distributions increases. In this case, the independent distributions are the distributions of the indicator functions of $N_i \cdot (1 - R_i) \cdot I_{[\tau_i < t]}$, which are independent when conditioned on the common factor X_M .

Given the conditional normal approach, the conditional expected loss for a tranche with attachment and detachment K_L^T and K_U^T can be easily computed in closed form as follows:

$$\begin{aligned} E(L^T(t)|X_M) = & (M_v - K_L^T) \Phi\left(\frac{M_v - K_L^T}{\sigma_v}\right) \\ & + \sigma_v \cdot \phi\left(\frac{M_v - K_L^T}{\sigma_v}\right) \\ & - (M_v - K_U^T) \Phi\left(\frac{M_v - K_U^T}{\sigma_v}\right) \\ & - \sigma_v \cdot \phi\left(\frac{M_v - K_U^T}{\sigma_v}\right) \end{aligned} \quad (16)$$

where ϕ is the one-dimensional normal density function.

With the calculated conditional expected loss, the unconditional expected loss is obtained simply by integrating over the common factor X_M .

$$E(L^T(t)) = \int_{-\infty}^{+\infty} E(L^T(t)|y) \cdot \phi(y) dy \quad (17)$$

However, by choosing normal distribution in its approximation, the approach has its limitations. First, a normal variable can have a negative value with non-zero probability. As we know, the loss in a portfolio should never be negative. However, this limitation only affects the equity tranche (the most junior tranche) and can be mitigated through the method described below. Second, as a loss is a summation of discrete loss variables, when a portfolio consists of only a few underlying names, then approximating the loss by a continuous variable (such as a normal variable) might not be a good approximation. This limitation also applies to some extreme case when the loss is dominated by only a few underlying names. In general, the conditional normal approach is a very good approximation when the number of names in a portfolio is larger than 30. Most of the CDO portfolios have the number of names larger than 30.

To mitigate the negative loss problem for an equity tranche one can use the following method, which preserves the expected loss of a CDO portfolio. An equity tranche $[0, K_U^T]$ with detachment point K_U^T has payoff as follows:

$$L^T(t) = L(t) - \max[L(t) - K_U^T, 0] \quad (18)$$

The conditional expected loss for the equity tranche is

$$\begin{aligned} E(L^T(t)|X_M) = & M_v - (M_v - K_U^T) \cdot \Phi\left(\frac{M_v - K_U^T}{\sigma_v}\right) \\ & - \sigma_v \cdot \phi\left(\frac{M_v - K_U^T}{\sigma_v}\right) \end{aligned} \quad (19)$$

This has been proven to work well for index equity tranche of size more than 2%. Alternatively, we can also use inverse Gaussian distribution to approximate for the equity tranche since inverse Gaussian distribution takes only a positive value.

Risk Measurement and Hedging

Once a model and a mapping algorithm are chosen we can price all credit portfolio trades, and produce a series of risk measures based on the model. These risk measures are then used to form a hedging strategy for the trading book. The commonly used risk measures are as follows:

- **Credit spread delta:** This is defined as the sensitivity of the mark-to-market value of a position to the instantaneous movement of the spread of a single entity, with all other parameters remaining constant. It is calculated through perturbation of the individual credit curves. Individual spread delta is reported as the change in value of the trade for a 1 basis point (1 bp) move in the indicated spread. Individual spread delta can be calculated as parallel moves in the individual curve (in which each spread on a particular curve is moved by 1 bp in a parallel fashion) or as bucketed moves in the curve. Individual spread delta is calculated trade-by-trade, and aggregated on the basis of issuer name, industry, or portfolio level. When we change the spread, we recalibrate the credit curve or instantaneous marginal default probability. Global spread delta is defined as the

change in the portfolio value change when all the underlying reference credit curves move by 1 bp. Global spread is calculated by bumping all spread curves of the underlying reference credits simultaneously in a parallel way or in buckets. Sometimes, we also study the sensitivities of our trade or book with respect to a large spread movement. Another common practice is to adjust the individual spread movement with respect to the index spreadsheet. The reason is that not all individual spread moves by the same amount when index moves. A statistical beta based on regression analysis is usually used.

- **Single-name spread gamma:** This is defined as the sensitivity of individual spread delta to a 1-bp move in a particular reference credit. As such, it represents the second-order price sensitivity with respect to a change in the spreads of the reference credit. Individual spread gamma is calculated by bumping one credit curve a time while all other credit curves remain the same for portfolio transactions. Global gamma is defined as the change in the global spread delta (which is defined as the portfolio value change when all the underlying reference credit curves move by 1 bp) of a portfolio for a 1-bp move in all reference credit spreads simultaneously. Global spread gamma is calculated by bumping all spread curves of the underlying reference credits simultaneously in a parallel way. Sometimes, we simply use a large spread movement as a measure of gamma risk by bumping the current spread by 50%. Similar to spread delta risk, we can also use bucket gamma risks which are more computationally challenging.
- **Jump-to-default risk:** We measure it by simply assuming one-name defaults right away or at a specific time in the future. We can also study the group jump-to-default risk.
- **Time-decay risk:** This measures the risk that as time passes, or maturity shortens, the value of portfolio transactions changes. For portfolio credit default swap, its survival time curve is most likely not flat, which makes the time decay an important risk factor.
- **Correlation risk:** Since we use a base correlation curve, we could measure the risk in terms of parallel change or bucket correlation change. In practice, we very often see a correlation curve twist, which reflects market changing perception

about different tranche risks. We can measure this risk by creating a sensitivity report for the whole book with respect to each base correlation point.

In practice, we tend to minimize spread and gamma risks, control jump-to-default risk, and also make correlation risk flat. We would also like to have positive carry: we receive more cash inflow than outflow. The hedging instruments we use are single name and index credit default swaps and index tranches. Very often, broker dealers tend to incur residual risks by using hedge ratios higher than the model-based amount to maintain a positive carry, but this strategy does not work well all the time, especially during turmoil, when there are unexpected defaults or jumps in spreads. We can use index tranche to hedge the base correlation risk. Sometimes, we can also use the index plus complementary tranches to hedge the correlation risk. In conclusion, for any hedging strategy, there will be a residual risk. Traders very often use their own view toward the market to selectively keep some residual risk.

In conclusion, the Gaussian copula function approach along with a base correlation method provides a simple and flexible framework to price basket credit derivatives. We further studied the framework and gained some more insights of it, especially from the conditional perspective of its correlation structure. This shows that the Gaussian copula function implies a too strong correlation structure. The reason for this is that we describe each credit using only two states: default or survival. This simple way of binary description creates too strong a conditional default property. It is also associated with the simple way of specifying the correlation structure using only one parameter or pairwise constant correlation, in practice, even though the original framework allows a completely flexible correlation matrix specification. Another possible reason is that this framework still misses certain fundamental driving factors such as volatilities of individual names in the framework.

We briefly discuss the risk measurement and risk management issues using the Gaussian copula function method. From the pricing formula, we can obtain all necessary risk measures, such as spread DV01, jump-to-default risk, and gamma risk of individual spreads or the general index. We can also obtain the sensitivities of the portfolio of portfolio transactions with respect to each point of base correlation curve.

The hedging instruments we could use include single name and index CDS, and index tranche, or even options on single name and index. However, we need to bear in mind that hedging strategies lead to residual risks.

There is an urgent need to come up with alternative models. Many alternative methods and enhancements of the current ones have been suggested (*see* **Random Factor Loading Model (for Portfolio Credit); Reduced Form Credit Risk Models; Structural Default Risk Models; Jarrow–Lando–Turnbull Model; Duffie–Singleton Model; Multiname Reduced Form Models; Intensity Gamma Model**). However, there is no market consensus on the pricing models for basic CDOs and *i*th-to-default transactions. The ultimate judge of a model should be its hedging performance. Extensive empirical studies on the performance of models from the hedging perspective need to be done comparing new models with the Gaussian copula plus the base correlation approach [2].

The current copula framework gained its popularity due to its simplicity. However, there is little economic justification for its framework. Its popularity in credit portfolio trading might match that of Black–Scholes formula for option valuation, but it lacks the theoretical background of the Black–Scholes formula. We essentially have a credit portfolio model without a solid credit portfolio theory. More theoretical studies are needed to make further advancement in this area besides various extensions and improvements, which attempt to fit the current market data.

Base Correlation

In the Gaussian copula model (*see Gaussian Copula Model*) for pricing collateralized debt obligation (CDO) tranches, the most important input is the correlation parameter defining the degree of dependence among the defaults in the portfolio. Given single-name default probabilities implied by credit default swap spreads and recovery assumptions, the Gaussian copula model thus establishes a correspondence between this correlation parameter and the spreads of CDO tranches. Using an analogy with the notion of Black–Scholes implied volatility of an equity option, one can define a notion of implied correlation for CDO tranches. Different notions of “implied correlation” are possible, but the one which ended up being adopted by the market has been the notion of *base correlation*, explained later.

In early applications of the Gaussian copula approach for valuation of CDO tranches, market participants were using different correlations for different tranches, leading to a correlation skew, similar to the implied volatility skew observed in equity and index options. Typically, the market tends to use higher correlation for senior tranches. This way of associating different correlations for different tranches is called a *compound correlation* method. However, this compound correlation approach of pricing each tranche using a different flat correlation is not self consistent. For example, the total loss of all tranches from a whole capital structure CDO might not add up to the total loss of the underlying portfolio. Another problem is that the implied compound correlation might not be unique since the correspondence between the correlation parameter in the Gaussian copula model and the tranche spread is not one-to-one for mezzanine tranches.

A more recent market development is to treat a CDO tranche as a call or put spread on the total loss of the underlying portfolio. For example, long a 3–7% tranche protection on the standard North America credit default swap spread index (CDX) is equivalent to long a call option on the total loss with a strike price of 3% of the total notional amount of the underlying portfolio and short a call with a strike price of 7% of the total notional amount of the underlying portfolio. Then we just need to price all equity tranches with different detachment levels or simply different equity tranche size since

the attachment for the equity tranche is always equal to zero. Correspondingly, the implied correlation could be given just for equity tranche with different tranche sizes or detachment levels. This way of quoting correlation and pricing CDOs by associating a correlation curve with different equity tranche sizes is called the *base correlation method* first introduced by J. P. Morgan.

To illustrate the base correlation method, we use simple synthetic CDO structures in which the investor of a given tranche provides default protection against the total loss (L) of a portfolio over a certain range $[B, B + \Delta]$ and over a time period of $[0, t]$. The loss function for the protection seller is as follows:

$$L(B, \Delta, t) = \begin{cases} 0, & L(t) \leq B \\ L(t) - B, & B < L(t) \leq B + \Delta \\ \Delta, & L(t) > B + \Delta \end{cases} \quad (1)$$

This is similar to an insurance contract with a deductible of B and a ceiling of $B + \Delta$. We can look at this payoff function from an option perspective. Figure 1 depicts the payoff function of a 5-tranche CDO against the total loss distribution. Buying a super senior tranche is equivalent to selling a call option on the total loss of the portfolio with a strike of the attachment point of the super senior tranche. Buying an equity tranche is equivalent to selling a put option with the strike price equal to the equity size. The investor of any middle tranche is equivalent to having an option strategy of *spread* in which he/she is long a call option with strike price of $B + \Delta$ and short a call with strike price of B . Looking at a tranche from this angle gives us alternative views to the properties of CDO tranches.

From valuation perspective, we just need to value both premium leg and loss protection leg. We assume that the accumulative tranche loss up to time t is $L^T(t)$, with the attachment level B and the detachment level $B + \Delta$, and the tranche size is $\Delta = K_U - K_L$. If we ignore the interest rate impact, the payoff of the tranche $[B, B + \Delta]$ can be expressed as follows:

$$L(B, \Delta, t) = \max(L(t) - B, 0) - \max(L(t) - (B + \Delta), 0) \quad (2)$$

The expected tranche loss is the area of the excess loss distribution bounded by the subordination levels

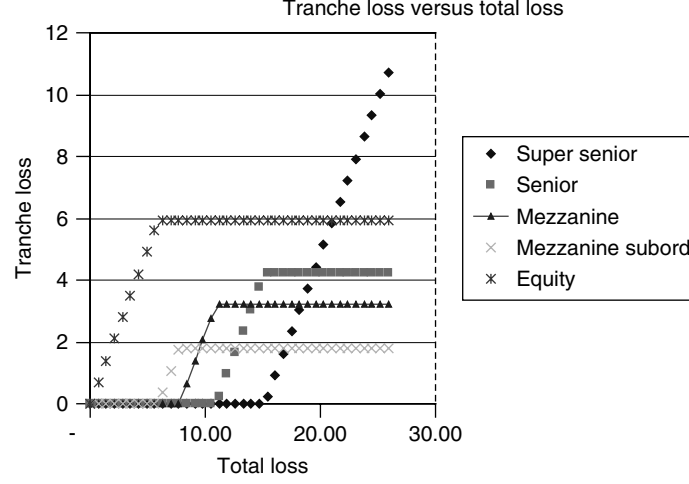

Figure 1 Tranche loss vs total loss

B and $B + \Delta$ if we ignore the interest rate. This can be taken as the difference of two equity tranche $[0, B + \Delta]$ and $[0, B]$. We can value them by simply attaching a correlation number to the tranche size or detachment point expressed by a base correlation. That is,

$$\begin{aligned} E[L(B, \Delta, t)] &= E[\max(L(t) - B, 0) | \rho(B)] \\ &\quad - E[\max(L(t) - (B - \Delta), 0) | \rho(B + \Delta)] \end{aligned} \quad (3)$$

However, the base correlation method does not guarantee absence of arbitrage. To make any credit portfolio model arbitrage free, we have the following necessary conditions around tranche loss function:

$$\begin{aligned} L(B, \Delta, t) &< L(B', \Delta, t) \quad \text{if } B < B' \quad \text{and} \\ L(B, \Delta, t_1) &< L(B, \Delta, t_2) \quad \text{if } t_1 < t_2 \end{aligned} \quad (4)$$

That is, for two tranches with everything else equal except its attachment point, the one with the higher attachment should have lower expected loss; for two tranches with everything else equal except the time interval over which we study the loss, the loss should become bigger as we increase the length of time over which we study the loss.

We have observed that for two tranches with the same tranche size, the one with more support or higher attachment level could have a break-even spread higher than the one with a lower attachment

level in the base correlation framework. In addition, the base correlation method along with the Gaussian copula model does not tell us too much about how to price nonindex portfolio tranches, neither more complicated structures such as CDO squared or CDO trades with both long and short credits as collaterals. We still need to use various loss mapping algorithms to derive a base correlation curve for the bespoke portfolio from the base correlation curve from an index tranche market.

The current market benchmark method is to use Gaussian copula function along with a base correlation method. In this framework, there is a one-to-one relationship between the tranche spread and implied base correlation curve. From a given set of index tranche spreads, we can use calibration to obtain a base correlation curve. Table 1 provides the market quote for CDX 9 on September 29, 2008 when the CDX 9 is 180 bps.

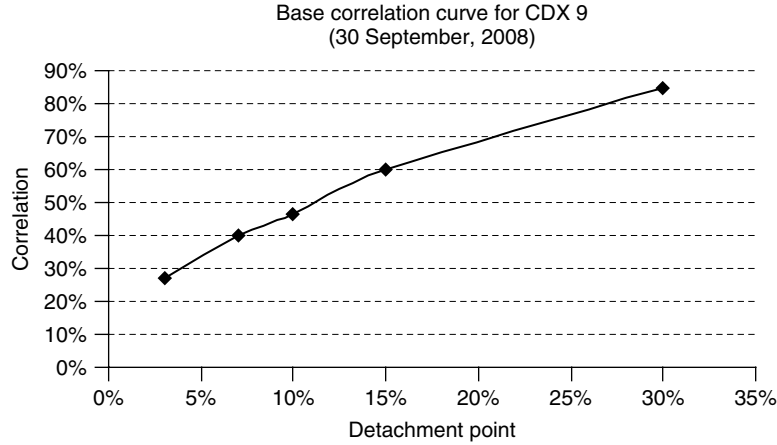

The base correlation graph is given in Figure 2.

Usually, the base correlation curve is an up sloping curve. Recently, owing to the high uncertainties in the financial market, we very often have trouble to calibrate a base correlation curve. We use a random recovery assumption to calibrate the base correlation curve. More importantly, we should incorporate the volatilities of the spreads into the framework, which has yet been formulated.

However, this base correlation approach does not tell us how to price bespoke portfolio tranches using a base correlation curve obtained from the index

Table 1 CDX 9 market quote and base correlation curve as of 29 September 2008

Swap Level 180.00					
Attachment (%)	Detachment (%)	Bid	Offer	Mid	Base correlation (%)
0.00	3.00	73 5/8	74 1/8	73 7/8	27.12
3.00	7.00	1097.00	1105.00	1101	40.16
7.00	10.00	492.00	497.00	494 1/2	46.53
10.00	15.00	199.00	204.00	201 1/2	59.77
15.00	30.00	92.00	96.00	94	84.78

tranche market. Practitioners in the market employ various mapping algorithms on the basis of the bespoke portfolio loss characteristics relative to the index portfolio loss to derive a bespoke portfolio base correlation curve from the index tranche market's base correlation curve. We provide a summary here and some general comments.

In the original copula function framework, we intend to study a portfolio problem in two stages. First, we use a credit curve to describe a single name default property. Second, we use a copula function to describe the default correlation problem. The correlation structures and correlation parameters are independent from the magnitude of single name default probabilities. That is why, we say that the correlation parameter is more rank-type correlation, which provides an order of default. In practice we often use a single correlation parameter. We have to emphasize that it is not the original framework that allows a single correlation parameter, but simply a convenient choice made by practitioners so that it is easy

to communicate with each other about the correlation.

Under these constraints, it is quite difficult to compare one credit portfolio against another credit portfolio with respect to the correlation. We simply try to link the correlation with the total loss distribution characteristics. Here are three most commonly used base correlation mapping methods.

1. Normalized strike (NS)

In this approach, we simply link the correlation on the basis of the expected loss of the portfolio. The intuitive idea is as follows: a mezzanine tranche of a bespoke credit portfolio with higher spreads should behave like an equity tranche of the index. Then we can use the following mapping approach

$$\rho_{\text{bespoke}}(K) = \rho_{\text{index}} \left[\frac{EL_{\text{index}}}{EL_{\text{bespoke}}} \cdot K \right] \quad (5)$$

This is easy to implement. However, it does not fully consider the dispersion of a credit portfolio relative

to the index. A few credits with a higher spreads could distort the scaling substantially. In addition, comparing two portfolios in terms of their expected values is a very simplistic comparison.

2. Normalized loss ratio

This approach uses the equity tranche loss, instead of the portfolio expected loss only, for the base correlation mapping. The formula is as follows:

$$\begin{aligned} & \frac{EL_{\text{bespoke}}[0, K] \text{ with } \rho_{\text{bespoke}}(K)}{EL_{\text{bespoke}}} \\ &= \frac{EL_{\text{index}}[0, K] \text{ with } \rho_{\text{index}}(K)}{EL_{\text{index}}} \end{aligned} \quad (6)$$

This is still easy to implement. It makes the use of equity tranches loss with different sizes in addition to the portfolio expected loss. From the comparison of two portfolios in terms of loss distribution perspective, it provides more detailed comparison than the normalized strike method, but still does not capture the loss variations within a tranche. Sometimes, it is impossible to find a solution for this method.

3. Percentile-to-percentile loss distribution mapping

$$\begin{aligned} & \Pr(L_{\text{bespoke}} > K_{\text{bespoke}}; \rho_{\text{index}}(K)) \\ &= \Pr(L_{\text{index}} > K; \rho_{\text{index}}(K)) \end{aligned} \quad (7)$$

This approach compares the loss distribution of bespoke portfolio against that of an index portfolio directly by the percentile-to-percentile comparison. We simply find a corresponding strike for the bespoke portfolio whose excess loss probability at the strike

(to be solved) is equal to that of the index portfolio while both excess probabilities are calculated at the same index base correlation at the index strike level. From loss distribution comparison perspective, it provides the most comprehensive comparison. Both average spread and the dispersion of spread should be captured by this method.

Although all these mapping algorithms based on loss distribution are intuitive, none of them are fully theoretically justifiable. Without fully using individual name information such as asset return volatilities and correlations, it is difficult to compare one portfolio against another portfolio as we do in equity portfolio.

Random Factor Loading Model (for Portfolio Credit)

Consider a portfolio of N risky assets, all assumed (for simplicity) to generate a \$1 loss at the time of default. Let τ_i denote the random default time for asset i , such that the total portfolio loss $L(T)$ on the horizon $[0, T]$ is

$$L(T) = \sum_{i=1}^N 1_{\tau_i \leq T} \quad (1)$$

From credit default swap (CDS) or bond markets, we can normally extract risk-neutral survival probabilities

$$Q_i(T) = \Pr(\tau_i > T), \quad i = 1, \dots, N \quad (2)$$

for all T ; this information locks risk-neutral expected portfolio losses at

$$E(L(T)) = \sum_{i=1}^N E(1_{\tau_i \leq T}) = \sum_{i=1}^N (1 - Q_i(T)) \quad (3)$$

To be able to construct the entire distribution of $L(T)$ —and not just its first moment—we need additional information about the default codependencies among the N assets.

The default codependence model that we consider here is in the class of *factor models*, in the sense that codependence is induced solely by a scalar^a random variable Z —the so-called *systematic factor*—that affects all assets through a factor “loading” function. Conditional on Z , all N default times τ_i are assumed to be independent of each other.

In practice, specification of factor loading is done using *conditional survival time distributions* $q_i : \mathbb{R}_+ \times \mathbb{R} \rightarrow [0, 1]$, defined by

$$q_i(t, z) \equiv \Pr(\tau_i > t | Z = z) \\ i = 1, \dots, N, \quad t \geq 0 \quad (4)$$

Complete prescription of a factor model requires specification of (i) all N functions q_i and (ii) the probability distribution of the systematic factor Z . As should be obvious, the q_i ’s cannot be prescribed

arbitrarily, as they are subject to strong consistency and regularity conditions. For instance, we know from basic probability

$$\Pr(\tau_i > T) = \int q_i(T, z) \Pr(Z \in dz) = Q_i(T) \quad (5)$$

which, for any given distribution of Z , provides an important constraint on q_i . Other regularity conditions—including those associated with the fact that L must be never decreasing in T —are reviewed in [1].

We emphasize the importance of the assumption of conditional independence, which allows for the application of efficient numerical methods to construct the (discrete) distribution of $L(T)$ in equation (1). Andersen *et al.* [4] give one such algorithm and discuss in detail its application in price and sensitivity computations for collateralized debt obligations (CDOs).

Random Factor Loading Models

A standard recipe for specifying the functions q_i ’s in a financially meaningful way is to assume that $\Pr(\tau_i > T) = \Pr(X_i > H_i(T))$ for a deterministic default barrier $H_i(T)$ and a *default driver* X_i of the form

$$X_i = \beta_i Z + e_i, \quad i = 1, \dots, N \quad (6)$$

where β_i is a firm-specific constant, Z is a one-dimensional systematic factor, and e_i is a residual variable idiosyncratic to firm i and independent of Z and e_j , $j \neq i$. As Z is often loosely considered a proxy for the state of the “market”, equation (6) has some qualitative similarity with the CAPM setup, with X_i loosely representing the asset returns on firm i . The Gaussian copula model falls in the class of equation (6) as do many Levy-type copula models.

The RFL (random factor loading) class starts from equation (6), but alters the dependence of X_i on Z from strictly linear to a generic functional relationship. Specifically, one writes

$$X_i = A_i(Z) + e_i, \quad i = 1, \dots, N \quad (7)$$

where A_i is a possibly firm-specific deterministic function. For reasons of tractability, it is most common to assume that Z and e_i are Gaussian, and to (arbitrarily) normalize such that $E(X_i) = 0$. In this case, one has

$$X_i = A_i(Z) + \epsilon_i + m_i, \quad i = 1, \dots, N \quad (8)$$

where Z and all residuals ϵ_i are independent standard Gaussian variables (i.e., distributed as $\mathcal{N}(0, 1)$), and the constant m_i is set to $m_i = -E(A_i(Z))$. Going forward, equation (8) shall be our working definition of a one-factor RFL model.

By moving away from strictly linear “loading” on the systematic variable, RFL models can incorporate a number of empirical observations about default codependence dynamics. Most importantly, we have the ability to increase the loading for low values of Z (= a “bad” market outcome) as a way of modeling the well-established fact that equity price correlations tend to increase in a market downturn. This, in turn, tends to fatten the upper tail of the distribution of $L(T)$, an effect that is consistent with the market for synthetic CDOs.

Some Analytical Results

For simplicity, let us now drop^b the subscript i on A_i and m_i . For completely arbitrary specifications of $A(z)$, there is obviously no hope that the distribution of X_i in equation (8) has a closed-form representation. If $A(z)$ is taken to be piecewise linear, however, such a result exists, as shown in [3]. To list it, let us define thresholds $\theta_0 < \theta_1 < \dots < \theta_{K-1}$ and then write

$$A(z) = (\alpha_0 z + \beta_0) 1_{z \leq \theta_0} + \sum_{k=1}^{K-1} (\alpha_k z + \beta_k) 1_{z \in (\theta_{k-1}, \theta_k]} + (\alpha_K z + \beta_K) 1_{z > \theta_{K-1}} \quad (9)$$

where the slopes $\{\alpha_k\}_{k=0}^K$ and intercepts $\{\beta_k\}_{k=0}^K$ are given constants. Let $\Phi(x)$ be the Gaussian conditional default functions (CDFs), and let $\Phi_2(x, y; \rho)$ be the bivariate Gaussian CDF at the correlation level ρ . Define, for $k = 1, \dots, K-1$,

$$\begin{aligned} \psi(k, x) = & \Phi_2 \left(\frac{x - \beta_k - m}{\sqrt{1 + \alpha_k^2}}, \theta_k; \frac{\alpha_k}{\sqrt{1 + \alpha_k^2}} \right) \\ & - \Phi_2 \left(\frac{x - \beta_k - m}{\sqrt{1 + \alpha_k^2}}, \theta_{k-1}; \frac{\alpha_k}{\sqrt{1 + \alpha_k^2}} \right) \end{aligned} \quad (10)$$

and

$$\psi(0, x) = \Phi_2 \left(\frac{x - m - \beta_0}{\sqrt{1 + \alpha_0^2}}, \theta_0; \frac{\alpha_0}{\sqrt{1 + \alpha_0^2}} \right) \quad (11)$$

$$\psi(K, x) = \Phi_2 \left(\frac{x - m - \beta_K}{\sqrt{1 + \alpha_K^2}}, -\theta_{K-1}; \frac{-\alpha_K}{\sqrt{1 + \alpha_K^2}} \right) \quad (12)$$

Then

$$\Pr(X_i \leq x) = \sum_{k=0}^K \psi(k, x) \quad (13)$$

We can use equation (13) to ensure that the model is in calibration with market-observed default probabilities, by insisting that the default barrier function $H_i(T)$ is set (by numerical root search) such that

$$\sum_{k=0}^K \psi(k, H_i(T)) = 1 - Q_i(T), \quad i = 1, \dots, N \quad (14)$$

We also notice that (with φ being the Gaussian density)

$$\begin{aligned} E(X_i) = & m - \alpha_0 \varphi(\theta_0) \theta_0 + \beta_0 \Phi(\theta_0) \\ & + \sum_{k=1}^{K-1} \alpha_k (\varphi(\theta_{k-1}) - \varphi(\theta_k)) \\ & + \sum_{k=1}^{K-1} \beta_k (\Phi(\theta_k) - \Phi(\theta_{k-1})) \\ & + \alpha_K \varphi(\theta_{K-1}) + \beta_K \Phi(-\theta_{K-1}) \end{aligned} \quad (15)$$

which can be used to set m such that $E(X_i) = 0$.

CDO Calibration

The free parameters of the RFL model are those involved in setting the function $A(z)$. Assuming that A is piecewise linear on K different intervals, we evidently have a total of $3K + 2$ parameters in

the model: K interval break-points $\theta_0, \theta_1, \dots, \theta_{K-1}$; $K + 1$ slopes $\alpha_0, \dots, \alpha_K$; and $K + 1$ intercepts $\beta_0, \dots, \beta_K$. In general, this number of parameters is too high, so to avoid overfitting one normally locks some of these parameters manually and calibrates the rest against observed CDO prices. A few common parameter strategies are listed below.

Classic RFL

In this approach, which was developed in [3], we set all $K + 1$ intercepts (β_k) to zero, leaving $2K + 1$ free parameters for the calibration. In typical applications, sufficient calibration accuracy is often reached with $K = 2$ break-points, for a total of five free calibration parameters. We note that when intercepts are forced to zero, the function A is of the form

$$A(z) = a(z) \cdot z \quad (16)$$

where a is piecewise flat. Comparison with equation (6) shows that, loosely, the function $\sqrt{a(z)}$ can be interpreted as a “random correlation” function. Consistent with earlier discussion, the calibrated $a(z)$ will always be decreasing in z , that is, when the economy variable Z is low (= bad economy) correlations increase, and *vice versa*.

Discrete RFL

In this style, we set all $K + 1$ slopes to zero, yielding

$$A(z) = b(z) \quad (17)$$

where b is piecewise flat at levels $b_0, b_1, \dots, b_K$. Evidently then, the distribution of $A(Z)$ is here simply a discrete distribution^c taking on $K + 1$ different values with $K + 1$ different probabilities. As the RFL model is normalized to work with the term $A(Z) - E(A(Z))$, we can add an arbitrary constant to the function $b(z)$ without altering the model; equivalently, we are free to lock one of the b_k values to a fixed constant (e.g., zero) without losing any generality. As a consequence, the effective number of parameters here is $2K$.

Fixed-slope RFL

Our setup here is similar to that in discrete RFL, but now we allow for a nonzero constant slope α to be used for all line segments: $\alpha_k = \alpha, k = 0, \dots, K$. We include this parameter in the set of free parameters to be optimized on, so now the problem dimension is $2K + 1$.

Comments and Extensions

Unlike a number of other factor models, the RFL model extends the basic Gaussian copula model by altering the CDF q_i , rather than the density of the systematic factor Z . On the other hand, we can rewrite the RFL model as

$$X_i = Y + \epsilon_i, \quad Y = A(Z) + m \quad (18)$$

So, if we elect to treat the variable Y , rather than Z , as our systematic factor, the RFL model can, in fact, also be interpreted as extending the Gaussian copula model through a change of systematic factor density. Indeed, by a suitable choice of A , *all* factor models with Gaussian residuals can be cast as an RFL model of the type in equation (8). Andersen and Piterbarg [2] discuss this in more detail, using the models in [5, 6, 8] as examples.

In [1], the RFL model is extended to allow for Poisson- or mixture-style jumps in both residuals and in the systematic factor; the model in [7] is a special case of such a jump-extended RFL model. Andersen [1] also discusses methods to introduce a dynamic element into RFL and other factor models, by letting the density of Z depend on time.

End Notes

^aExtensions to vector-valued Z is straightforward; see, for example, [3].

^bTo keep free parameters at a manageable level, it is, in fact, common to use a single A for an entire portfolio. Firm-specific A functions may, however, be of use when mixing portfolios or as part of a bespoke mapping rule.

^cSo rather than optimizing on the θ_k parameters, we can work directly with the discrete probabilities $\Phi(\theta_k) - \Phi(\theta_{k-1})$.

Local Correlation Model

The local correlation model is a credit portfolio loss model that generalizes the Gaussian copula model (see **Gaussian Copula Model**) and allows to account for the base correlation smile (see **Base Correlation**).

The local correlation model is essentially similar to an exotic copula model; its originality lies mainly in its economic interpretation. The model consists of a slight modification in the analytical specification of the Gaussian copula (see **Gaussian Copula Model**):

$$A_i = \sqrt{\rho(X)}X + \sqrt{1 - \rho(X)}\varepsilon_i \quad (1)$$

Each reference entity in the portfolio is represented by its asset value A_i , driven by a specific factor ε_i , and an economic factor X , common to all names in the economy. In the Gaussian framework, the correlation parameter ρ is constant and therefore A_i is Gaussian. On the contrary, in the local correlation model, $\rho(X)$ is a function of the economy factor, making assets non-Gaussian. As a result, $\rho(X)$ is not a measure of the actual asset correlation in the traditional sense. In the local correlation model, default correlation does not depend on the average spread of the portfolio, its dispersion, rating, or industrial sectors, but rather on the global state of the economy. In other words, the local correlation function is universal and can be used regardless of the composition of the reference portfolio. We can, therefore, calibrate our local correlation function to standard Collateralized Debt Obligation (CDO) tranches and use it to price bespoke CDOs. The model's applications are discussed later.

Large Pool Framework

Conditional on a state of the economy, the local correlation model behaves just like any other Gaussian copula model. The conditional cumulative loss is given as

$$\begin{aligned} L(K|X) \\ = P \left[(1 - RR) \times \frac{1}{n} \sum_{i=1}^n 1_{\{A_i \leq G_i^{-1}(p_i)\}} \leq K | X \right] \end{aligned} \quad (2)$$

In equation (2), RR is a fixed recovery rate assumption, n is the number of obligors in the portfolio, A_i is the i th asset value as defined in the previous section, p_i is the probability of default for the i th obligor, and G_i is A_i 's cumulative distribution function. P is the risk-neutral probability. In an infinitely diversified portfolio, asset distributions and default probabilities do not depend on the obligor, and equation (2) becomes

$$\begin{aligned} L(K|X) &= P \left[1_{\{A \leq G^{-1}(p)\}} \leq \frac{K}{1 - RR} | X = x \right] \\ &= 1 \left\{ N \left(\frac{G^{-1}(p) + x\sqrt{\rho(x)}}{\sqrt{1 - \rho(x)}} \right) \leq \frac{K}{1 - RR} \right\} \end{aligned} \quad (3)$$

Finally, equation (3) yields the expression for unconditional cumulative loss:

$$L(K) = P \left[N \left(\frac{G^{-1}(p) + X\sqrt{\rho(X)}}{\sqrt{1 - \rho(X)}} \right) \leq \frac{K}{1 - RR} \right] \quad (4)$$

Assuming that cumulative loss distribution L and asset distribution G are known, we can use equation (4) to obtain the local correlation function.

Implied Loss Distribution

Let us first derive an expression for cumulative loss distribution. The only information we have about a portfolio's cumulative loss comes from CDO market quotes. For example, five single-tranche CDOs are quoted based on the iTraxx Main portfolio—the European credit benchmark—and the CDX IG portfolio—the US credit benchmark. These prices form the “base correlation skew”—five constant correlations obtained using the Gaussian copula framework (see **Gaussian Copula Model; Base Correlation**). We write the naïve cumulative loss obtained using constant base correlations as $L(K, \rho_K^{\text{Base}})$. The naïve cumulative loss coincides with the actual cumulative loss $L(K)$ on the five market points. $L(K)$ can then be continuously interpolated using the following formula:

$$\begin{aligned} L(K) &= L(K, \rho_K^{\text{Base}}) + \frac{\partial L}{\partial K}(K, \rho_K^{\text{Base}}) \\ &\quad \times \int_0^K \frac{\partial L}{\partial \rho}(k, \rho_K^{\text{Base}}) dk \end{aligned} \quad (5)$$

Results and Interpretation

One last assumption is made before we derive the final result: we need to assume that the asset distribution G is a Gaussian distribution, that is, $G \equiv N$. We drop this assumption later on. Equations (4) and (5) can finally be combined to obtain an analytical expression for local correlation $\rho(X)$.

Let us now discuss the economic interpretation of equation (4). We define the idiosyncratic threshold as

$$\tilde{\varepsilon}(X) = \frac{G^{-1}(p) + X\sqrt{\rho(X)}}{\sqrt{1 - \rho(X)}} \quad (6)$$

Equation (4) can be rewritten according to the following equation:

$$L(K) = N(x_K), \quad x_K = \tilde{\varepsilon}^{-1} \left(N^{-1} \left(\frac{K}{1 - RR} \right) \right) \quad (7)$$

This means that for each level of loss K in the portfolio, there is an equivalent^a state of the economy x_K . Thus, for every state of the economy, there is a single corresponding loss level for any diversified portfolio. We can, therefore, interpret the local correlation $\rho(X)$ in a given state of the economy as the equivalent constant correlation to be used for a tiny tranche of size dK , centered at strike $K = L^{-1} \cdot N(X)$.

The results so far are summarized as follows. The large pool assumption allows us to relate the local correlation function to the cumulative loss distribution. Furthermore, assuming that assets are normally distributed, we can generate a mapping of each state of the economy into a loss level for any given portfolio. The local correlation can, therefore, be interpreted as the correlation of a tiny tranche centered at the corresponding loss level in a given state of the economy.

Relaxing the Gaussian Assumption

We made two crucial assumptions in the previous sections: we assumed that the portfolio could be considered infinitely diversified—the large pool assumption—and we also assumed that despite the local correlation specification (1), assets could be considered to be Gaussian.

If we drop the Gaussian assumption, the law of assets becomes

$$G_i^\rho(z) = P[A_i \leq z] \\ = \int N \left(\frac{z + x\sqrt{\rho(x)}}{\sqrt{1 - \rho(x)}} \right) \varphi(x) dx \quad (8)$$

Equations (2) and (8) can be used simultaneously to solve both the local correlation function $\rho(x)$ and asset distribution G at the same time, through a fixed-point algorithm. We initialize the algorithm by setting $G \equiv N$ and solve equation (2) to get the corresponding $\rho(x)$ function. The result is substituted into equation (8), which yields a new version of G . We iterate this process until the local correlation function is stable.

Relaxing the Large Pool Assumption

We now relax the large pool assumption. Considering equation (2), individual default probabilities are now used in their general form:

$$g_{i|X} = N \left(\frac{G^{-1}(p_i) + X\sqrt{\rho(X)}}{\sqrt{1 - \rho(X)}} \right) \quad (9)$$

Assuming that the function $\rho(X)$ is known, we can compute the loss distribution $L(K)$ via equation (2), using Andersen's combinatorial algorithm as presented in [2]. We, therefore, need to provide the model with a functional form for local correlation such as a parametric representation. In [1] (see **Random Factor Loading Model (for Portfolio Credit)**), Andersen *et al.* use a piecewise constant correlation function in their random factor loading model. Continuous functions such as piecewise linear functions or cubic splines can also be used. Such a parameterization suggests that the model needs to be calibrated to market prices through high-dimension optimization. Such an optimization is beyond the scope of this article.

Application to Exotic CDO Valuation

The problem of mapping the correlation of bespoke portfolios against standard ones has been a hot topic ever since standard CDO tranches started to trade. The question is, “How do we obtain the Gaussian correlation assumption to use with a nonstandard

portfolio and nonstandard subordination from standard CDO quotes?” Amongst other authors, Turc and Very [4] have described several ways of choosing the right equivalent correlation for nonstandard CDO pricing [3]. The probability-matching approach turns out to be the most consistent technique. It suggests using the index correlation corresponding to an equivalent strike in probabilistic terms. In other words, the index strike and bespoke strike are equivalent if they have the same probability of being reached. In the local correlation model, remember that the function $\rho(X)$ is considered as a universal constant, independent of the portfolio. Thus, equation (7) yields

$$L_{\text{index}}(K_{\text{index}}) = N(X) = L_{\text{bespoke}}(K_{\text{bespoke}}) \quad (10)$$

Equation (10) shows that the local correlation model is equivalent to the probability-matching approach. It is, therefore, consistent with one of the most popular market practices for bespoke CDO pricing.

Acknowledgments

We would like to acknowledge the contribution of Philippe Very, of Natixis, for the development of the local correlation model.

Intensity Gamma Model

The intensity gamma model is a model for pricing portfolio credit derivatives developed in [2]. Its innovation was to use stochastic time change (*see Time Change*) to achieve clustering of defaults and therefore correlation between them. This was in contrast to the popular models available at the time, which relied on copulas, such as the Gaussian copula model (*see Gaussian Copula Model*). The model is designed to infer the joint distribution of the default times of some set of names from the marginal distributions. Some additional market information about the level of correlation is required for calibration; this is typically obtained from liquid correlation products.

Once a joint distribution for the default times has been obtained (in some suitable pricing measure), products whose cash flows depend on those defaults can be priced. The classic examples include collateralized debt obligations (CDOs) (*see Collateralized Debt Obligations (CDO)*) and n th-to-default baskets (*see Basket Default Swaps*). However, it is no more difficult to handle other products in which the cash flows depend on the exact defaults occurring in quite arbitrary ways, such as CDO-squared (*see CDO Square*). This approach is more robust and more general than techniques founded on mapping methodologies such as base correlation (*see Base Correlation*). The intensity gamma model, like other reduced-form models (*see Reduced Form Credit Risk Models*), is an arbitrage-free model that matches the market and allows pricing of derivatives on arbitrary functions of defaults, rather than attempting to interpolate prices of nontraded tranches.

On the other hand, the intensity gamma model is not designed to capture the volatility of credit spreads or stochastic correlation. The credit spreads of individual names are deterministic functions of time, within the model, up until their default. This is a significant limitation and certainly prevents the use of the model for handling certain products such as options on CDOs.

Model Definition

The core idea of the model is that defaults are driven by a business time process, X_t , which is an increasing

adapted process with $X_0 = 0$. This process intuitively represents the amount of bad news that has arrived by time t , and as bad news arrives, each name has a chance of defaulting in response to the bad news, with names behaving *conditionally* independently, that is, for a given amount of bad news, each name then defaults independently with a certain probability. The fact that all names are driven by the same business time process introduces correlation into the defaults.

To describe more precisely, we start by considering a homogeneous default process in which individual default rates are constant across the time period of interest. The business time process (X_t) will be a subordinator, that is, an increasing Lévy process (*see Lévy Processes*), and in practice it is normally taken to be a constant drift at rate a plus either a gamma process or the sum of two independent gamma processes [1]. A gamma process, (Γ_t) , is described by two parameters, which we denote by γ and λ , and then Γ_t has a gamma($\gamma t, \lambda$)-distribution, that is to say a density function f given as

$$f(x) = \frac{\lambda^{\gamma t}}{\Gamma(\gamma t)} x^{\gamma t-1} e^{-\lambda x} \quad (1)$$

Suppose that we have some set of reference names $\{A_i : i \in I\}$. In the most basic form of the intensity gamma model, each name A_i defaults at some constant rate c_i with respect to the passage of business time as given by the process (X_t) . That is to say, conditional on the path $(X_t)_{t \leq T}$, the name A_i will have survived (i.e., not defaulted) to time T with probability

$$e^{-c_i X_T} \quad (2)$$

with the default events being independent after conditioning on (X_t) .

Calibration of the Model to Individual Default Probabilities

We assume that single-name survival probabilities have been inferred from CDS spreads or bond prices using some simple recovery rate assumption, as is common practice in CDO pricing. The model survival

probability is given by integrating the conditional survival probability (2) against the law of X_T , which amounts to taking a Laplace transform of this law. Suppose for now that this law (and its parameters) has somehow been determined. In the case when it is a single gamma distribution with parameters $(\gamma T, \lambda)$, the required Laplace transform is simple and well known to be

$$\frac{1}{(1 + c_i/\lambda)^{\gamma T}} \quad (3)$$

When X_T is a sum of independent gamma processes, then the survival probability is the product of the corresponding probabilities for each gamma process (3); similarly, a drift of rate a introduces a further multiplicative term into the survival probability of $e^{-ac_i T}$. Thus, there is a straightforward analytic expression for the survival probability of an individual name, and we can use this to quickly solve for c_i to fit the market-implied survival probability for the time horizon of interest.

More generally, we may wish to calibrate to market-implied survival probabilities for a series of time horizons $0 = t_0 < t_1 < t_2 < \dots < t_n = T$. This can be done by generalizing the definition to allow a default rate (with respect to business time) $c_i(t)$, which is a function of calendar time t , which is constant over each subinterval of calendar time of the form $[t_j, t_{j+1}]$.

Pricing Correlation Products

In the following section, we discuss the issue of how to choose the parameters of our business time process X_t and describe now how we price a correlation product, such as a CDO, once these parameters have been specified. From the preceding section, we rapidly calibrate the default rates of all relevant individual names to the single-name credit market at some fixed sequence of time horizons, $0 = t_0 < t_1 < \dots < t_n = T$. The correlation product is then priced by Monte Carlo. For each Monte Carlo path, we must first draw the random business time process, $(X_t)_{t \leq T}$, where T is the last relevant possible default date for the product; this can be done with a finite-dimensional random draw

and results in an (arbitrarily precise) approximation to the business time path by one which contains a finite number of jumps imposed on a path with a constant drift: details can be found in [2] adapted from a method in [1]. Having determined the random path (X_t) , one can then generate the defaults by drawing an independent uniformly distributed random variable U_i for each name A_i and saying that A_i has defaulted by time S if and only if

$$\exp\left(-\int_0^S c_i(t) dX_t\right) < U_i \quad (4)$$

Calibrating to the Correlation Market

First, note that doubling the business time process (corresponding to doubling the λ parameters and the drift parameter a) would be canceled out exactly by halving all the default intensities c_i ; thus, the business time process effectively has a redundant parameter and we may assume, without loss of generality, that $a = 1$. Therefore, if there are two independent gamma processes, there are four free parameters controlling the process and hence the default correlation.

With four free parameters, it is possible to obtain a variety of shapes of the correlation graph, and one can therefore calibrate to multiple tranches simultaneously rather than having to use different correlations for each tranche. This ability to match the correlation smile was a major motivation for the model's introduction. For any given choice of business process parameters, calibrating to the single-name market is instant and pricing CDO tranches by Monte Carlo is fairly quick. A multidimensional route finder can then be used to calibrate the business process parameters to as many independent tranche prices as there are parameters. In practice, one will choose the quoted tranche prices from some major index such as iTraxx or CDX. The index will typically be chosen to have similar properties in terms of maturity, region, diversity, and credit quality as the bespoke correlation product that we are ultimately aiming to price.

For further details on the model, we refer the reader to the original paper [2] or to the recent book [3].

Modeling Correlation of Structured Instruments in a Portfolio Setting

Credit events are correlated. Corporate or retail loan portfolios can exhibit wide swings in losses as economic factors common to the underlying entities drive defaults or deterioration in credit quality. Though challenging, the modeling and data issues related to single-name credit instruments are well understood [9, 10]. However, the correlation of structured instruments remains much more complicated and less understood. Traditional approaches to modeling economic capital, credit-VaR (Value-at-Risk), or structured instruments whose underlying collateral is composed of structured instruments treat structured instruments as a single-name credit instrument (i.e., a loan-equivalent).^a Though tractable, the loan-equivalent approach requires appropriate parameterization to achieve a reasonable description of the cross-correlation between the structured instrument and the rest of the portfolio. We address this challenge by calibrating the loan-equivalent correlation parameters to the dynamics observed in a granular model of the structured instrument.

In the granular model, the underlying reference entities associated with the collateral pool are used to simulate collateral losses, which are translated to structured instrument loss using its subordination level. For ease of exposition, we assume pass-through waterfalls throughout the article; the waterfall structure and subordination level are completely determined by attachment and detachment points. The structured instrument is said to be in distress if it incurs a loss. Simulated losses are used to calculate a probability of distress and loss given distress for each structured instrument and a joint probability of distress (JPD) for the structured instrument and other instruments in the portfolio. The JPD and the individual probabilities of distress are then used to back out an implied “asset return” correlation associated with the structures’ loan-equivalent reference entities (henceforth, *the loan-equivalent correlation*). By taking the probability of distress as the loan-equivalent probability of default (PD), the loss given distress as the loan-equivalent loss given

default, and the deal maturity as the loan-equivalent maturity the parameterization of the loan-equivalent is complete.

In addition to the benefits of using loan-equivalents in a portfolio setting, the simplicity associated with loan-equivalent correlations serves as a useful summary statistic for understanding portfolio-referent risk characteristics. For example, when the collateral pool is parameterized under a wide range of values, the resulting correlation of the structure instrument with the rest of the portfolio is far higher than that of the underlying collateral pool or for other classes of single-name instruments, such as corporate exposures. This is because the idiosyncratic shocks in a collateral pool offset one another, and the systematic portion is left to “run the show”. Moreover, loan-equivalent correlations between two subordinated tranches can be substantially lower than their senior counterparts. The higher correlation exhibited between two credit instruments in the tail region of the loss distribution (the loss region of the collateral pool where a senior tranche enters distress) drives the difference. This is because a senior tranche distress is most likely driven by systematic shock, which makes it more likely that it will be accompanied by a distress in the other senior tranche.

Correlation among CDOs can also stem from the overlap in reference entities associated with their collateral pools. Although it is intuitive that loan-equivalent correlations increase with the degree of overlap, the effect is stronger for more junior tranches. This finding follows from the junior tranches’ susceptibility to idiosyncratic noise. With a higher degree of overlap, the tranches share more of the idiosyncratic shocks.

Recent literature on structured instruments’ correlation primarily addresses correlations between collateral pool reference entities and their effect on tranche pricing. For example, Agca and Islam [1] examines the impact of correlation increase among underlying assets on the value of a CDO equity tranche, and shows that CDO equity can be short on correlation. The normal copula model, studied in detail in [4], has become the industry standard for pricing structured instruments and often results in a market price-implied correlation smile. Several papers address this phenomenon; Moosbrucker [5] explains it using variance-gamma distributions. This article, however, focuses on the

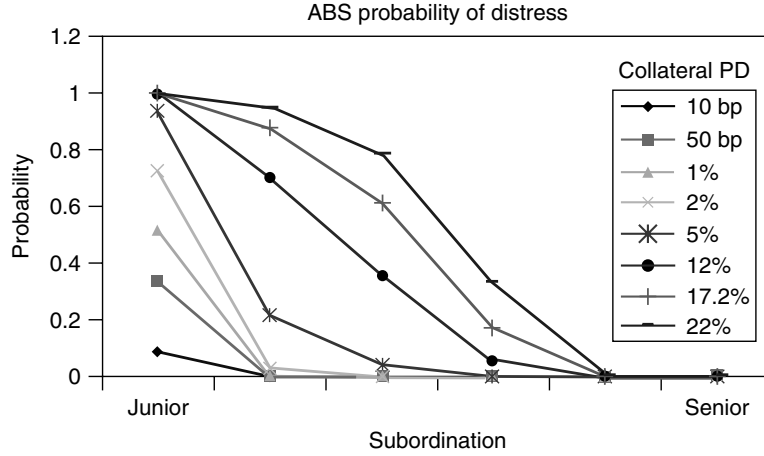

Figure 1 ABS probability of distress changing with subordination for collateral parameters: $R^2 = 10\%$, $LGD = 70\%$, and collateral PD ranging from 10 basis points to 22%

correlation structure between a structured instrument and other instruments in the portfolio. This structured instrument correlation is a function of the correlation of the underlying collateral instruments among themselves and with other instruments in the portfolio, as well as of the deal's waterfall structure and the instrument's subordination level. Coval *et al.* [2] show that, similar to economic catastrophe bonds, structured instruments are highly correlated with the market, but offer far less compensation than economic catastrophe bonds. The authors suggest in [3] that this lower compensation occurs because rating agencies base their structured instrument ratings on distress probability and expected loss, ignoring the high correlation with the market.

Modeling the Correlation of Two ABSs

Consider an asset-backed security (ABS) with a homogeneous collateral pool (e.g., similar risk California auto-loans). In a homogeneous pool, we can model the systematic portion of reference entity i 's asset return process (r_i) using a single factor (Z) with a common factor loading (R):

$$r_i = R \cdot Z + \sqrt{1 - R^2} \cdot \varepsilon_i \quad (1)$$

Henceforth, we use the square form of the factor loading, R^2 , because of its interpretation as the proportion of asset return variation explained by the common factor Z . The single factor Z and the idiosyncratic portion ε_i are standard Brownian motion processes and, therefore, so is the asset return. A default occurs when the asset return process drops below a default threshold (DT), which happens with probability PD. These PDs and other parameters for the underlying instruments in the collateral pool are publicly available.^b

In analyzing ABS characteristics, we made simplifying assumptions. We assumed a single period, and the analysis abstracted from subtleties such as reinvestment, collateralization, or wrapping. Collateral pools were composed of instruments with Loss Given Default (LGD) = 70% and reference entities with $R^2 = 10\%$. Each deal consisted of seven ABSs at different subordination levels. Deal maturity was set at 1 year. All deals were simulated 100 000 times in Moody's KMV's RiskFrontierTM to obtain the ABSs' probabilities of distress and losses given distress, as well as to account for collateral pool correlations properly. See [8] for the methodology used in RiskFrontierTM.

Figure 1 demonstrates how the ABS 1-year distress probability changes with the subordination level for collateral pools; PD values range from as low as 10 basis points to as high as 22%, covering a

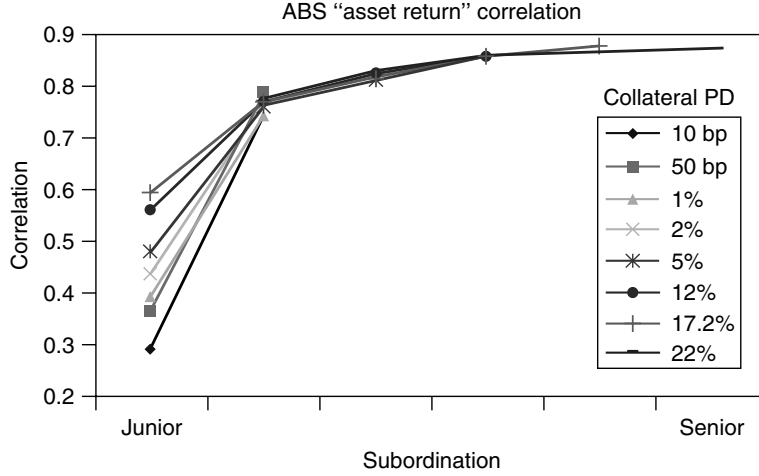

Figure 2 ABS loan-equivalent reference entity’s “asset return” correlation for collateral parameters: $R^2 = 10\%$, $LGD = 70\%$, and collateral PD ranging from 10 basis points to 22%

variety of instruments in varying economic environments—from prime loans in boom times to subprime mortgages during downturns. As expected, the ABS probability of distress is decreasing in the subordination level. Moreover, it appears that the distress probability curve starts out concave, switches, and then becomes convex. This convexity switch occurs at the maximum point of the bell-shaped collateral loss distribution function. Higher collateral PD pushes this maximum point to higher loss points.

To better understand the correlation structure of these ABSs, we compute the loan-equivalent reference entity’s R^2 for each deal. To this end, the simulation holds two similar copies of each ABS. Collateral pools for the two copies contain statistically similar instruments (but not the same instruments, i.e., different idiosyncratic shocks). The empirical JPD (JPD_{sim}) of the similar ABS pairs is calculated from the simulation results. Using a normal copula, we choose the loan-equivalent reference entity’s “asset return” correlation ρ_{12}^A , which results in the empirical JPD :

$$JPD(PD_1, PD_2, \rho_{12}^A) = JPD_{sim} \quad (2)$$

where $JPD(PD_1, PD_2, \rho_{12}^A)$ is the joint, 1-year distress probability of the two ABSs in a normal copula with correlation ρ_{12}^A and 1-year default probabilities

PD_1, PD_2 . To be clear, the “asset return” correlation ρ_{12}^A differs from the ABSs’ distress correlation ρ_{12}^D . Of course, the two are related:

$$\rho_{12}^D = \frac{JPD(PD_1, PD_2, \rho_{12}^A) - PD_1 \cdot PD_2}{\sqrt{PD_1 \cdot (1 - PD_1) \cdot PD_2 \cdot (1 - PD_2)}} \quad (3)$$

Generally, ABS “asset return” correlations are much higher than those of the underlying collateral. In our example, the asset return correlation for any pair of auto-loans, one from each ABS, is 10%. However, the “asset return” correlation for ABS loan-equivalents is 29% for the junior note and low collateral PD and significantly increases with subordination (Figure 2). This shows that the average collateral correlation is a highly biased estimate for the loan-equivalent correlation, since most of the idiosyncratic noise in the collateral pools washes out as the idiosyncratic shocks in the pool offset one another, leaving the common systematic factor to drive dynamics.

Results in Figures 1 and 2 are based on collateral pools of, for example, homogeneous auto-loans that share exposure to the same systematic factor (e.g., all in California). Therefore, the initial correlation between pairs of auto-loans was high to begin with. To examine the significance of pool diversification, consider an example with 50 state factors

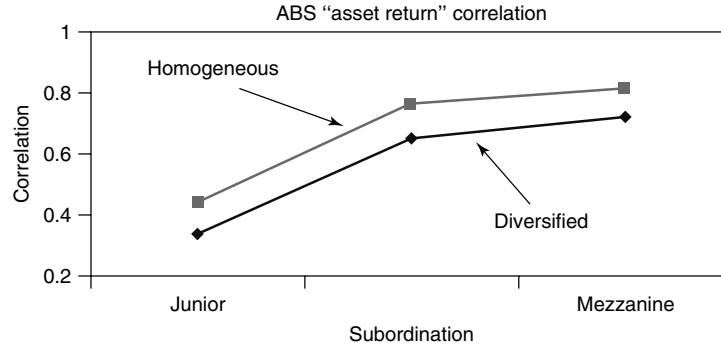

Figure 3 ABS loan-equivalent reference entity's "asset return" correlation—diversified pool (50 factors) *versus* homogeneous pool (common factor) with collateral pool parameters: $PD = 2\%$, $R^2 = 10\%$, $LGD = 70\%$

$(Z_1, \dots, Z_{50})$, where the auto-loans are equally distributed between the states. Each auto loan i has an associated state factor $k(i)$, such that $r_i = R \cdot Z_{k(i)} + \sqrt{1 - R^2} \cdot \varepsilon_i$. Using Moody's KMV's GCorr Retail™, we set the correlation between any two state factors to be 65% ($\rho(Z_k, Z_l) = 0.65$ for any $1 \leq k < l \leq 50$).^c Figure 3 compares the ABS "asset return" correlations between the diversified pool (50 factors) and the homogeneous pool (common factor) for pools with collateral $R^2 = 10\%$ corresponding with a range of retail loans including student loans and consumer loans [8]. Collateral PD was set to 2%.

Figure 3 demonstrates that the loan-equivalent reference entity associated with a diversified pool is less correlated than that of a homogeneous pool. This finding is not surprising, given that state factors are not perfectly correlated, allowing for diversification. This exercise is particularly important when modeling a CDO of ABSs whose collateral pools are focused on different geographic locations.

Collateralized Debt Obligation (CDO) Correlations

Even though CDO deals are similar to ABS deals, several important dynamics specific to CDOs impact correlation structure. First, corporate entities have lower default probabilities and higher R^2 than typical reference entities associated with ABS collateral instruments. Second, names commonly overlap

in collateral pools of different CDO deals. Thompson and Rajendra [7] show that some names appear in more than 50% of deals in Fitch's Synthetic CDO Index (Ford Motor Co -56.52% , and General Motors Corp -52.40%). Third, credit portfolios commonly have overlapping names across the single-name portion of the portfolio and the CDO collateral pool.

This section is divided into two subsections. The first analyzes the correlation between a CDO and a single-named instrument whose reference entity does not overlap with the CDO collateral pool. The second analyzes the correlation between two CDOs with varying degrees of collateral overlap.

Correlation between a Collateralized Debt Obligation (CDO) and a Single-name Instrument

Morokoff [6] calculated the loan-equivalent reference entity R^2 for a pass-through CDO tranche from the joint probability of tranche distress and single-name instrument default (outside the CDO's collateral pool), known henceforth as the joint default-distress probability. He considered a collateral pool of N -homogeneous instruments in a single factor environment. The single-name instrument was assumed similar to the instruments in the homogeneous collateral pool. Morokoff's methodology relies on using the independence of defaults, conditional on the realization of systematic risk factors, to compute the conditional joint default probability and then the expectation is taken over the systematic risk factor:

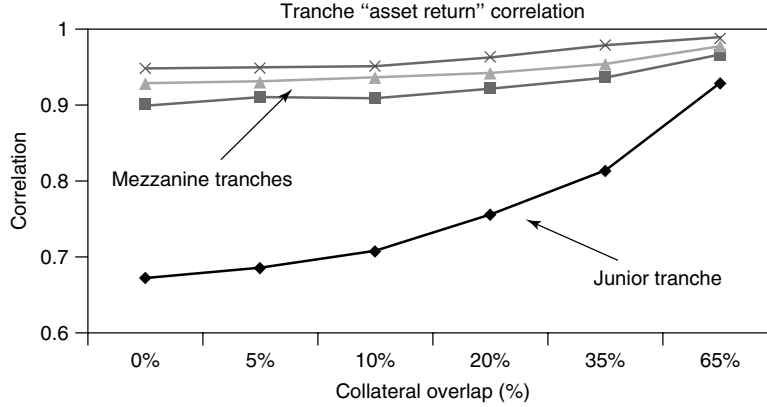

Figure 4 The effect of collateral overlap on tranche loan-equivalent reference entity's "asset return" correlation with collateral pool parameters: $PD = 2\%$, $R^2 = 25\%$, $LGD = 70\%$

$$\begin{aligned}
 P(\text{Tranche distress and single default}) &= E_Z(P(\text{Tranche distress and single default} | Z = z)) \\
 &= E_Z(P(\# \text{ defaults in pool} \geq \hat{a} | Z = z) \cdot p(z)) \\
 &= E_Z\left(\left(1 - \sum_{k=0}^{\hat{a}-1} P(\# \text{ defaults in pool} = k | Z = z)\right) \cdot p(z)\right) \\
 &= E_Z\left(\left(1 - \sum_{k=0}^{\hat{a}-1} \binom{N}{k} p(z)^k (1 - p(z))^{N-k}\right) \cdot p(z)\right) \\
 &= p - \sum_{k=0}^{\hat{a}-1} \binom{N}{k} E_z(p(z)^{k+1} (1 - p(z))^{N-k})
 \end{aligned} \tag{4}$$

where $\hat{a}$ is the required number of defaults in the pool to cause a distress to the tranche, $p(z) = N \left(\frac{N^{-1}(p) - R \cdot z}{\sqrt{1 - R^2}} \right)$ represents the PD conditional on the common factor $Z = z$, and $p = E_Z[p(Z)]$.

Similar to our analysis of ABS correlations, one can infer an "asset return" correlation ρ from the default probability, distress probability, and joint default-distress probability using a normal copula: $JPD = N(N^{-1}(\text{tranche distress prob}), N^{-1}(p), \rho)$.

Finally, $R^2_{\text{Loan equivalent}}$ can be computed as $\frac{\rho^2}{R^2}$.

Note that these calculations present an alternative to the simulations in the ABS section. However, the computation becomes infeasible for large pools and is, therefore, more suitable for CDOs. The normal approximation to the binomial distribution

can alleviate the cumbersome calculations, but for some values of the systematic factors z , the conditional default probability $p(z)$ is too small for the normal approximation to work.

Correlation of Collateralized Debt Obligations (CDOs) with Overlapping Names

Intuitively, the degree of overlap associated with two CDO tranches increases their correlation. To better understand the quantitative impact of overlap, we used simulation methods similar to those in the section Modeling the Correlation of Two ABSs. The relevant difference is that a certain percentage of the collateral pool is assumed to overlap when analyzing the correlations across the deals. Figure 4

presents the tranche loan-equivalent asset return correlations computed using the methodology in the section Modeling the Correlation of Two ABSs. The analysis was conducted on a high-yield deal with typical high-yield CDO properties ($PD = 2\%$ and $R^2 = 25\%$). Along the x -axis, the collateral overlap varies from 0 to 65%. Each curve represents a subordination level for the tranche. Interestingly, the loan-equivalent asset correlation increase with overlap is more substantial for junior tranches. This follows from the susceptibility of junior tranches to idiosyncratic shocks. After all, the junior tranche can easily experience distress even when the systematic shock is high; all it takes is a single reference entity to realize a particularly low idiosyncratic shock. On the other hand, senior tranches are extremely unlikely to experience distress when the systematic shock is high. Therefore, the degree of overlap, which only affects idiosyncratic shocks, has a much greater effect on junior tranches.

Acknowledgments

We would like to thank Zhenya Hu for help with the simulations and Mikael Nyberg for his suggestions.

Special-purpose Vehicle (SPV)

A special-purpose vehicle (SPV) is a legal entity created by a firm for a specific business objective, usually in the context of **securitization**. SPVs are often used to finance a project or issue securities without putting at risk the original holder of the securitized portfolio.

We focus here on quasi-operating companies, which are SPVs operating in primarily one type of business: interest rate and foreign exchange derivatives, credit derivatives, and buy and hold assets or others. Derivative product companies (DPCs), structured investment vehicles (SIVs), and credit derivative product companies (CDPCs) are the most well-known operating companies.

Derivative Product Companies (DPCs)

(DPCs) are intermediaries between financial institutions (known as their *parents* or *sponsors*) and their third-party counterparties [2, 5]. DPCs intermediate swaps between the sponsor and third parties under the approved International Swaps and Derivatives Association (ISDA) Master Agreement. Enhanced subsidiaries differ from other derivative-product subsidiaries, as their credit ratings do not depend on their parent's guarantee. A DPC may engage in over-the-counter interest rate, currency, and equity swaps and options as well as certain exchange-traded futures and options depending on its individual structure. A DPC is capitalized at a level appropriate for the scope of its business activities and desired rating. In most cases, DPCs have been set up to overcome credit sensitivity in the derivative-product markets. There are two types of DPCs: continuation and termination structures. The continuation structures are designed to honor their contracts to full maturity even when a wind-down event occurs, while termination structures are designed to honor their contracts to full maturity, or should certain events occur, to terminate and cash settle all their contracts prior to their final maturity. DPCs are typically AAA rated and are often referred to be the *AAA face of the sponsor*. They are market risk neutral by mirroring their trades with the third parties with the parent

or the sponsor. They are exposed to the credit risk of third parties. The structure is equipped with exit strategies and resources so that upon certain wind-down scenarios, the vehicle is expected to meet its derivative obligations with AAA certainty.

The market for DPCs developed in early 1990. Every bank seeking to be eligible as an AAA counterparty in derivative contracts sponsored its own DPC.

Credit risk of third-party counterparties is quantified by sophisticated models. Potential future market environment is simulated and valuation modules are used to project the mark-to-market of each swap contract. By combining market paths with credit paths (in which the creditworthiness of the counterparty is simulated), one can assess where capital is being deployed to cover for losses. The potential losses corresponding to each market path can be analyzed by combining the results of default simulations and the counterparty exposures. A consideration of losses across all market paths permits the construction of a distribution of potential credit losses. The credit enhancement to protect against losses at a given level of confidence may be analyzed. This risk model can also quantify the potential change in the portfolio's value over a period of time.

A DPC with a continuation structure generally receives collateral from the parent to cover its exposure to the parent resulting from the back-to-back trades. This collateral amount, after appropriate discount factors are applied, is equivalent to the net mark-to-market value of the DPC's portfolio of contracts with its parent. Upon the occurrence of certain events, however, the management of the DPC's portfolio will typically be passed on to a contingent manager.

In the short period prior to the transfer of portfolio management to the contingent manager, the value of the DPC's contracts with its parent could rise. Using the capabilities of the risk model, the potential increase in the DPC's credit exposure to the parent may be quantified.

In a termination structure, the value of the DPC's portfolio can change over the period beginning with the last regular valuation date and ending at the early termination valuation date upon occurrence of a termination trigger event. Again, the potential change in the portfolio's value may be determined at the desired level of confidence by using the same risk model.

DPCs are equipped with a liquidity model that covers short-term liquidity squeezes and with operational capital that covers operational risks.

Structured Investment Vehicles (SIVs)

SIVs are limited-purpose operating companies that take arbitrage opportunities by purchasing mostly highly rated medium- and long-term assets and funding themselves with cheaper short-term commercial paper (CP) and medium-term notes (MTNs) [3, 6, 7].

SIV-Lites combine features of both collateralized debt obligations (CDOs) and SIV technologies. They typically purchase high-grade asset-backed securities (ABSs), primarily residential mortgage-backed securities (RMBS), but may also include a small portion of commercial mortgage-backed securities (CMBS) or other ABSs and fund themselves by issuing short-term CP or repurchase agreements (REPOs) and MTNs. SIVs and SIV-Lites roll their senior short-term liabilities (REPOs and CPs) unless a market disruption event occurs or any other liquidation trigger is reached.

When analyzing SIVs or SIV-Lites, stochastic cash-flow models could be used to quantify the risks they are exposed to. The main risk factors of the asset portfolio, which include credit migration and market risk, are captured and projected by Monte Carlo simulation. Credit migration measures the new credit profile of the portfolio. Defaults net of recovery result in loss in the portfolio. Upgrades and downgrades directly affect the credit profile and the market value of the portfolio. Asset spreads and asset market values are projected in the capital model as well as credit migration. Historical spread data are used to calibrate the asset spread model. Rating migration, default correlation, and recovery assumptions are based on historical default studies and applied to the capital model. Market risk involves interest rates and foreign exchange rates (if there exists foreign currency valuation) modeling. SIVs or SIV-Lites are designed to be market risk neutral. Additional interest rate and foreign exchange rate sensitivity tests are usually used to this end. These tests mainly measure the change in the net asset portfolio value caused by a sudden change in the interest rates or foreign exchange rates. Liquidation risk is the most complicated risk factor to be modeled. Liquidation assumptions on the assets are required

when senior debts cannot be rolled over. Haircuts on the assets for the liquidation purpose are based on stressed historical asset price movements and applied appropriately when needed.

Since the stability of capital requirement is one of the key components in the risk management of SIVs or SIV-Lites, a certain large number of Monte Carlo paths are generated to test whether the model converges in a good manner.

A liquidity model might be used to monitor the vehicle's internal liquidity relative to the liabilities. Net cumulative outflow (NCO) tests are normally calculated for each rolling 1, 5, 10, and 15 business day period commencing on the next day of calculation through and including the day that is one year from the day of such calculation, for example, the vehicle needs to determine on a daily basis its 1, 5, 10, and 15 day peak NCO requirements over a period of one year.

SIVs and SIV-Lites also face management and operational risk that is covered by additional capital.

In mid-2007, SIVs and SIV-Lites experienced a number of difficulties owing to, among other things, the liquidity crunch and spread widening. Various SIVs and SIV-lites were downgraded by rating agencies. Some of them went into default. SIV exposures in rated funds have dropped dramatically since the last quarter of 2007.

Credit Derivative Product Companies (CDPCs)

CDPCs are special-purpose entities that sell credit protection under credit default swaps (CDS) or certain approved forms of insurance policies [1, 4]. Unlike traditional DPCs, which are engaged in interest rate, currency, and equity swaps and options, CDPCs sell protection on single-name obligors, such as corporate, sovereign, and asset-backed securities, or on tranching, structured finance obligations. CDPCs can also buy protections or enter interest rate and currency swaps. However, that is mainly for hedging purposes.

When analyzing CDPCs, sophisticated models are built to quantify the risk of CDPCs and analyze the amount of capital needed to meet the obligations for their counterparty ratings and various debt-note ratings, respectively. These obligations include payments on credit events, payments on senior fees

expenses, and potential termination payments upon counterparty defaults.

The key risk factors that CDPCs might be exposed to are credit risk for the reference entities, counterparty risk, and market risk. Credit risk is the primary concern for a CDPC. If the reference entity on which a CDPC sells protection defaults, the CDPC will suffer a loss. Historical default studies and rating analysis are applied to simulate the time to default of the reference portfolio. Correlation and recovery assumptions are used to size the loss. Single-period time-to-default models are efficient tools to model credit risk. However, multiperiod rating transition models become necessary when the credit qualities of the underlying assets are required to be featured in the capital model. When modeling the credit risk of CDO tranches, drilling down to the underlying obligors is more effective to model the correlation risk.

When a CDS counterparty experiences a default, the swap contracts that are associated with that counterparty are unwound and a termination payment (fair market value) may need to be calculated. Credit spread widening can lead to large termination payments upon counterparty default. Spread models quantify the potential deterioration in the creditworthiness of the assets as well as market volatility. Spread data are usually grouped in rating and industry categories.

Market standard valuation modules for single-name CDS contracts and tranching CDO transactions are generally used to calculate the fair market value upon the counterparty defaults. Besides credit spreads, interest rate projection is necessary for the discounting of future cash flows in order to calculate present values, the amount of coupon paid on the notes, and the amortization schedule for CDPCs that invest in prepayment-sensitive assets such as ABSs. A CDPC is exposed to foreign exchange risk when it makes or receives payments in more than one currency, and no hedge has been set up to neutralize the mismatch. In this case, the foreign exchange rate is modeled in the capital model. The cash-flow waterfall is added to the default model according to

the structure of the CDPCs. CDPCs also face liquidity risk. A liquidity model might be developed to size capital for short-term needs.

Like modeling SIVs or SIV-Lites, the model calibration is a complex exercise. A certain large number of Monte Carlo paths are generated to test appropriate model convergence.

CDPCs also face operational risks and CDPC management risk. Additional capital is typically assigned for these risks.

Since CDPCs have no market value triggers that would force them to sell assets or reduce leverage, they have not been affected as significantly by the subprime mortgage crunch as SIVs or SIV-Lites in 2007. However, CDPCs have been experiencing a hard time to find counterparties because of the volatility of the spreads.

Credit Portfolio Insurance

Credit portfolio insurance products such as credit constant proportion portfolio insurance (CPPI) and constant proportion debt obligations (CPDOs) utilize similar technologies that use leverage as a mechanism to enhance returns. Credit CPPIs and CPDOs evolved in the low credit spread environment witnessed recently, especially between the years 2004 to about mid-2007 as shown in Figure 1. For many investors, the tightness in investment grade spreads rendered investment grade return targets difficult to achieve other than through rule-based, leveraged credit strategies. Credit CPPIs and CPDOs are two alternative formats of gaining leverage in a similar class of investments,^a with the first credit CPPI products being introduced in 2004 followed by CPDO products in 2006.

Credit CPPI

Historically, the CPPI concept came into being in the context of equity portfolios. Some of the earlier works in this area are by Black and Jones [1], Black and Perold [2], and Black and Rouhani [3]. For a CPPI, the term *insurance* is a loosely defined expression that refers to principal protection of the issued CPPI notes. The principal component of the notes, called the *bond floor*, is secured by virtue of the fact that an appropriate portion of the note issuance proceeds is invested in risk-free assets. The remainder of the proceeds, called *cushion* or *reserve*, is used to take leveraged exposure to risky credit assets in the case of a credit CPPI. Combined earnings from the risk-free and risky assets generate the cashflows to pay the periodic interest and final principal on the CPPI notes.

A simple example of a CPPI would be a structure where proceeds from the CPPI note issuance are divided into two components—the first component is invested in a “risk-free” zero coupon bond with a face value equal to the principal of the CPPI note and the second component acts as a reserve account for taking exposure to more risky assets through credit default swaps (CDSs). The idea is that the risk-free bond will back the repayment of principal at maturity, while the more risky portfolio of CDS assets will be used to generate spread income and to pay the interest on the CPPI note.

Figure 2 describes the structure of a CPPI. The CPPI investor provides the initial funds equivalent to the notional amount of the issued CPPI notes and the proceeds are utilized to set up (i) a reserve account for investing in risky assets and (ii) a deposit account for investing in “risk-free” assets. Leverage is obtained on the risky portion of the balance sheet by taking positions that make the notional exposure to the risky assets to be some multiple of the reserve account balance. Although the choice of these risky assets can include all types of assets, for a credit CPPI the typical investment would be in the form of exposure to a credit index, standardized or bespoke synthetic CDOs, cash flow CDOs, equity default swaps (EDSs),^b and so on.

Figure 3 shows the expected evolution of the *bond floor* and the more risky portfolio value over the term of the CPPI. The actual value of the risky portfolio and *bond floor* at a particular point in time will, however, depend on the evolution of credit CPPI risk factors such as movements in credit migrations, default events, interest rates, and loss given default. Moreover, the performance of the CPPI is quite sensitive to the leverage multiplier, and to mitigate this risk, the CPPI is often required to reduce leverage through rebalancing as losses on the risky portfolio eat into the reserve account.^c

Credit CPPI Risk Factors

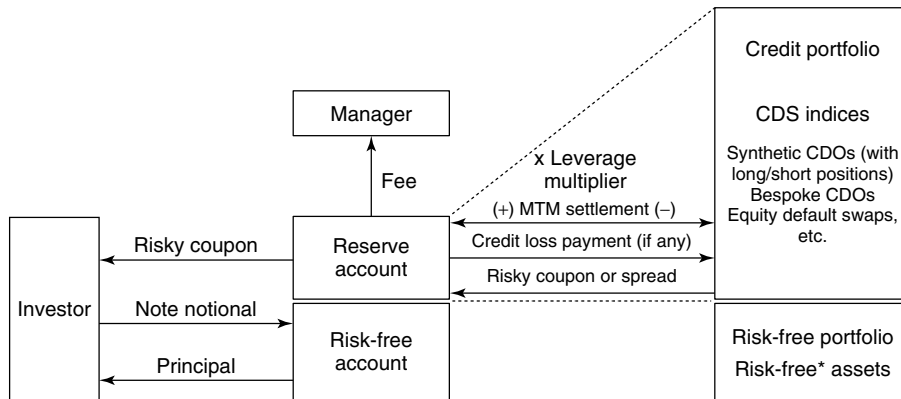

Gap risk: This is the possibility that rebalancing the risky portfolio may not happen at the speed of its market value deterioration. In such a scenario, a loss of principal could occur if a sudden loss in market value exceeds the reserve cash account in the form of the *cushion*. Moreover, the higher the leverage multiplier, the higher the gap risk. A less drastic scenario is when a loss on the risky portfolio nearly erases the *cushion* and leaves only risk-free assets in the portfolio—in that case although the principal is still protected, the promised CPPI note coupon can no longer be paid in full.

Default risk: Defaults in the more risky portfolio, both in terms of timing and loss given default, affect the expected returns and the principal protection of the CPPI notes. Some structures mitigate default risk by imposing restrictions on investments in subinvestment grade assets.

Interest rate risk: Changes in interest rates lead to fluctuations in the zero coupon *bond floor*, which

Figure 1 Evolution of the CDX North American Investment Grade (CDX.NA.IG) Index over the period July 2004 to July 2007

* These assets have no default risk but may be subject to interest rate or prepayment risk.

Figure 2 Cash flow diagram describing a credit CPPI structure

in turn impacts the reserve available for taking leveraged exposure to credit risk assets. Since the objective of the credit CPPI is to limit downside while maximizing returns through dynamic rebalancing of the portfolio between “risk-free” and more risky assets, changes in the *bond floor* due to interest rate movements affect the rebalancing strategies.

Performance risk: The CPPI manager’s ability in implementing the credit CPPI dynamic portfolio rebalancing strategy may also be important.

Modeling a Credit CPPI

A Monte Carlo simulation approach is an effective means of modeling the risk of a credit CPPI transaction. The four main features of a bottom-up

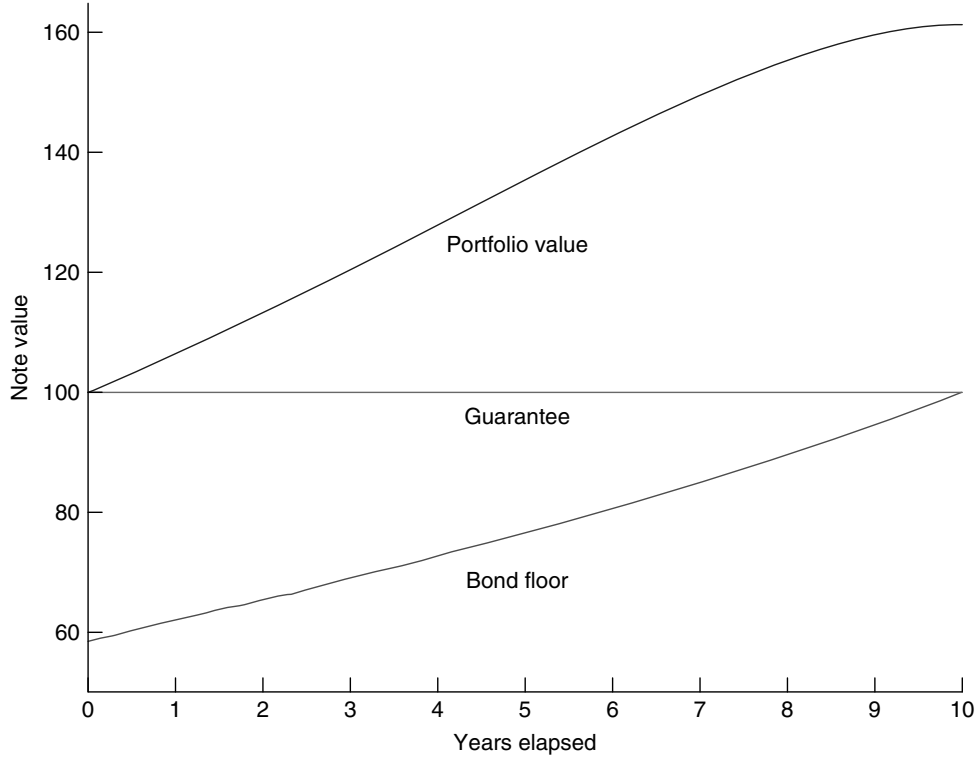

Figure 3 Expected value of the bond floor and the more risky portfolio over the life of a CPPI

credit CPPI model should include (i) single name CDS spread curve dynamics, (ii) correlation between spread movements and credit migrations across the names in the portfolio or index, (iii) losses due to defaults and associated recoveries, and (iv) interest rate dynamics for cash flow discounting, *bond floor* value estimation, and liability payment calculations.

Credit quality changes in the form of rating migrations may be modeled in a structural framework where the normalized asset return, A_k , of asset k can be decomposed into systematic and idiosyncratic components:

$$A_k = \sqrt{\rho}z + \sqrt{1 - \rho}\varepsilon_k \quad (1)$$

For a Gaussian copula framework, the systematic and idiosyncratic latent factors, that is, z and ε_k , respectively, would have standard normal distributions and ρ would be the asset correlation parameter. The probability of asset k migrating from its current rating level R_i to a new rating level R_j would be given by the following expression in this

case:

$$\sum_{m=1}^{j-1} \Pr(R_i \rightarrow R_j) \leq \Phi(A_k) < \sum_{m=1}^j \Pr(R_i \rightarrow R_j) \quad (2)$$

Credit spreads are often modeled as mean reverting processes, where the mean reversion speed and spread volatility could be made functions of rating levels. One such specification for the spread model could be

$$\begin{aligned} \log(S_k(t_{i+1})) &= \delta \log(S_k(t_i)) + (1 - \delta) \\ &\times \log(S^*(R_k(t_{i+1}))) + \sigma \sqrt{\delta} \Delta t \\ &\times (\sqrt{\rho_s} A_k + \sqrt{1 - \rho_s} \varphi_k) \end{aligned} \quad (3)$$

where $\delta = \exp(-\kappa \Delta t)$, κ is the mean reversion speed, σ is the spread volatility, S^* is the average spread associated with rating R , A_k is the asset return used in the credit migration simulation, ρ_s is the correlation between the asset return and the spread, and $\varphi_k \sim N(0,1)$.

One may also include a jump component in the above specification, or a regime switching module, for enhancing the possibility of more sudden and drastic spread moves for a more conservative estimation of gap risk. For example, Cont and Tankov [5] developed a model that includes jumps in the asset price process.

Lastly, an appropriate interest rate process based on any popular spot rate or forward rate model such as the one by Hull and White [7] or Heath *et al.* [6] can be incorporated in the above framework for cash flow discounting calculations.

CPDO

CPDOs use a similar leveraging technology as described previously for CPPIs but with two major exceptions. First, there is no guaranteed return of principal and, second, rebalancing in the form of leverage changes is in the opposite direction to that of a CPPI, that is, CPDO rebalancing is based on a “buy low, sell high” strategy where a spread widening leads to an increase in the notional exposure to the more risky portfolio, subject to the maximum leverage cap. This is designed to allow the structure to compensate for the loss in value due to the spread widening by increasing the spread income from more risky assets in future periods.

The economics behind CPDO transactions backed by exposure to investment grade credits such as an index CPDO is the fact that investment grade

names typically display an upward sloping term structure of spreads. The theory is that the CPDO can take exposure to a new on-the-run index series at a relatively high spread level (corresponding to $5\frac{1}{4}$ years maturity) but trade out of the series at a significantly lower spread level (corresponding to $4\frac{3}{4}$ years) as the index becomes off-the-run.^d In the context of CPDOs, this dynamic is known as the *roll down the curve* benefit and the aim of the CPDO is to maximize this advantage by employing leverage.

Figure 4 describes a typical CPDO structure. Upon initiation, all cash proceeds from the CPDO investor are placed in a deposit account and get invested in short-term liquid instruments that earn interest at the risk-free benchmark rate, typically LIBOR. The deposit account also acts as the reserve account for taking exposure to a more risky credit portfolio of CDS assets (or a CDS index) where the credit portfolio notional = CPDO note notional* leverage factor. The most popular choice for the risky assets is a portfolio providing equal exposure to the CDX North American Investment Grade (CDX.NA.IG) and the iTraxx Europe Investment Grade indices.^e Moreover, to mitigate default and liquidity risk, such index CPDOs are generally required to sell protection only for “on-the-run” index series so that exposure to index constituents’ names that get downgraded to below investment grade rating levels is automatically limited because of the substitution rules imposed when indices roll over every six months.

The deposit account is credited with interest from the liquid short-term assets, spread premia from

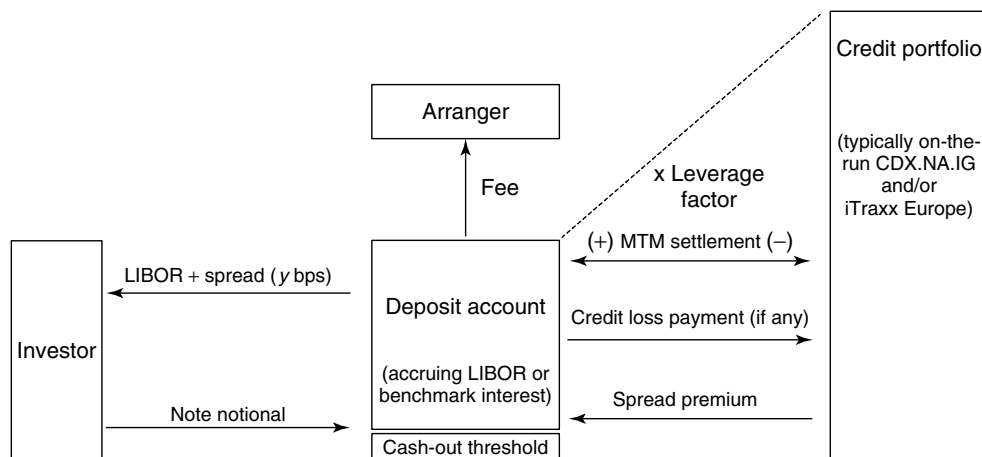

Figure 4 Cash flow diagram describing a CPDO structure

the CDS credit portfolio, and any positive mark-to-market (m-t-m) settlements on the credit portfolio. The deposit account gets debited with coupon payments to the CPDO investor, management fees to the arranger, any negative m-t-m settlements, or credit loss payments due to defaults in the CDS portfolio. The performance of the CPDO thus depends on how the *net asset value* (NAV) at time t , which is equal to the sum of the deposit account balance, the m-t-m of the CDS portfolio, and the accrued spread income, compares to the *target value* (TV) at time t , which is the amount if invested at the risk-free rate would be sufficient to meet the CPDO coupon and principal payment obligations, as well as any fees.^f The difference between $TV(t)$ and $NAV(t)$ is called the *shortfall*, that is,

$$\text{Shortfall}(t) = TV(t) - NAV(t) \quad (4)$$

The leverage employed in the CPDO transaction is a function of the ratio of the *shortfall* to the risky income calculated as the present value of the expected spread premium earnings. Note that this ratio quantifies the amount of the current shortfall when compared with the cash flow expected from the risky assets. More specifically, the transaction has predefined rules for estimating a target notional defined as

$$\begin{aligned} \text{Target notional} &= \text{Gearing factor} \\ &\times \frac{\text{Shortfall}}{PV(\text{expected CDS premia})} \end{aligned} \quad (5)$$

Some structures define a flat gearing factor, while others may employ a time-dependent gearing factor. Leverage is then simply the ratio of the target notional to the CPDO note notional. From equation (5), it can be seen that if spreads widen, causing the CPDO to incur m-t-m losses that increase the *shortfall* relative to the expected risky spread earnings, leverage increases. This is contrary to a CPPI leverage strategy where any m-t-m losses on the more risky portfolio lead to a delivering of the transaction.

At the commencement of a CPDO transaction, the *shortfall* is positive as $NAV(t_0)$ is simply the CPDO note notional proceeds *minus* any upfront structuring fees since the value of the CDS portfolio is zero at initiation and there are no accrued spread premium earnings yet. With time, however, the shortfall is

expected to decrease to zero, in which case the CPDO is said to have a “cash-in” event. This implies that the structure no longer needs to take on any risky exposure and the reserve deposit account is large enough to meet all future interest, principal, and fee payment obligations by simply investing in risk-free assets. In adverse market conditions, however, frequent and large m-t-m losses on the portfolio and/or defaults may lead to severe erosion of the deposit reserve account. In some instances, the NAV may drop below a certain threshold, typically defined at 10% of the issued CPDO note notional. In this case, the CPDO transaction is unwound and is said to have suffered a “cash-out” event. The only other event possible is when the transaction fails to redeem the CPDO note at par upon maturity, in which case the CPDO investor incurs a loss, though not as severe as under a “cash-out” event.

CPDO Risk Factors

Similar to CPPIs, the main risk factors for a CPDO structure are as follows:

Spread risk: Sudden (and correlated) widening of spreads can lead to large m-t-m losses that eat into the cash reserve account. With index CPDOs, this risk may also be in the form of rollover risk, whereby index constituent names that deteriorate in credit (and show spread widening) get downgraded and get replaced with tighter spread names. Since the CPDO is generally required to roll over its exposure to the on-the-run index series, the effect of the rollover is twofold. On the one hand, riskier names have to be effectively unwound at wider spreads, resulting in m-t-m losses. On the other hand, these names get replaced in the index with higher rated names, implying lower spread earnings after the roll that would have ordinarily compensated for the m-t-m losses.^g

Default risk: Similar to CPPIs, CPDO investors are exposed to default risk as protection sellers. However, generally speaking, this risk is greatly mitigated in index CPDOs due to the rollover every six months.

Liquidity risk: Since index CPDOs are required to roll their exposure to the index series every six months, they can be more prone to liquidity risk. Even though on-the-run index series are the most liquid, bid–offer spreads may widen at the time of rollover as dealers anticipate more one-sided trades.

Interest rate risk: In “normal” circumstances, a natural hedge exists since liabilities, that is, CPDO notes outstanding (paid LIBOR) are less than or equal to the cash reserve account (earns LIBOR). However, interest rate risk may become significant if large m-t-m (or default) losses eat into the reserve account, leading to a mismatch between the CPDO notes outstanding and the size of this reserve deposit account.

Modeling a CPDO

CPDOs can be modeled using a similar bottom-up Monte Carlo approach as described for CPPIs. For index CPDOs, the analysis should also include a means of modeling index changes to capture the impact of rollover risk on the CPDO note performance. This can be incorporated in the suggested framework by using the ratings-based credit migration model to analyze changes to the index by appropriate replacement of credits that get downgraded to below investment grade rating categories.

Cont and Jensen [4] provided an alternative modeling approach using a top-down method. In their framework, rollover effects are incorporated *via* jumps in the index spread at each roll date.

End Notes

^aSome investors also consider synthetic CDO tranches as an alternative means of gaining leverage in this class of investments. We, however, differentiate CPPIs and CPDOs from synthetic tranches since the latter are correlation products.

^bEDSs have risk characteristics that are similar to CDSs and hence a CPPI with exposure to EDSs is classified as a credit CPPI.

^cAlternatively, an increase in the more risky portfolio value may result in an increase in the notional exposure to the more risky assets up to a predefined maximum leverage

cap. For this reason, a credit CPPI strategy is also known as *buy high, sell low*.

^dThis assumes that the average credit quality of the index remains more or less the same over the six-month period.

^eThis equally weighted combination of the CDX and iTraxx indices is frequently referred to as the *GLOBOXX index*.

^fIn other words, the *target value* is the present value of all liabilities discounted at the risk-free rate.

^gIn actual practice, the CPDO takes exposure to the index directly and not individual names, so the effect of the index rollover is a sudden drop in the index spread as the more risky names get replaced with the less risky ones.

Structured Finance

Rating Methodologies

Rating agencies are among the most important players in the securitization market and they have contributed significantly in the development of the market. Rating agencies have the expertise and access to necessary information to rate the multiple tranches of structured finance transactions. Their ratings are independent assessments of the credit and noncredit risks in a transaction. Investors who do not have the expertise and the required information to assess the credit quality of the issued structured finance products can use the ratings in their investment decision process. In addition, rating agencies provide transparency and increase the effectiveness in the securitization market. Finally, rating agencies have contributed significantly to the rapid development of the securitization market in the recent years.

Rating agencies have developed methodologies for structured finance ratings, which are significantly more complex than those they use to rate traditional instruments. Quantitative modeling is essential for rating structured finance securities. All three major agencies use a three-step rating process to model the assets and liabilities of a transaction. Although the rating methodologies across asset classes share the same basic principles, the modeling differs across asset classes and jurisdictions.

We examine the asset-backed securities (ABS) (see **Securitization**) and collateralized debt obligation (CDO) (see **Collateralized Debt Obligations (CDO)**) rating methodologies applied in the securitization market ([5, 6] for an introduction to securitization process). We focus on the quantitative aspects of the modeling that the major rating agencies apply in order to rate ABS and CDO tranches with a discussion on the importance and uses of the ratings in the securitization market.

Rating Methodologies

Rating agencies update their rating methodologies regularly to increase the accuracy and to incorporate new structures that appear in the market. For previous reviews on rating methodologies, see [1, 7].

Although the rating methodologies differ across rating agencies, all three major agencies, that is, Fitch, Moody's, and Standard & Poor's follow a three-step rating approach. The basic principles of this three-step approach are applied to structured finance transactions. In general, the three steps of a rating process are the following:

1. calculation of the default/loss distribution of the portfolio of assets;
2. generation of the asset cash flows using the portfolio loss characteristics; and
3. generation of the liability cash flows using the asset cash flows.

However, the modeling of each of the above steps can be very different depending on the type of structure (synthetic or cash) or the type of collateral (such as auto loans, mortgages, bonds, or others). The first two steps focus on the asset side and the third step on the liabilities side of the transaction. The next two sections discuss the basic principles of the assets and liabilities modeling that the agencies use to determine structured finance ratings.

Asset Side Modeling

In the first step of their respective methodologies, the agencies assess the credit risk in the underlying asset portfolio. They do so by modeling the default/loss distribution of the portfolio. The three main inputs driving these models are the following:

1. *Term structure of probabilities of default* (PDs) of each individual obligor in the portfolio across the life of the transaction.
2. *Recovery rates* (or losses-given-default (LGD), which is equal to one minus the recovery rate in the event of default).
3. *Asset correlations* within the portfolio, which determine default correlations and thus the likelihood of occurrence of joint defaults in a given period.

The main outputs of the credit risk assessment models are the loss characteristics of the portfolio, that is, the portfolio loss and default distributions.

Typical ABS portfolios usually contain large, granular, and homogeneous pools of assets. Hence, the systematic risk factors are typically the primary

drivers of the default distribution of the ABS portfolios. Moreover, model inputs, such as the default probabilities, the recovery rates, and the correlation assumptions, are usually estimated on a portfolio level. On the other hand, CDOs are typically nongranular portfolios of a small number of assets. Thus, the idiosyncratic risk is much more important in CDOs than the ABS portfolios. As a result of this, one has to carefully consider each obligor's individual probability of default and recovery rates.

As of February 2008, for rating CDO transactions, Standard and Poor's [10, 20] and Fitch [11, 14, 18] use very similar Monte Carlo simulation methodologies to calculate the loss/default distribution of CDO portfolios. Both the agencies use structural form models, where an obligor defaults if its assets value falls below its liabilities (also referred to as *default threshold*); see [16]. In these models, copulas are used to model the joint defaults of the obligors in the portfolio. In February 2007, Moody's introduced a Monte Carlo simulation approach [15] similar to the other agencies' methodologies to compute the expected loss for static synthetic CDOs and CDOs-squared. As of February 2008, Moody's continues to use the binomial expansion technique (BET) [3, 8, 21] for assessing the credit risk of other types of CDOs. For a comparison of the BET against the copula models, see [9]. In spite of the similarities in the agencies' methodologies, there are also some disparities in their approaches. Specifically, there are differences in the correlation structures and the recovery assumptions that the rating agencies employ.

The approaches that the rating agencies apply to all the other ABS transactions differ across asset classes and jurisdictions. These approaches are described next as of February 2008. Fitch uses a simulation-based methodology [2] appropriate for large, granular ABS portfolios composed of consumer and auto loans or leases for the European transactions, whereas it employs an actuarial approach to rate US ABS transactions; for example, it uses historical default rates to specify the credit risk of such portfolios. The key difference between the CDO and ABS simulation approaches is that the default probabilities inputs in the latter are specified at a pool level and not at an asset level. Fitch uses similar simulation-based methodology to the one that is used for CDOs in order to calculate the loss distributions of commercial mortgage-backed securities (CMBS) portfolios [4]. Fitch rates residential mortgage-backed securities

(RMBS) transactions by applying standard criteria at a country level. Historical information on a loan-by-loan level as well as on the level of the originator is used to arrive at probability defaults at a loan-by-loan level before aggregating to pool level. Moody's applies an actuarial approach to calculate the loss distribution in most ABS transactions. It analyzes historical data on pools of loans provided by the originators to calculate the expected loss and the volatility of the losses for the underlying asset portfolio. Once expected losses and volatility have been estimated, a lognormal distribution is used to approximate the loss distribution of the portfolio [13]. Standard and Poor's also estimates the default probability of ABS portfolio using historical default rates provided by the originator. Standard and Poor's estimates the probability of default of an RMBS portfolio at a country level [12]. More specifically, the agency estimates the defaults in a portfolio and the loss severity in a portfolio by calculating the weighted average foreclosure frequency and the weighed average loss severity. These estimates increase for the higher stressed ratings scenarios.

The loss characteristics of the asset portfolio along with the recovery rate and interest rate movement assumptions are the main inputs in the model, which generates the cash flows of the assets. In this second step, cash flows of the underlying assets are generated for different stress scenarios, which correspond to different ratings. Note that for many synthetic CDOs usually there is no need to measure any impact on the credit enhancement levels *via* the cash flow model. For these CDOs, the credit enhancement levels can be directly determined from the loss distribution of the underlying credit portfolio [14].

Liabilities Side Modeling

The asset cash flows and the default assumptions that have been determined in the first two steps of the rating process are the key inputs to the liabilities cash flow model. The purpose of the cash flow model is to determine whether the various tranches of the liabilities receive the principal and interest payments in accordance with the terms of the transaction. In order to achieve this aim, the cash flow modeling usually takes into account the following noncredit risk factors [1, 19], which are known to affect the performance of the transaction:

1. *Capital structure of the transaction, principal, and interest waterfall triggers*, for example, the mechanics through which the assets cash flows are allocated to pay the tranches and all the other transaction fees and expenses.
2. *Market risks* such as prepayment, interest rate, currency, and potential basis risks.
3. *Operational and administrative risks*, that is, the performance risks which are related to the participants in the transaction such as asset managers and servicers.
4. *Counterparty risk*, that is, the performance risks of credit enhancement providers and hedge counterparties.
5. *Legal and regulatory risks* that may rise from imperfect isolation of the securitized assets from the bankruptcy risk of the special purpose vehicle (SPV) under the applicable legal and regulatory framework.

The cash flow modeling procedures differ across the asset classes. Also, cash flow modeling is based heavily on the distinct characteristics of each specific transaction. Thus, in many instances, agencies apply deal-specific cash flow modeling. Usually, the ABS structures are more complicated than those of CDOs and thus cash flow modeling is, in general, the most important part of the ABS rating process. For more technical details on cash flow modeling, refer to [17].

Nested Simulation

Stochastic default-intensity (“reduced-form”) models are widely applied in the pricing of single-name credit instruments such as credit default swap (CDS) and corporate bonds (*see Duffie–Singleton Model; Intensity-based Credit Risk Models*). Duffie and Gârleanu [5] demonstrate how collateralized debt obligations (CDO) tranches may be priced using a multiname extension of the stochastic intensity framework (*see Multiname Reduced Form Models*). This article remains influential as a conceptual benchmark, but practitioners generally find the computational burden of this model prohibitive for real-time trading.^a

Risk-management applications introduce additional challenges. Time constraints are less pressing than in trading applications, but the computational task may appear more formidable. When loss is measured on a mark-to-market basis, estimation *via* simulation of VaR and other risk measures calls for a nested procedure: In the outer step, one draws realizations of all default intensities up to the horizon, and in the inner step one uses simulation to reprice each instrument in the portfolio at the horizon conditional on the realized intensities. At first glance, simulation-based pricing algorithms would seem to be impractical in the inner step, because the inner pricing simulation must be executed for each trial in the outer step. This intuition is misleading because a relatively small number of trials in the inner step can suffice, particularly when the portfolio contains a large number of positions.

Model Framework

For simplicity in exposition, we consider a portfolio of K unfunded, synthetic CDO tranches.^b The reference names in the CDO collateral pools are drawn from a universe consisting of m obligors. Each CDO tranche is defined by a set of variables $(A_t, L_t, \Gamma, \Delta, s, T)$ where

- A_t is a vector $A_t = (a_{1t}, \dots, a_{mt})$ of exposures in the CDO pool to each name in the underlying universe, expressed in currency units. Exposure is zero for names not included in a pool.

- L_t is the cumulative default loss since origination as of time t .
- Γ and Δ are the original attachment and detachment points, respectively, for a tranche. These too are expressed in currency units. The residual face value of the tranche at time t is $F_t \equiv \max\{\Delta - L_t, 0\} - \max\{\Gamma - L_t, 0\}$.
- s is the spread on the tranche. We assume that the CDO issuer pays the tranche holder a continuous stochastic premium of sF_t .
- T is the maturity of the CDO.

Let λ_{jt} denote the stochastic default intensity for obligor j . The vector of default intensities is denoted by Λ_t . In models of multiname derivatives, such as CDOs and basket-default swaps, cross-sectional dependence in Λ_t is a central concern. For now, we simply assume that the joint process for Λ_t is specified under risk-neutral and physical measures and defaults are independent conditional on Λ_t (i.e., we rule out contagion and “frailty” in the sense of what is discussed in [6]). Conditional independence implies that default event risk is diversifiable, and so it should attract no risk premium in a large and efficient market. In this case, the risk-neutral intensity $\tilde{\Lambda}_t$ equals the empirical intensity Λ_t at each moment t , even though the two processes evolve into the future under different laws [12].

To keep the focus on credit risk, we assume that risk-free interest rates are constant at r . In this case, the price of position k at time t is a memory-less function of $(\Lambda(t), A_k(t), L_k(t), \Gamma_k, \Delta_k, s_k, T_k - t)$.

Simulation of Value-at-Risk

We now develop notation related to the simulation process. The simulation is nested: There is an “outer step” in which we draw histories up to the horizon H . For each trial in the outer step, there is an “inner step” simulation needed for repricing at the horizon. Loss is measured on a mark-to-market basis, inclusive of interim cash flows. We normalize the present time to zero and the model horizon is H .

Let M be the number of trials in the outer step. In each of these trials, we perform the following:

1. Draw a path for $\Lambda(t)$ for $t = (0, H]$ under the physical measure.
2. Conditional on the $\{\lambda_j(t)\}$, draw default times τ_j up to H and sort them in increasing order. For

each default in $(0, H]$, the following steps are followed:

- (a) Draw a recovery rate R_j for defaulted obligor j .
- (b) For each CDO with exposure to j , increment cumulative loss $L_k(t)$ at $t = \tau_j$ by $(1 - R_j)a_{k,j}(\tau_j)$ and decrement residual face value $F_k(\tau_j)$ accordingly. Record the accrued value at H of the default-leg payment, that is, $e^{r(H-\tau_j)}dF_k(\tau_j)$.
- (c) Adjust exposure vector $A_k(t)$ for termination of exposure to the defaulted obligor.

The information set generated by the outer step trial, denoted by ξ , consists of $\{\tau_j, R_j\}$ for obligors defaulting before time H and $\{\lambda_j(H)\}$ for the survivors.

3. Evaluate the accrued value at H of the premium-leg cash flows.^c
4. Evaluate the price of each position at H with N “inner step” trials for each position. Paths for $\Lambda(t)$ for $t = (H, T_k]$ are simulated under the risk-neutral measure.
5. Discount prices and cash flows back to time zero and subtract from current prices to get portfolio loss $Y(\xi)$.

Observe that the full dependence structure across the portfolio is captured in the period up to the model horizon. Inner step simulations, in contrast, are run independently across positions. This is because the value of position k at time H is simply a conditional expectation (given ξ_H and under the risk-neutral measure) of its own subsequent cash flows, and does not depend on the future cash flows of other positions. Independent repricing implies that pricing errors are independent across the positions, and so they tend to diversify away at the portfolio level. Furthermore, when the positions are priced sequentially, to price tranche k we need to only draw joint paths for the obligors in the collateral pool for CDO k . This may greatly reduce the memory footprint of the simulation.

We now consider the problem of efficient estimation of VaR for Y . For a target insolvency probability α , VaR is the value y_α given by

$$y_\alpha = \text{VaR}_\alpha[Y] = \inf\{y : P(Y \leq y) \geq 1 - \alpha\} \quad (1)$$

Under mild regularity conditions, Y is a continuous random variable so that $P(Y \geq y_\alpha) = \alpha$.

If we had analytical pricing formulae, then $Y(\xi)$ would be a nonstochastic function of ξ , and simulation would involve generating i.i.d. samples $Y(\xi_1), Y(\xi_2), \dots, Y(\xi_M)$. We would sort these draws as $Y_{[1]} \geq \dots \geq Y_{[M]}$, so that $Y_{[\alpha M]}$ provides an estimate of $y_{[\alpha]}$, where $[\alpha]$ denotes the integer ceiling of the real number α .

In the absence of an analytical pricing formula, $Y(\xi)$ is replaced by a noisy estimate $\tilde{Y}(\xi)$, which is obtained *via* the inner step simulations. In place of $Y_{[\alpha M]}$, we have the empirical quantile $\tilde{Y}_{[\alpha M]}$ as our estimate of y_α . Our interest is in characterizing the mean square error (MSE) $E(\tilde{Y}_{[\alpha M]} - y_\alpha)^2$, and then minimizing it. We decompose MSE into variance and squared bias:

$$E[(\tilde{Y}_{[\alpha M]} - y_\alpha)^2] = V[\tilde{Y}_{[\alpha M]}] + E[\tilde{Y}_{[\alpha M]} - y_\alpha]^2 \quad (2)$$

The variance is proportional to $1/M$, whereas the bias vanishes with $1/N$. It can be shown [11, 16] that

$$E[\tilde{Y}_{[\alpha M]}] - y_\alpha \approx \frac{\theta_\alpha}{Nf(y_\alpha)} \quad (3)$$

where

$$\theta_\alpha = \frac{-1}{2} \frac{d}{du} f(u) E[\sigma_\xi^2 | Y = u] \Big|_{u=y_\alpha} \quad (4)$$

and where σ_ξ^2 denotes the conditional variance of the mean-zero pricing error $(\tilde{Y}(\xi) - Y(\xi))$ (conditioned on ξ) and f is the density of Y . A result parallel to equation (4) appears in the literature on “granularity adjustment” of credit VaR to adjust asymptotic approximations of VaR for undiversified idiosyncratic risk [10, 14]. Except in contrived pathological cases, we will generally find $\theta_\alpha > 0$, so that $\tilde{Y}_{[\alpha M]}$ is biased upward as an estimate of VaR.

We suppose that the overall computational budget is fixed at B , and choose (N, M) to minimize the MSE of the estimator $\tilde{Y}_{[\alpha M]}$ subject to the budget constraint. Letting $B \rightarrow \infty$, we find that N^* grows in proportion to $(\theta_\alpha^2 B)^{1/3}$ and M^* grows in proportion to $(B/\theta_\alpha)^{2/3}$. That is, for large computational budgets, M^* grows with the square of N^* . Thus, marginal increments to B are allocated mainly to the outer step. It is easy to intuitively see the imbalance between N^* and M^* . Note that when N and M are of the same order $\sqrt{B}$, the squared bias term contributes much less to the MSE compared to the variance term. By increasing M at the expense of N , we reduce the variance till it matches up in contribution to the squared bias term.

As we increase the number of positions K , the conditional variance σ_ξ^2 falls, and θ_α falls proportionately. If the computation budget grows in proportion to K , then the optimal N^* falls to one, for large-enough K [11]. The intuition is that idiosyncratic pricing error is diversified away at the portfolio level, so a single inner step trial suffices.

Importance Sampling

By recentring the outer step simulation on the region of the state space in which large losses are more common, importance sampling (see **Variance Reduction**) can lead to orders of magnitude improvement in performance. Importance sampling has been applied to structural models of portfolio credit risk [2, 9], but the existing literature does not yet offer a well-developed importance sampling theory for reduced-form models.^d Bassamboo and Jain [1] did some initial work in this direction. They consider the case where the intensity Λ_t is an affine process. Observing that the intensity remains affine under a constant exponential twist, they developed an asymptotically efficient importance sampling change-of-measure to estimate the probability of a large number of defaults in a portfolio.

We now discuss two specifications for correlated intensity processes. Duffie and Gârleanu [5] consider the case where each intensity is the sum of common and idiosyncratic affine processes, that is,

$$\lambda_{i,t} = \lambda_t^* + \zeta_{i,t} \quad (5)$$

Here λ_t^* and $\zeta_{i,t}$ for each i are mutually independent nonnegative affine processes. Under suitable parameter restrictions, the resultant process $\lambda_{i,t}$ is also a nonnegative affine process. For moderately large pools, one expects that large pool losses are most likely to occur when the compensator of the common intensity process, that is, $\int_0^H \lambda_t^* dt$, is unusually large. When an exponential twist of $\theta > 0$ is applied to this variable, the processes remain affine under the new measure and the likelihood ratio has a straightforward representation using results from [7]. If we wish to estimate the α quantile of the overall loss distribution, we choose θ so that the mean of $\int_0^H \lambda_t^* dt$ under the new measure equals its α quantile under the original measure. The latter is unknown at the beginning of the simulation, but may be adaptively learnt as the simulation proceeds.

The Black–Karasinski specification is increasingly popular for modeling single-name default intensities [15] and is readily extended to multiname models. Let

$$d \log \lambda_i(t) = \kappa_i(\mu_i - \log \lambda_i(t)) dt + \sigma_i dW_i(t) \quad (6)$$

where κ_i , μ_i , and σ_i are constants. The diffusion $W_i(t)$ is decomposed into common and idiosyncratic components

$$W_i(t) = \sqrt{\rho_i} W^*(t) + \sqrt{1 - \rho_i} V_i(t) \quad (7)$$

where $W^*(t)$ and $V_i(t)$ for each i are mutually independent standard Brownian motions and ρ_i is a constant. An importance sampling scheme that alters the drift of $W^*(t)$ is straightforward to implement.

Discussion

These methods for nested simulation apply in a much more general setting. We could have structural or ratings-based pricing models in place of the stochastic intensity models, which could introduce stochastic interest rates, and allow for long and short positions. Indeed, we can allow for general derivative portfolios (not just portfolios of CDOs), in which case the intensities $\Lambda(t)$ are replaced by a vector of state variables that could include interest rates, commodity prices, equity prices, and so on. The asymptotic allocation of workload between outer and inner steps remains unchanged. Furthermore, the same analysis applies to estimation of expected shortfall and large loss probabilities, to pricing of compound options, and to the credit rating of structured products under parameter uncertainty.

Optimal allocation schemes and important sampling can be combined and extended in a variety of ways. First, for senior tranches of CDOs in particular, importance sampling within the inner step pricing (as well as the outer step) may offer large efficiency gains. Second, a *jackknife* procedure in the inner step simulation can be used to eliminate the $1/N$ order term in the bias [11]. Third, a scheme for *dynamic allocation* [11] can easily be implemented. An initial estimate of loss $\tilde{Y}^n(\xi)$ is obtained for a given ξ from a small inner step sample of n trials. If $\tilde{Y}^n(\xi)$ is large (and therefore in the neighborhood of VaR), the estimate is refined through drawing additional samples of the inner step. Similar to this is a *screening and restarting* scheme [3, 13] developed for expected

shortfall and other coherent risk measures. In the first phase, an initial sample of M outer step trials is obtained using a small number of inner step samples. These samples are screened or filtered to pick out the large loss samples that are likely to contribute to the expected shortfall. In the second phase, for the short-listed samples, inner steps are resampled to improve the statistical properties of the resultant estimator.

These various refinements can alter the trade-off between bias and variance, so that optimal N^* may grow at a slower or faster rate with the budget. Nonetheless, the essential lesson of the analysis is robust: in a large portfolio VaR setting, inner step pricing simulations can be run with few trials. Despite the high likelihood of grotesque pricing errors at the instrument level, the impact on estimated VaR is small and can be controlled.

CDO Tranches: Impact on Economic Capital

With the recent rapid growth in the collateralization debt obligation (CDO) market since its inception in the mid-1990s, many financial institutions, in particular banks, are holding CDO tranches of many different transactions in their credit portfolios. Thus, evaluation of the impact of CDO tranches on the economic capital of a credit portfolio is becoming increasingly important. This article discusses how to measure the impact of CDO tranches on economic capital and capital allocation in credit portfolios. The economic capital of a credit portfolio is the amount of capital reserved to pay for any unexpected losses up to a confidence level as required by the financial institution. The purpose of economic capital is to buffer the effect of large losses in the portfolio. Capital allocation measures the incremental economic capital requirement of a portfolio as a result of adding an asset, such as a CDO tranche. Economic capital and capital allocation are calculated from the probability distribution of portfolio losses. Monte Carlo simulation has been widely applied to calculate the probability distribution of portfolio loss in credit portfolios comprised of bonds and loans. However, it is only recently that Monte Carlo simulations are being used in credit portfolios that comprise CDO tranches in addition to bonds and loans. The methodology presented here addresses this important application in a consistent framework.

The article is organized as follows. In the section Monte Carlo Simulation of Credit Portfolios Comprised of Bonds, Loans, and Collateralization Debt Obligation (CDO) Tranches, a brief introduction is given to the methodology for calculating portfolio loss distribution of credit portfolios comprised of bonds, loans, and CDO tranches. The section Economic Capital and Capital Allocation discusses the calculation of economic capital and capital allocation from the portfolio loss distribution. In the section An Example of Calculating Portfolio Loss Distribution, an example is presented for calculating the probability distribution of portfolio loss for a portfolio comprised of loans and one synthetic CDO tranche. From the loss distribution, economic allocation to the tranche is calculated and compared with the capital

allocation of a loan of the same maturity and similar credit quality.

Monte Carlo Simulation of Credit Portfolios Comprised of Bonds, Loans, and Collateralization Debt Obligation (CDO) Tranches

In credit portfolio management, Monte Carlo methods are the industry standard approach for calculating risk figures from a portfolio loss distribution. Even though the synthetic index-based market has seen considerable development of analytic and semianalytic approaches, these methods do not fully apply to credit portfolio management. This is mainly a consequence of the heterogeneity of underlying assets and the need for default indicators at individual asset levels.

Following standard industry convention, we use a bottom-up approach to model correlated defaults in a pool of names by applying an asset value factor model first introduced by Merton [1] and Vasicek [4]. The calculation of correlated defaults in a pool composed of loans and CDO tranches consists of two basic steps. The first step is to determine the default or credit migration of bonds and loans in the portfolio together with the underlying assets of CDO tranches over a horizon. The second step is valuing the CDO tranches at horizon. For a CDO tranche, its value would be the sum of the cash flows received over the horizon plus a forward value calculated on the basis of the future credit state of its underlying assets at horizon. Cash flows received by a synthetic tranche over the horizon would consist mainly of interest payments, while those received by a cash CDO tranche would consist of interest payments and principal repayments. The loss of a tranche over a horizon is then calculated as the difference between the tranche value at horizon and its current value. This yields a loss distribution at horizon for a credit portfolio comprised of bonds, loans, and CDO tranches, from which its economic capital and capital allocation are calculated.

Although the methodology discussed here for the calculation of economic capital in a credit portfolio is conceptually simple, it is highly complex in practice because it requires nested Monte Carlo simulations. A nested Monte Carlo simulation consists of an outer simulation and an inner simulation at every scenario

of the outer simulation. In the outer simulation, systematic and idiosyncratic risk factors are drawn

within the interval defined by its lower edge, $k_j^{r, \text{lower}}$, and upper edge, $k_j^{r, \text{upper}}$, as follows:

$$\left[k_j^{r, \text{lower}}, k_j^{r, \text{upper}} \right] = \left[\Phi^{-1} \left(PD_j + \sum_k^{r-1} T_{j,k} \right), \Phi^{-1} \left(PD_j + \sum_k^r T_{j,k} \right) \right] \quad (2)$$

at each scenario over a horizon to calculate the defaults and new credit states of nondefaulted assets. The purpose of the inner simulation is to value a CDO tranche conditional on the credit states of its underlying assets at horizon. Valuation of the bonds and loans based on the future credit states of their obligors is also required at a horizon, but their valuation generally does not require a simulation. Even though development of efficient techniques to perform nested Monte Carlo simulations is an interesting and important area of research, a more thorough discussion would be well beyond the scope of the present article.

For the purpose of illustrating the Monte Carlo simulation methodology, we discuss an example of calculating the probability distribution of portfolio loss for a credit portfolio comprised of N loans and one CDO tranche, T_r , over a horizon of 1 year. Furthermore, we assume that the CDO is backed by these loans of the portfolio.

To determine the defaults and credit migrations of the loans at horizon, we calculate their asset value correlation with a single-factor model. The asset value and credit state of a loan in this article refer to those of its obligor. In the single-factor model framework, the sensitivity of the asset value of a loan, X_i , to the systematic risk factor is given in terms of the correlation parameter ρ_i as follows:

$$X_i = \rho_i Y + \sqrt{1 - \rho_i^2} Z_i \quad (1)$$

where Y and Z_i are the systematic risk factor and the idiosyncratic risk factor of the loan, respectively. Both Y and Z_i are independent and have standard normal distribution.

Furthermore, we assume that the calculation of the default and credit migration of a loan at horizon is based on the change of its asset value as given by equation (1). Specifically, a loan is defaulted if its asset value falls below its default threshold, which is defined by its default probability to horizon. Analogously, a loan i initially in the state j is migrated to a state r if its asset value at horizon falls

where $\Phi^{-1}[\bullet]$ is the inverse of the standard normal distribution and $T_{j,k}$ is the probability for the transition from state j to state k . The calculation of the defaults and credit migrations of the portfolio's loans from this first step would be used to determine the loss of the portfolio over the horizon.

The contribution to the loss of portfolio value consists of the loss of the loans defaulted over the horizon and the loss in value of the loans which are not defaulted and the CDO tranche. The total loss of the portfolio at horizon is calculated as follows:

$$L_M = \sum_N \omega_i \times I_i^D \times LGD_i + \sum_{N, T_r} \omega_i \times (1 - I_i^D) \times (PV_{i, t_0} \times DF_{t_0 \rightarrow H} - PV_{i, H}) \quad (3)$$

where ω_i is the weight of the notional value of the loan relative to the total notional value of the portfolio. LGD_i is the fixed percentage loss of the notional value of the loan at default. I_i^D is the default indicator of the loan, which is defined as $I_i^D = 1$, if $X_i < k_i^D$ and $I_i^D = 0$, if $X_i \geq k_i^D$. $PV_{i, H}$ and PV_{i, t_0} are the values of asset i at H and t_0 , respectively, and $DF_{t_0 \rightarrow H}$ is the discount factor from t_0 to H . The first sum of equation (3) consists of the loss of the loans defaulted over the horizon and the second sum consists of the loss in value of the loans which are not defaulted and the CDO tranche.

Valuation of a loan at the horizon assumes that the future credit state of a loan sufficiently determine its value. Similarly, valuation of a CDO tranche at horizon assumes that the future credit states of its underlying assets at horizon sufficiently determine its value although the valuation could require another simulation.

Although the calculation of loss distribution discussed here is based on a single-factor asset value model, extension of the calculation to a multifactor asset model is fairly straightforward. Thus, employing a multifactor asset model in the calculation of loss distribution allows one to apply the methodology discussed in this article to portfolios with heterogeneous asset compositions.

Economic Capital and Capital Allocation

Economic capital of a credit portfolio is defined as the loss exceeding the portfolio expected loss (EL) for the quantiles of the loss distribution to a given confidence level α , that is, $EC_p(\alpha) = q(\alpha) - EL$ with $q(\alpha) = \min\{x : P(L < x) \geq \alpha\}$. This confidence level is interpreted as the probability that the credit portfolio of a financial institution would suffer a loss, which will use up the institution's capital. Since capital exhaustion implies institutional failure, the confidence level α is equivalent to the default risk of an institution.

In the calculation of capital allocation for the CDO tranche of the credit portfolio discussed in the previous section, we apply the methodology of expected shortfall. The expected shortfall^a of an asset, either of the loans or the CDO tranche, is defined in terms of the portfolio loss distribution as follows:

$$ES_i = E[L_{i,H} | L_{\text{portfolio},H} > q(\alpha)] - E[L_{i,H}] \quad (4)$$

where $L_{i,H}$ and $L_{\text{portfolio},H}$ are the losses of asset i and the portfolio at H . Then, the capital allocation of the CDO tranche in terms of its expected shortfall ES_{tranche} and the expected shortfalls of the loans in the portfolio is calculated as follows:

$$EC_{\text{tranche}}(\alpha) = EC_p(\alpha) \frac{ES_{\text{tranche}}}{\sum_{N,T_r} ES_i} \quad (5)$$

An Example of Calculating Portfolio Loss Distribution

We discuss an example of calculating the portfolio loss distribution over a horizon of 1 year for a credit portfolio of loans and a CDO tranche.

Data and Modeling Assumptions

A credit portfolio is assumed to be composed of 125 loans and one synthetic CDO tranche. Each loan is a unique entity, which is taken from the entities of the iTraxx Europe S8 index. The iTraxx Europe index is a credit default swap (CDS) index composed of the most liquid 125 CDSs referencing European investment grade credits. Each loan assumes a notional amount of €1 million, a maturity of 1 year, and a fixed recovery rate of 25%. The synthetic CDO is based on

a portfolio of 125 CDSs. Each CDS assumes a 5-year maturity, the same maturity as the CDO. Each CDS references the entity of one of the loans of the credit portfolio. Therefore, this example considers a case where there is a strong overlap between the credit portfolio's assets and the underlying assets of the CDO.

The nested Monte Carlo simulation as discussed in the section Monte Carlo Simulation of Credit Portfolios Comprised of Bonds, Loans, and Collateralization Debt Obligation (CDO) Tranches is applied to calculate the contribution of the synthetic CDO tranche to the portfolio loss distribution. At each scenario of the outer simulation, we determine which loan is defaulted and a future credit state for the one which is not defaulted. Then, since the loans mature at horizon, we calculate the loss in the notional value of the portfolio from the defaults of the loans over the horizon. To calculate the loss of the synthetic CDO tranche, we value the tranche at horizon based on the future credit states of its underlying assets and compare the value at horizon to its current value. In this example, the future credit states of the underlying assets are exactly those of the loans of the credit portfolio.

The standard industry practice is to use the risk-neutral default probabilities of the underlying assets based on their future credit states to value the synthetic CDO tranche at horizon. One would calculate a mark-to-market (MTM) value of the tranche by using the risk-neutral default probabilities of the underlying assets calibrated to their market spreads and the correlation parameter calibrated to the pricing of tranches of similar structures.^b The calculation is fairly straightforward once the parameters are determined. However, calculating an MTM value of the tranche at horizon is much more challenging because one must determine the future credit states of its underlying assets and apply them to derive their forward risk-neutral default probabilities.

Instead of calculating the loss of the CDO tranche at horizon from its MTM values, we approximate its loss at each scenario of the outer simulation by the conditional expected loss of the tranche. The conditional expected loss of the tranche at horizon in each scenario of the outer simulation is calculated as the average loss over the scenarios of the inner simulation. We employ the following assumptions in the calculation of conditional expected loss at horizon. First, the future credit state of a loan is

4 CDO Tranches: Impact on Economic Capital

represented by an S&P credit rating. The S&P credit rating of a loan at horizon is calculated from its current S&P credit rating with the empirical S&P transition matrix [2]. Second, the best estimation of the forward default probability of a loan at horizon is the forward default probability derived from the default term structure based on its S&P rating. We are assuming that default is a Markov process, but properly inhomogeneous in time. Lastly, we include only the loss of principal in the calculation of conditional expected loss, thereby neglecting any loss from interest payments to the tranche. In addition, we assume a zero interest rate. Under these assumptions, we use a semianalytical approach [3] to calculate the conditional expected loss of the CDO tranche at horizon instead of performing an inner simulation.

We calculate economic capital for the credit portfolio as the loss of its value exceeding the portfolio expected loss at the confidence level of 99% and calculate capital allocation based on expected shortfall methodology at the confidence level of 95%. We assume a correlation parameter of 31% for the underlying assets. We consider a synthetic CDO tranche with an attachment point of 0.0, 3, or 6% and a corresponding detachment point of 3, 6, or 9%. Table 1 shows the expected loss of a tranche as of today and at horizon and Table 2 shows the economic capital allocation of the tranche at different notional amounts. Expected loss of the tranche as of today is calculated with a 5-year cumulative default probability for the underlying assets based on their current S&P ratings. Expected loss of the tranche at horizon is calculated by averaging the conditional expected loss of the tranche at horizon over the scenarios of the outer simulation of the nested Monte Carlo simulation.

Analysis of Results

Now, we would like to discuss the results for the *EL* of the tranche and its capital allocation as shown in Tables 1 and 2. Table 1 clearly shows that

Table 1 Tranche statistics

	0–3%	3–6%	6–9%
EL today	34.71%	2.61%	0.23%
EL at horizon	38.81%	3.43%	0.33%

Table 2 Economic capital allocation to the CDO tranche

Notional (MM)	Exposure (MM)	0–3%	3–6%	6–9%
10	0.3	28.13%	10.46%	1.36%
20	0.6	32.04%	10.48%	1.37%
30	0.9	35.49%	11.12%	1.38%
40	1.2	38.44%	11.41%	1.39%
50	1.5	40.94%	11.69%	1.39%

the *EL* values of the tranche at horizon are larger than the values as of today. In particular, for the 6–9% tranche, the difference is as much as 50%. However, the difference decreases with decreasing tranche subordination and becomes much smaller for the 0–3% tranche. This should suggest that calculating the correlated defaults of the underlying assets plays an important role in determining these results. The *EL* of the 6–9% tranche is more sensitive to default clusters in the portfolio than the *EL* of the 0–3% tranche.

Calculating the *EL* of a tranche as of today and at horizon requires modeling the assets defaults in the pool over the life of a transaction. The calculation of the *EL* of a tranche as of today is based on the approach of Merton [1]. We calculate the defaults of the underlying assets over a horizon of 5 years. The timing of the defaults is not required because the calculation of the expected loss assumes a zero interest rate. It is a one-step calculation of default since both the systematic and idiosyncratic risk factors are drawn once at each scenario of the Monte Carlo simulation. However, the calculation of the *EL* of the tranche at horizon assumes two steps although the calculation of the defaults in each of these steps is also based on the approach of Merton. It is a two-step calculation of default because both the systematic and idiosyncratic risk factors are drawn independently twice in the outer and inner simulations of the nested Monte Carlo simulation. As a result of calculating the default in a single step in the calculation of *EL* as of today and in two steps in the calculation of *EL* at horizon, one should expect the results to be different because of the difference in capturing the correlated defaults in the portfolio.^c Since the calculation of portfolio loss distribution requires using this two-step approach in calculating defaults, we should adopt this approach in the calculation of *EL* of the tranche as of today and at

Table 3 Loan statistics

	AA–	BBB+	BBB–	BB
EL today	0.30%	1.45%	3.71%	7.49%
EL at horizon	0.33%	1.58%	3.69%	7.49%

horizon. Consequently, both *ELs* would be calculated to have the same value.

The results in Table 3 also show that the *EL* of a 5-year loan at horizon is larger than its *EL* as of today for different S&P ratings although the difference is less than 10%. This is simply the consequence of using empirically measured S&P transition matrix and default probability term structures. However, since in comparing a CDO tranche to a loan of similar credit risk we have opted to measure credit risk by an asset's *EL* at horizon, this kind of discrepancy from using empirically measured transition matrix and default probability term structures should not affect the comparison of the results of this article.

In Table 2, we present the tranche's capital allocations at different notional values. Capital allocation is reported as per unit exposure of the tranche. Since the maximum loss of a tranche depends on its thickness defined as the difference between its detachment point and attachment point, it is more meaningful to report capital per unit of exposure rather than per unit of notional amount. These results clearly show that capital allocation per unit of exposure increases with increasing exposure. However, the increase is much larger for the 0–3% tranche than for the 6–9% tranche. This is because the 6–9% tranche is mostly sensitive to systematic risk, while the 0–3% tranche is sensitive to both systematic and idiosyncratic risks. An asset that is mostly sensitive to systematic risk and an asset in a very granular portfolio should have capital requirements that scale approximately the same extent with the size of exposures. Capital allocation per unit of exposure of an asset in a very granular portfolio is approximately constant independent of the asset's exposure size. Thus, as shown in Table 2, the capital allocation of a senior tranche increases slowly with exposure size as compared to a junior tranche.

Now, we would like to compare the capital allocation of a tranche with that of a loan of similar credit quality and the same maturity. In a separate calculation, we substitute the CDO tranche in the credit

Table 4 Economic capital allocation to a loan substituting the CDO tranche

Exposure (MM)	AA–	BBB+	BBB–	BB
0.3	0.87%	3.88%	5.94%	11.03%
0.6	1.11%	4.49%	6.95%	12.55%
0.9	1.18%	4.85%	7.53%	13.35%
1.2	1.24%	5.03%	7.95%	13.66%
1.5	1.24%	5.10%	8.24%	14.49%

portfolio with a loan of 5 years' maturity and re-run the Monte Carlo simulation to calculate the capital allocation of the substituted loan. Table 4 presents the capital allocations for the substituted loans with different S&P ratings.

To compare the capital allocation of a CDO tranche with that of its loan equivalent, we define a loan equivalent of a CDO tranche as a loan that has the same value of *EL* at horizon as the CDO tranche. We assume that a CDO tranche and its loan equivalent have similar credit risks as of today. For example, the loan with AA–rating of Table 4 is a loan equivalent of the 6–9% tranche. However, for the 3–6% tranche, we cannot find a loan from Table 4 with its *EL* at horizon matching that of the CDO tranche. For the purpose of comparing the capital allocation of the 3–6% tranche to its loan equivalent, we scale the capital allocations of the loan with BBB–rating by a ratio of the tranche's *EL* at horizon over the loan's *EL* at horizon. We assume that the scaled capital allocations are for the loan equivalent of the 3–6% tranche.

In Table 5, we compare the capital allocations of the 3–6% and 6–9% tranches with those of their loan equivalents. The results clearly show that the capital

Table 5 Capital allocations: CDO tranche *versus* loan equivalent

Exposure (MM)	AA–	6–9%	Scaled of BBB–*	3–6%
0.3	0.87%	1.36%	5.52%	10.46%
0.6	1.11%	1.37%	6.46%	10.48%
0.9	1.18%	1.38%	7.00%	11.12%
1.2	1.24%	1.39%	7.39%	11.41%
1.5	1.24%	1.39%	7.66%	11.69%

* Capital allocations calculated by multiplying a constant factor of 0.93 with the capital allocations of the loan with a BBB–rating

allocation of a CDO tranche can be larger than that of its loan equivalent by as much as 80%.

We can understand these results in terms of the increase in the systematic risk of the credit portfolio as a result of adding a CDO tranche or a loan. In general, a credit portfolio with larger systematic risk would require higher economic capital. A CDO transaction backed by a pool of assets is mostly sensitive to systematic risks since its exposures to idiosyncratic risk factors are already significantly reduced through the diversification of the assets in the pool. Therefore, adding CDO tranches to a credit portfolio could significantly increase the portfolio's systematic risk compared to adding a loan equivalent. As a result, one should expect that holding a CDO tranche in a credit portfolio would require extra economic capital compared to holding a loan of similar credit rating and the same maturity.

Conclusion

In this article, we presented the methodology based on nested Monte Carlo simulation to measure the impact of CDO tranches on economic capital and capital allocation of credit portfolios. One of the advantages of using the methodology presented here is in the calculation of the correlated defaults of the assets in a portfolio. Calculation of correlated defaults is important in calculating economic capital for a portfolio especially for those holding CDO tranches because CDO tranches are mostly sensitive to systematic risk. As an example, we applied the methodology of calculating capital allocation to a synthetic CDO tranche in a credit portfolio. This portfolio also comprises of the loans to which the underlying assets of the CDO are referencing. The results of our calculation show that the capital allocation of adding a CDO tranche to a credit portfolio can be much larger than that of adding a loan of similar credit quality and the same maturity. In some cases, the increase in capital allocation is as much as 80%. Our finding clearly suggests that by treating a CDO tranche as a loan equivalent, only a poor approximation of economic capital is obtained. This explains why the methodology presented in this article is necessary to measure the impact of CDO tranches in credit portfolios.

Acknowledgments

I would like to thank David Cao, Michele Freed, Saiyid Islam, and Liming Yang for many useful discussions. I especially want to thank Bill Morokoff and Christoff Goessl for careful reading of the manuscript and providing me with many useful comments. Equity–Credit Problem

The equity–credit problem, perhaps the most significant problem of corporate finance, is the problem of linking the value of a firm’s equity with that of its debt. Etymologically, the word “credit” is linked to credence, belief, faith, and confidence. As such it is passive and absolute; the only contingency that may affect it is default. One lends money to another on the faith that he/she will pay back the same. This introduces an asymmetry. The debtor may renege and the creditor will try to put his/her assets or company in bankruptcy. Equity, by contrast, is symmetric. Participating in somebody’s equity is agreeing to share the profits, the losses, and the risks of the enterprise. Its only contingency is what action (not passion) the future has in stock for the shareholders. The word *equity* means “fairness” and the word for *share*, in French, is *action*.

The pricing and hedging of convertible bonds (*see* **Convertible Bonds**) is an example of equity-to-credit problem: the optimal conversion policy intimately fuses the two. Once the hazard rate (*see* **Hazard Rate**) is made explicit alongside the price process of the underlying stock, it is followed by the question what kind of correlation can prevail between the two. Trying to model this correlation is the quantitative side of the equity-to-credit problem.

Derivative pricing models are almost never used normatively, going from theoretical parameter to derivative theoretical value. They are used in reverse, going from derivative *market* price to implied parameters (*see* **Implied Volatility Surface**). From this, it becomes apparent that a single volatility parameter cannot explain the variety of prices of options of different strikes and different maturities (the volatility smile), not mentioning that credit default swaps (CDSs, *see* **Credit Default Swaps**) are also written on the company and traded. The equity-to-credit problem, as it is understood today, is to find a unifying derivative pricing framework where the full volatility surface of equity options and the full term-structure of CDS spreads can be explained.

Corporate events, which may have been lost under the impassive writing of derivative payoffs, thus reemerge as the script, waiting for our examination, that the prices of equity derivatives and the prices of credit derivatives now *jointly* compose. The

volatility skew of out-of-the-money puts, the term structures of volatility and credit spread, all of which are commonly observed on single names, cannot be handled by Black–Scholes–Merton (BSM) or by any of the models that tried to improve on it simply by tweaking its assumptions (local volatility (*see* **Local Volatility Model**), Heston stochastic volatility model (*see* **Heston Model**), etc.). These price structures are best (and most robustly) explained by a *regime-switching model* (*see* **Regime-switching Models**). In this model, the volatility of the underlying share and the hazard rate can suddenly switch between different and very dissimilar regimes, accompanied by substantial jumps of the underlying equity price. Default itself is one such regime, except that it is a regime of a very extreme sort. Takeover and restructuring are other regimes. Poisson processes trigger the various switches, and the regime changes then lend themselves naturally to a reinterpretation in terms of *corporate events* [1]. The equity-to-credit problem, when it is reinterpreted in terms of derivative pricing, imprints back corporate events on market prices.

A Regime-switching Model

There exist K volatility regimes, indexed from 1 to K , and one default regime, indexed by d . We assume that the regimes are observable and known at any time. By convention, regime 1 can be set as the present regime when we use the model, either to value contingent claims or to calibrate the model against their market prices. We let the discrete variable u_t describe the current regime at time t . The dynamics of the regime is driven by a continuous time Markov process with a finite number of states or regimes. The important correlation between the stock price and its volatility, as well as between the stock price and the hazard rate, is captured by a possible jump on the stock price as a regime switch occurs. Here, we chose to model jumps by a very simple fixed percentage size jump; it would be possible to generalize to a density of jumps.

- $\hat{\lambda}_{k \rightarrow l}$ is the (risk neutral) intensity of going from regime k to regime l . This occurs with a percentage jump $y_{k \rightarrow l}$ on the stock price.
- $\hat{\lambda}_{k \rightarrow d}$ is the (risk neutral) intensity of going from regime k to default. The corresponding jump on

the stock price is $y_{k \rightarrow d}$. When $y_{k \rightarrow d} = -1$, the stock goes to zero upon default.

- We let v_k and v_d be the volatility in regime k and in default, respectively. The jumps indexed from $i = K$ to J correspond to stock price jumps inside a regime, which may be the default regime. Both the size and the intensity of the jumps depend on the regime.
- In every regime, we index the jumps in the following way. For i between 1 and $(K - 1)$, the jump corresponds to a regime switch, which is also denoted as $y_{k \rightarrow l}$ if the current regime is k and if the jump goes into regime l . For i between K and J , the jump is a pure stock price jump within a regime. For $i = (J + 1)$, the jump corresponds to default, also denoted as $y_{k \rightarrow d}$ if the current regime is k .
- There is no recovery from the default regime so that $\hat{\lambda}_{d \rightarrow k} = 0$. However, there may be jumps in the stock price within the default regime.

For simplicity, we consider a nonstochastic risk-free term structure, and we denote the deterministic instantaneous forward rate at time t as r_t . We consider the most general setting with both continuous and discrete time dividends, although both are usually not present at the same time. r_t^f is the nonstochastic continuous dividend rate at time t (this notation stems from the foreign exchange market).

Pricing Equations

We consider a general derivative instrument with value $F(t, S_t, u_t)$ at time t when the stock price is S_t and the current regime is u_t . We have the following partial decoupling between the nondefault regimes and the default one.

- The value $F(t, S_t, d)$ in the default regime can be computed on a stand-alone basis, without knowledge of F in the nondefault regimes.
- The value of F in the nondefault regimes gives rise to K -coupled equations, which, in general, involve the value of F in the default regime, unless the derivative is a call and the stock goes to zero upon default.

Stand-alone Default Regime

We start by evaluating the value of the general derivative F in the default regime. It is given by

the following stand-alone equation, which does not depend on the value of F in the nondefault regimes:

$$\begin{aligned} \frac{\partial F}{\partial t} + \frac{1}{2} v_d^2 S_t^2 \frac{\partial^2 F}{\partial S_t^2} + \left(r - r^f - \sum_{j=K}^J \hat{\lambda}_j y_j \right) S_t \frac{\partial F}{\partial S_t} \\ + \sum_{j=K}^J \hat{\lambda}_j (F(t, S_t(1 + y_j), d) - F(t, S_t, d)) = rF \end{aligned} \quad (1)$$

with appropriate boundary conditions. The sums $\sum_{j=K}^J \hat{\lambda}_j y_j$ and $\sum_{j=K}^J \hat{\lambda}_j \Delta F$ correspond to stock price jumps inside the default regime.

Coupled Nondefault Regimes

For every nondefault regime u_t ,

$$\begin{aligned} \frac{\partial F}{\partial t} + \frac{1}{2} v_{u_t}^2 S_t^2 \frac{\partial^2 F}{\partial S_t^2} + \left(r - r^f - \sum_{j=1}^{J+1} \hat{\lambda}_j y_j \right) S_t \frac{\partial F}{\partial S_t} \\ + \sum_{j=K}^J \hat{\lambda}_j (F(t, S_t(1 + y_j), u_t) - F(t, S_t, u_t)) \\ + \sum_{l \neq u_t} \hat{\lambda}_{u_t \rightarrow l} (F(t, S_t(1 + y_{u_t \rightarrow l}), l) \\ - F(t, S_t, u_t)) \\ + \hat{\lambda}_{u_t \rightarrow d} (F(t, S_t(1 + y_{u_t \rightarrow d}), d) \\ - F(t, S_t, u_t)) = rF \end{aligned} \quad (2)$$

again with appropriate boundary conditions. A few remarks concerning this equation are given below:

- We note that in the general case the value of F in the default regime is needed here.
- The sum $\sum_{j=1}^{J+1} \hat{\lambda}_j y_j$ corresponds to a sum on all stock price jumps that may occur from the current regime u_t , both inside the regime and from the regime u_t to another one, including default. Although the notation is not explicit, the terms of this sum depend on the current regime u_t .
- The sum $\sum_{j=K}^J \hat{\lambda}_j \Delta F$ corresponds to the stock price jumps inside the current regime u_t .
- The sum $\sum_{l \neq u_t} \hat{\lambda}_{u_t \rightarrow l} \Delta F$ corresponds to the changes in regime, from the current regime u_t to the other nondefault regimes indexed by l .

- The last term $\hat{\lambda}_{u_t \rightarrow d} \Delta F$ corresponds to a jump from the current regime u_t to the default.

Dividends

In the absence of arbitrage, the derivative must be continuous across the payment of dividends. At a time t_i when a fixed dividend $d_i(S_{t_i-})$ is paid by the company, we have

$$\begin{aligned} F(t_i-, S_{t_i-}, u_{t_i}) &= F(t_i, S_{t_i}, u_{t_i}) \\ &= F(t_i, S_{t_i-} - d_i(S_{t_i-}), u_{t_i}) \end{aligned} \quad (3)$$

where u_{t_i} can be any regime, including default.

The same reasoning applies for proportional dividends. At a time t_j when a proportional dividend $\delta_j S_{t_j-}$ is paid by the company, we have

$$\begin{aligned} F(t_j-, S_{t_j-}, u_{t_j}) &= F(t_j, S_{t_j}, u_{t_j}) \\ &= F(t_j, (1 - \delta_j)S_{t_j-}, u_{t_j}) \end{aligned} \quad (4)$$

where again u_{t_j} can be any regime, including default.

Credit Default Swaps

Definitions

We describe the contingent cash flows of the CDS, when the current time is t and the current nondefault regime is u_t .

- The nominal of the CDS is 1.
- The payment frequency of the premium is Δt , a fraction of a year, which can be 1 for one year, 1/2 for a semester, 1/4 for a quarter, or 1/12 for one month.
- We let $N \geq 1$ be the number of remaining premium payments, assuming no default up to maturity of the CDS.
- The first premium payment occurs at time t_1 , with the constraint that $0 < (t_1 - t) \leq \Delta t$.
- The remaining premium payments occur after t_1 with a constant interval Δt , which means that the dates of premium payments are denoted as $t_i = t_1 + (i - 1)\Delta t$ for i between 1 and N .
- The maturity T of the CDS is the last premium payment, that is, $T = t_N = t_1 + (N - 1)\Delta t$.

- We define $t_0 = t_1 - \Delta t$, which is either the date of the last premium payment before t or the issue date of the CDS.
- S is the premium of the CDS paid until default with the payment frequency Δt after the first payment date t_1 . If default occurs at time τ and the last premium payment was at time t_i , then the buyer of insurance still owes the accrued premium, defined as the linear fraction of the next premium payment, that is, $S(\tau - t_i)/\Delta t$.
- Let R be the recovery, between 0 and 1. Upon default, the party insured receives $(1 - R)$ at the time τ of default, if default occurs before maturity T , and nothing otherwise.
- For a time t and a regime u_t , we let $F^{\text{CDS}}(t, u_t; t_1, \Delta t, N, S, R)$ be the value at time t when the regime is u_t of the CDS with premium S and recovery R , whose sequence of premium payment dates is described by t_1 , the date of the first one, Δt the constant time between two premium payments after the first one, and N the total number of premium payments. Its maturity is $T = t_1 + (N - 1)\Delta t$. This value assumes the point of view of the holder of the CDS. He/she is the party who seeks insurance against default risk and who pays the streams of premia in exchange for a compensation in the case of default. When $u_t = d$, we assume that default occurred at time t exactly, and $F^{\text{CDS}}(t, d; t_1, \Delta t, N, S, R)$ values the benefit of the insurance upon default. At a time t_i of premium payment, we assume that $F^{\text{CDS}}(t_i, u_t; t_1, \Delta t, N, S, R)$ corresponds to the value ex premium payment, that is, just after the payment of the premium S . When $(t_1, \Delta t, N)$, the maturity T , the premium S , and the recovery R are understood, we simply write $F^{\text{CDS}}(t, u_t)$.

Value in Default

Let $F^{\text{CDS}}(t, d)$ be the value of the CDS at time t assuming that default has occurred at time t . It is the difference between the compensation immediately received and the accrued premium still owed:

$$F^{\text{CDS}}(t, d) = 1 - R - S \frac{(t - [t])}{\Delta t} \quad (5)$$

Backward Equation

We derive a backward equation for the value $F^{\text{CDS}}(t, u_t)$ of the CDS. At maturity T and for every nondefault regime k , we have

$$F^{\text{CDS}}(T, k) = 0 \quad (6)$$

$$F^{\text{CDS}}(T-, k) = -S \quad (7)$$

since maturity T corresponds to the last premium payment. At a time t different from any premium payment date and for every nondefault regime k , we have

$$\begin{aligned} \frac{\partial F^{\text{CDS}}}{\partial t}(t, k) + \sum_{l \neq k} \hat{\lambda}_{k \rightarrow l} \\ \times \left(F^{\text{CDS}}(t, l) - F^{\text{CDS}}(t, k) \right) \\ + \hat{\lambda}_{k \rightarrow d} \left(F^{\text{CDS}}(t, d) - F^{\text{CDS}}(t, k) \right) \\ = r F^{\text{CDS}}(t, k) \end{aligned} \quad (8)$$

where the value in default $F^{\text{CDS}}(t, d)$ has been derived in equation (5). At a time $t_i = t_1 + (i - 1)\Delta t$ where the premium S is paid, we have

$$F^{\text{CDS}}(t_i-, k) = F^{\text{CDS}}(t_i, k) - S \quad (9)$$

which means that the value of the CDS increases by S after each premium payment. This yields a system of K -coupled backward equations.

The regime-switching model represents *corporate events* in terms of jumps. The volatility parameters v_k and v_d , the regime-switching intensities $\hat{\lambda}_{k \rightarrow l}$ and $\hat{\lambda}_{k \rightarrow d}$, and the corresponding jump sizes $y_{k \rightarrow l}$ and $y_{k \rightarrow d}$ are all inferred by calibration of the model to the market prices of equity options and CDS spreads. This is achieved by solving an inverse problem characterized by the pricing equations above. For this reason, the regime-switching model is perfectly suited

for pricing the convertible bond (see **Convertible Bonds**).

Convertible Bonds

A convertible bond (CB) is a *corporate bond* that may be converted into a certain number of shares of the issuing company, also known as the *underlying equity*. By offering the investor an option to participate in its future growth, the company is able to finance itself at a lower cost. Alternatively, the CB provides a means to issue equity in a deferred fashion when the market context or timing may not be right for the company.

Like any corporate bond, the CB is issued with a nominal, *principal*, or face value, to be redeemed at maturity, sometimes at a premium, and pays interest, typically periodic coupons, fixed or floating. In some cases (in particular, when no coupons are paid), the principal accretes continuously at a rate guaranteeing a given *yield to maturity* (YTM), and the final redemption value is the result of the accretion. The CB can be redeemed earlier than maturity at the option of the issuer (issuer's call), often with penalties in *call protection* periods (make-whole premium, guaranteed yield). Alternatively, the holder can opt out of the convertible and get his/her money back at certain prespecified discrete dates, or *put* dates. Coupons can be fixed or floating. The number of shares against which the CB can be converted is the *conversion ratio*. The value the holder obtains following conversion is the *conversion value*: ratio $\times$ share value. The *conversion price* is the ratio of nominal over conversion ratio. It is the value of the underlying above which conversion value becomes greater than the nominal, thus making the conversion potentially attractive.

The interplay of options that are embedded in the CB (part held by the investor, part by the issuer) translates into a hierarchy of conditions bounding and constraining its value. Given the many ways in which the principal may be redeemed (coupons, redemption at a premium, accretion, mixture of the two) and the fact that the process of redemption may be interrupted prematurely, either by the holder's option to convert (or to put) or by the issuer's call, we first need to define the intermediate notion of the holder's *claim*. This is the amount the investor is entitled to claim at any intervening time between issue date and maturity, should the bond terminate at that time, in order to

secure the same yield on investment as the YTM.

$$\text{claim}(t) = \sum_{T \geq t_i \geq t} \frac{C_i}{(1 + \text{YTM})^{(t_i - t)}} + \frac{\text{redemption}}{(1 + \text{YTM})^{(T - t)}} \quad (1)$$

where C_i is the coupon payment at time t_i ; t_i is a coupon date (in number of years since a reference date); YTM is the annualized yield to maturity guaranteed by the claim; and redemption is the amount redeemed at the maturity date.

$$\text{redemption} = \text{principal (possibly accreted)} + \text{redemption premium} \quad (2)$$

At time $t = 0$, the claim is, by definition, the issue price, which is also the initial amount of money that gets invested, and this defines the annualized yield to maturity, YTM. At maturity, the claim is the redemption amount.

The claim serves as the basis of all three options characterizing the CB. Conditions on the CB value are enforced in the following sequence order.

Whenever the issuer has the right to exercise his/her early call option, he/she will do so optimally as soon as the CB value exceeds the amount he/she would otherwise be contractually bound to redeem, should he/she opt for early redemption (early redemption price). This entails the following constraint:

$$V(S, t) \leq \text{early redemption price} \quad (3)$$

The early redemption price is usually defined as a percentage of the claim at the time or early call. Alternatively, it can be set in such a way as to guarantee a certain yield up to the date of call, which may be different from the yield to maturity.

The holder's conversion option overrides the issuer's call. It is expressed by the following condition:

$$V(S, t) \geq \text{conversion ratio} \times S \quad (4)$$

and applied hierarchically after the issuer's call.

At maturity T , note that the combination of the early redemption option (which is no longer "early" and no longer an option) and the conversion option yields the following final payoff condition:

$$V(S, T) = \max(\text{conversion ratio} \times S, \text{redemption}) \quad (5)$$

Finally, the put condition is the last one to be applied. If the investor finds, at put dates, that the CB value is still lower than the put strike (even after allowing for the option to convert), he/she will exercise his/her put. Thus

$$V(S, t_p) \geq \text{put price} \quad (6)$$

where t_p is a put date.

Similar to the early redemption price, put price is defined as a percentage of the claim or through a guaranteed yield to put.

Options versus Convertible Securities

The convertible bond is a hybrid security belonging to the category of *corporate debt* (as such, subject to credit risk) and to the category of *convertible security*. Convertible securities are claims, issued by a company that can be *converted* into the underlying equity of the company during their lifetime. Warrants belong to this general category. They feature a strike price and are very similar to American call options.

The terminology of warrants differs from that of options for reasons that run deeper than casual jargon. We do not *exercise* a warrant; we *convert* it. The warrant is not the right to *buy* the underlying share; we say it is *convertible* into that share. Indeed, the warrant is issued by the company, whereas the call option is written by an independent counterparty; *option buyers* and *option sellers* exchange their contracts independently, in the over-the-counter (OTC) market or on a listed exchange. To put it bluntly, the difference between convertible securities and options is the whole difference between being an investor in the company and taking an external view (bet) on the evolution of the price of its underlying equity. It is the difference between *corporate events* and *incorporeal events* (which is discussed later).

The number of convertible bonds that a corporation can issue cannot exceed the total number of shares that it would eventually have to issue upon conversion. Issuing convertibles alters its capital structure and dilutes the earnings of the existing shareholders. Options, by contrast, can be written in unlimited amounts, all the more so because the procedure of cash settlement no longer compels the option seller to actually deliver the underlying share.

Dynamics of Abstraction

It is important to emphasize the difference between convertible securities and options, if only for the reason that the first are of earthly nature (they tend to remain and “deposit”), whereas the latter are volatile (they tend to “evaporate”). This material difference has ramifications bordering on ethics. Indeed, options lend themselves easily to the logic, therefore to the charge, of betting and gambling. Not everybody is aware that the fathers of volatility arbitrage, Sheen Kassouf and Ed Thorp, first exercised their skills and “system” in the convertibles area, and not in options [7]. Options had been banned in the aftermath of the 1929 market crash, and it was not until the early 1970s that they regained some liquidity and Black and Scholes were able to study them in order to derive their formula. The Chicago Board Options Exchange played no little role, subsequently, in bringing options back in favor, truly resurrecting their markets. (The belief had caught on that the Black–Scholes–Merton (BSM) formula, and the option trading it involved, were not about speculation and gambling after all, but about *efficient pricing* [6].)

As a matter of fact, the BSM paradigm put all derivatives on an equal footing. It led to the mathematization of their valuation, thus leveling out all their genealogical or ethical differences. From the valuation perspective, everybody now viewed derivatives as *pure payoff structures*, that is to say, as cash flow events that were simply triggered by the price trajectory of the underlying. From then on, the only dynamics that mattered was the price dynamics of the underlying. Find the right stochastic process to model the underlying behavior, and all the derivative pricing problems will be solved. This was the beginning of the *quant* era: the heedless, unstoppable sophistication of valuation models and payoff structures.

This pricing paradigm treated convertible securities, and more specifically convertible bonds, no differently than equity options. The convertible bond was identified with a corporate bond, whose valuation posed no greater difficulty than the rest of fixed income, bundled with an equity option, whose valuation posed no greater difficulty than BSM, or so everybody thought. Owing to the American-styled conversion feature, the suggestion was to price the

CB by dynamic programming techniques, for example, Cox's binomial tree (see **Binomial Tree; American Options**). The procedure is initialized with the terminal payoff condition: either convert into equity or have the principal redeemed. Rolling backward, the cash payments accruing from the fixed-income part are simply added in the nodes at coupon dates and they become an integral part of the value of the CB. The procedure keeps comparing this value to conversion value, as it progresses to the present date, in order to check for early conversion [5, 9].

Credit risk started posing a problem though, when it was observed that the convertible bond had effectively a shorter maturity than the advertised one due to the probability of early conversion. How could the fixed-income component of the CB be valued using the same credit spread as the corporate bond of same official maturity? Is not the CB in effect less subject to credit risk than the pure bond because it is likely to wind up as equity, and this, "of course," bears no credit risk?

In terms of the pricing procedure, this is the question of the rate with which to discount the value of the CB in the tree. Should it be the risk-free rate (as in BSM), the risky rate (risk-free + credit spread), or a mixture of the two? Some have suggested using a weighted average of the two rates, depending on the probability of early conversion [4]. The delta of the CB would be the estimate of this probability. Others have proposed to split the CB into a credit-risky component and a riskless component (as the hybrid nature of the instrument naturally suggests) and the dynamic programming technique would now determine the splitting, because this obviously depends on the optimal conversion policy [8].

Ultimately, the right approach was to abandon the whole idea of patching together two pricing paradigms that had nothing in common: BSM (with dynamic hedging and dynamic programming) and fixed income (with static discounting using credit spreads). Rather, credit risk should be brought to bear right at the heart of the dynamics, and the process of the underlying equity itself revised. The vague notion of credit risk was thus reduced to the definite, probabilistic occurrence of a *default event*.

Default risk was modeled through a Poisson process superimposed on the traditional BSM diffusion. Its intensity, or hazard rate, measured the instantaneous probability of default, conditionally on default

not having occurred earlier. The Poisson process triggers a massive jump both in the underlying equity price and in the derivative price. Typically, the convertible bond would jump to its recovery value, modeled as a fraction of the claim at the time of default. All equity and credit derivatives could now be valued in this reduced-form, unified framework. To that end, the dynamic hedging argument of BSM had to be generalized to cover the jump to default. A second, credit-sensitive, hedging instrument would thus be needed on top of the underlying. There was no need to split the CB any longer, as the insertion of the hazard rate in the pricing equation, combined with the explicit expression of the fate of the CB after default (recovery), mechanically determined the "rate" with which to discount values in the tree or in the PDE (see **Partial Differential Equations**) [2, 3].

$$\frac{\partial V}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + (r + \lambda) S \frac{\partial V}{\partial S} = rV + \lambda(V - R \text{ claim}(t)) \quad (7)$$

where σ is the diffusion coefficient, λ is the hazard rate, r is the risk-free interest rate, and R is the recovery ratio.

The Equity-Credit Problem

This revision of the underlying dynamics set up the stage for the *equity-to-credit problem*. As the hazard rate was now recognized as the second factor alongside the diffusion coefficient, it could potentially be made stochastic and correlated with the process of the underlying [1].

Equity-to-credit, or rather, credit-to-equity dynamics is the real dynamics ruling the CB. *Conversion is but a movement from credit to equity*. Debt, passively binding creditor and debtor, is converted into activity, project, enterprise, participation in the upside (see **Equity-Credit Problem**). Recall that conversion is an altogether more consequential transmutation than just exercising a right. The entire convertible can be reread in the light of this difference. The owner of a convertible security is more involved in the company than the buyer of an option. As such, he/she has to be *protected*. *Dividend protection, takeover protection, call protection*, and so on, are among the many clauses that make for the increasingly thicker CB prospectuses nowadays. Dividend protection dates

back to the warrants that Thorp and Kassouf used to trade. It protects the holder of the convertible security against the fall of the underlying share following dividend announcements, by readjustment of the conversion ratio or by a “pass-through” procedure. Takeover protection entitles the holder to sell back the convertible (takeover put) or to convert it against a greater number of shares than initially promised (ratchet clause), when a change of control or takeover is announced. Alternatively, the conversion ratio can be adjusted in proportion with the ratio of the price of the share of the company taking over and of the company being taken over.

As for the events that may trigger a change in the CB structure (early conversion by the holder, early redemption by the issuer, reset of the conversion price in case of resettable CBs, etc.), there is not one of them that is not “slowed down” and “mashed down” by a host of averaging clauses (as if the convertible had truly to *digest* the event). Only if the underlying trades 20 days out of 30 above a certain trigger level is the issuer entitled to call back the bond (soft call), or is the holder entitled to convert it (contingent conversion); the conversion price is reset at the average of closing prices of the underlying over a certain number of days before the reset date, etc.

From the point of view of holders of options (as opposed to convertible securities), all that matters is the price process of the underlying equity, which screens off all the deeper corporate changes. Dividend announcements, takeover announcements, and so on, are among many factors that may otherwise affect the price of the underlying, so why would option holders regard them any differently than the rest of price shocks and jumps that they prepare to face anyway? In their view, events are incorporeal and are

only expressed in terms of underlying price changes: barriers and triggers may very well be breached punctually and without averaging clauses, so long as everybody agrees.

Holders of convertible securities, by contrast, are the *patient* readers of grave and significant corporate events, and the convertible is the book that binds and encodes those events.

ÉLIE AYACHE

Bond

A *bond*, or a *debt security*, is a financial claim by which the *issuer*, or the borrower, is committed to paying back to the *bond holder* or the lender, the cash amount borrowed, called *principal*, plus periodic coupon interests calculated on this amount during a given period. It can have either a standard or a nonstandard structure. A *standard bond* is a fixed coupon bond without any embedded option, delivering its coupons on periodic dates and principal on the maturity date. Nonstandard bonds include, among others, zero-coupon bonds, floating rate notes, inflation-linked bonds, callable and puttable bonds, and convertible bonds.

An example of a standard bond would be a US treasury bond with coupon interest 4%, maturity date November 15, 2017, and a nominal issued amount of \$20 billion, paying a semiannual interest of \$400 million ($\$20 \text{ billion} \times 4\%/2$) every six months until November 15, 2017 included, as well as \$20 billion on the maturity date.

A bond issuer has a direct access to the market, and so avoids borrowing from investment banks at higher interest rates. A bond holder has the status of a creditor, unlike an equity holder, who has the status of an owner of the issuing corporation. This is the reason why a bond is less risky than an equity.

A bond issue is mainly characterized by the following components [4]:

- *The issuer name*: For example, France for a treasury bond issued in France.
- *The issuer type*: This is mainly the economic sector the issuer belongs to.
- *The issuer domicile*.
- *The issuance market*: The issuance market may differ from the issuer domicile. For example, the Eurodollar market corresponds to bonds denominated in USD and issued in any country other than the United States.
- *The bond currency denomination*.
- *The maturity date*: This is the date on which the principal amount is due.
- *The coupon rate*: It is expressed in percentage of the principal amount.
- *The coupon type*: It can be fixed, floating, or a mix of the two.
- *The coupon frequency*: Most commonly, it is semiannual in the United States, the United Kingdom, and Japan, and annual in the Euro zone, except for Italy, where it is semiannual.
- *The day-count type*: The most common types are actual/actual, actual/365, actual/360, and 30/360. Actual/actual (actual/365, actual/360) means that the accrued interest between two given dates is computed using the exact number of calendar days between the two dates divided by the exact number of calendar days of the ongoing year (365, 360). The term 30/360 means that the number of calendar days between the two dates is computed, assuming each month count as 30 days.
- *The interest accrual date*: This is the date when interest begins to accrue.
- *The settlement date*: This is the date on which payment is due in exchange for the bond. It is equal to the trade date plus a number of working days (generally, one to three, depending on the country).
- *The issuance price*: This is the percentage price paid at issuance.
- *The spread at issuance*: The spread in basis points to the benchmark treasury curve or the swap curve.
- *The rating*: A ranking of a bond's quality and its record in paying interest and principal. The three major rating agencies are Moody's, Standard and Poor's, and Fitch.
- *The outstanding amount*: This is the amount of the issue still outstanding.
- *The par or nominal or principal amount*: The face value of the bond.
- *The redemption value*: Expressed in percentage of the nominal amount, it is the price at which the bond is redeemed on the maturity date.
- *The identifying code*: The most popular ones are the *ISIN* (International Securities Identification Number) and the *CUSIP* (Committee on Uniform Securities Identification Procedures) numbers.

Bond Price and Yield to Maturity

Bonds are usually quoted in price, yield, or spread against an underlying benchmark bond or reference swap rate. The price of a bond is always expressed in percentage of its nominal amount. The *quoted price*
